(See also Section 3.) The essential features of a transformer consist of a primary winding having a number of turns interlinked with a magnetic circuit, and a secondary winding also interlinked with the same magnetic circuit, as shown in Fig. 5.

SIMPLE THEORY, NEGLECTING LEAKAGE REACTANCE. In the following discussion the assumption will first be made that all the flux links both primary and secondary windings; the effect of the leakage flux will be discussed later.

In Fig. 5, S_1 is the primary winding, M the magnetic circuit (of iron), and S_2 the secondary winding. If an alternating current is caused to flow in S_1 it will set up a flux in M which at any instant is proportional to the current i_1. Thus

$$\phi = \frac{4\pi S_1 i_1}{10\,\mathcal{R}}$$

where S_1 is the number of turns, i_1 the instantaneous value of the current, and $\mathcal{R}$ the magnetic reluctance of the path in M.

Thus ϕ alternates with i_1 and since it interlinks with S_2 it will induce a voltage in S_2 at any instant equal to

$$e_2 = -S_2 \frac{d\phi}{dt} 10^{-8} \quad \text{volt}$$

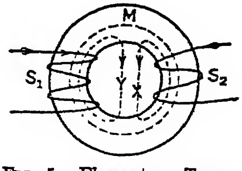

FIG. 5. Elementary Transformer

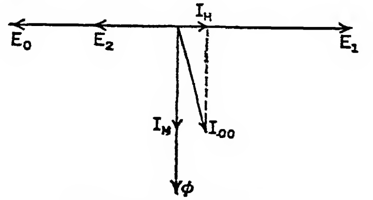

FIG. 6. No-load Relations

in which S_2 is the number of turns. The negative sign means that any current due to e_2 will tend to diminish ϕ.

NO-LOAD CONDITIONS. When there is no current in the secondary, the vector relations are as shown in Fig. 6. Let E_1 be the voltage impressed upon S_1; then the maximum value of the alternating flux will be

$$\phi = \frac{10^8 E_1}{4.44 f S_1}$$

where f is the frequency of alternation of E_1. Strictly, the numerator is $10^8 (E_1 - r_1 I_{00})$, where I_{00} is the exciting current and r_1 the resistance of the primary, but the term $r_1 I_{00}$ is practically negligible. This flux will lag 90 deg behind E_1 or 90 deg ahead of the counter emf E_0 which it induces in S_1. The true magnetizing current I_m will be in phase with the flux, and the hysteresis component of current I_H will be in phase with E_1. Hence the total no-load current I_{00} will assume some phase a little less than 90 deg behind E_1.

The flux ϕ will induce in the secondary turns S_2 an emf 90 deg behind the flux, hence 180 deg behind E_1 or in phase with the primary counter emf. The effective value of this emf is

$$E_2 = 4.44 f S_2 \phi \, 10^{-8}$$

RESISTIVE LOAD ON SECONDARY. When the secondary is closed through a non-inductive external circuit a current will flow. This current will tend to demagnetize the iron, that is, to reduce the flux and hence the counter emf of the primary. This action, however, allows the current in the primary to increase until the secondary mmf is balanced and there is left an excess mmf in the primary just large enough to give sufficient flux to induce the counter emf E_1'. The vector relations are as shown in Fig. 7, again neglecting the leakage flux.

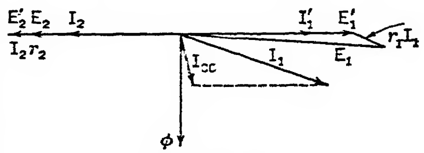

FIG. 7. Full Load, No Leakage

LEAKAGE REACTANCE. Because part of the lines of induction set up by the currents in the two windings pass through the air space (X in Fig. 5), the mmf's set up by the secondary current and the load current in the primary (the current I_1' in Fig. 7) cannot neutralize each other, since the leakage fluxes established by the two currents are in the same direction, and not in opposition as are the fluxes in the iron. The primary leakage flux is in phase with the total primary current and the secondary leakage flux is in phase with the secondary current; these leakage fluxes are therefore not in phase with the useful flux (i.e., the flux which links both primary and secondary). The result is that the leakage fluxes cause a decrease in the secondary voltage and also a shifting of its phase with respect to the primary voltage.

Since the two leakage fluxes are in phase with the total currents in the primary and secondary respectively the voltages induced by the alternation of these fluxes are in quadrature with the currents. The quotient of the voltage induced in the primary by the alternating primary leakage flux divided by the primary current is called the "primary leakage reactance," and the quotient of the voltage induced in the secondary by the alternating secondary leakage flux divided by the secondary current is called the "secondary leakage reactance." These reactances are practically constant, since the major portion of the leakage path is in the air.

COMPLETE VECTOR DIAGRAM OF TRANSFORMER. Fig. 8 shows diagram-

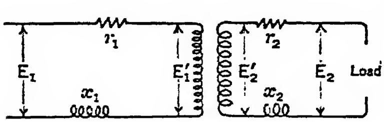

FIG. 8. Diagram of Circuits

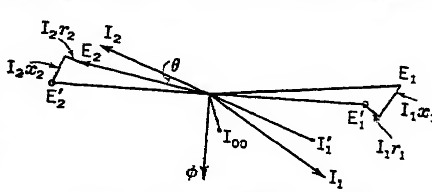

FIG. 9. Complete Vector Diagram

matically the primary and secondary windings of the transformer and Fig. 9 the vector diagram.

E_2 = the secondary terminal emf.
$\cos\theta$ = power factor of load.
I_2 = secondary current, lagging by angle θ behind E_2.
$I_2 r_2$ = secondary resistance drop in volts; in phase with I_2.
$I_2 x_2$ = secondary reactance drop in volts, due to $1/2$ of leakage flux, at 90 deg to I_2.
E_2' = induced emf in the secondary (hypothetical).
E_1' = emf necessary to overcome counter emf in primary; opposed and proportional to E_2' by ratio u.
u = ratio of transformation = S_1/S_2.
I_1' = primary load current; opposed and proportional to I_2 by ratio $1/u$.

ϕ = mutual or useful flux.
I_{00} = primary no-load current.
I_1 = total or resultant primary current.
$I_1 r_1$ = primary resistance drop; parallel to I_1.
$I_1 x_1$ = primary reactance drop, at 90 deg to I_1.
E_1 = the required voltage on the primary, that is, the impressed emf.

"EQUIVALENT" CIRCUIT OF TRANSFORMER. In practice it is not possible to measure the primary and secondary reactances separately. They must be measured together and treated as one quantity, called the total reactance x_t of the transformer, which may be expressed in terms of either the primary turns or the secondary turns.

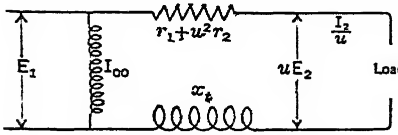

FIG. 10. Equivalent Circuit

A simple approximate method which is sufficiently accurate for all practical purposes is based on the equivalent circuits shown in Fig. 10. This method is used in calculating the characteristics of a transformer from constants obtained from tests.

Let E_2 = terminal emf of secondary.
$\cos\theta_2$ = power factor of load.
I_2 = secondary current.
u = ratio of transformation = S_1/S_2.
$E_2' = uE_2$.
$I_2' = \frac{I_2}{u}$.
R = total resistance in terms of primary = $r_1 + u^2 r_2$.
X = total reactance in terms of primary.
I_M = primary magnetizing current.
$I_H = \frac{\text{core loss}}{uE_2}$, to a close approximation.
E_1 = primary impressed emf.
I_1 = total primary current.
$\cos\theta_1$ = power factor of transformer with load, i.e., power factor at primary terminals.
P_1 = watts input at primary terminals.
η = per cent efficiency.

Then

$$I_1 = \sqrt{(I_2'\cos\theta_2 + I_H)^2 + (I_2'\sin\theta_2 + I_M)^2}$$
$$E_1 = \sqrt{(E_2'\cos\theta_2 + RI_1)^2 + (E_2'\sin\theta_2 + XI_1)^2}$$
$$P_1 = E_2 I_2 \cos\theta_2 + R(I_2')^2 + E_2' I_H$$
$$\cos\theta_1 = \frac{P_1}{E_1 I_1}$$
$$\eta = \frac{100\,P_2}{P_1}$$
$$P_2 = E_2 I_2 \cos\theta_2$$
$$\text{Per cent regulation} = \frac{100\,(E_1 - uE_2)}{uE_2}$$

CONSTANT-CURRENT TRANSFORMERS. These are used for supplying current to arc lamps connected in a series circuit which requires from 4 to 10 amp and about 2000 volts. The principle of operation for this type of transformer is based on the existence of the leakage or useless flux which causes a repelling force between the primary and secondary windings. One winding is arranged so that it may move with respect to the other. As the current in the windings increases, the repelling force increases and the windings move apart. This allows more flux to leak or pass between the windings and less to thread the secondary. Therefore the voltage induced in the secondary decreases as the current tends to increase. A counterweight is attached to the movable winding to regulate the amount of movement. The current in the primary remains fairly constant, but the power factor decreases with decreasing load on the secondary so the power in the primary is approximately proportional to the output of the secondary.

SERIES TRANSFORMERS operate under conditions similar to those in a constant-potential transformer with short-circuited secondary. Under operating conditions the flux is small as the only voltage to be induced in the secondary is that required to overcome the impedance drop in that winding and the instrument which it supplies. The only counter

emf in the primary is that due to impedance drop. The series transformer must be operated with the secondary short-circuited by low impedance. If the secondary circuit is open there is no counter mmf to balance the primary turns, which, being in series with the main line, carry a current irrespective of the secondary circuit. The primary ampere-turns would then set up a magnetic flux of considerable magnitude. As the transformer is not designed for this condition, the density would become very high in the magnetic circuit of small cross-section, and the transformer is likely to burn up from the heat due to core loss.

3. TRANSFORMER CONNECTIONS

The various transformer connections which are commonly used in lighting and power services are described below; see also Article 13 on Operation.

Single-phase System with Three-wire Secondary (Fig. 11). Standard practice in residence lighting with the a-c system involves grounding the neutral wire on the low-tension side, the primary side not being grounded. Lamps or motors operating at 110

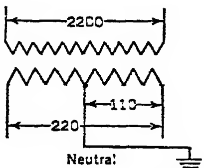

Fig. 11. Single-phase, Three-wire

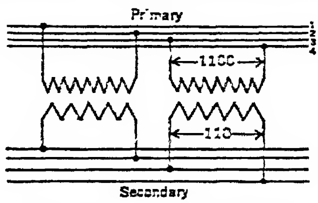

Fig. 12. Two-phase, Four-wire

volts are connected between the neutral and either side. The maximum potential between any secondary and ground is 110 volts, but if either of the outside wires becomes grounded it constitutes a short circuit on that half of the transformer.

Two-phase or Quarter-phase Four-wire System (Fig. 12). The standard two-phase or quarter-phase system is essentially two independent single-phase systems which are usually independent electrically throughout. When the two phases are not electrically connected inside the generator, either wire of one phase may be connected to either wire of the other phase, without any flow of current resulting. In certain two-phase generators, however, the windings are interconnected, in which case any interconnection of the wires coming from the generator will cause a flow of current through this connection.

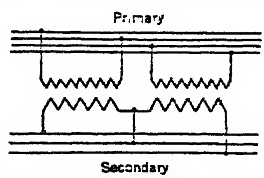

Fig. 13. Two-phase, Three-wire

Two-phase Three-wire System (Fig. 13). This connection is occasionally used for the distribution of power in small systems. There is a possibility of a slight saving in copper, but the chances of unbalanced voltage and bad regulation, particularly with an inductive load, render it objectionable.

Three-phase Y and Δ Connections (Figs. 14 and 15). Transformation in a three-phase system with either three independent single-phase transformers or with a three-phase transformer, having three primary coils and three secondary coils on one iron core,

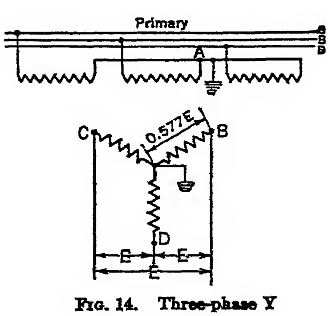

Fig. 14. Three-phase Y

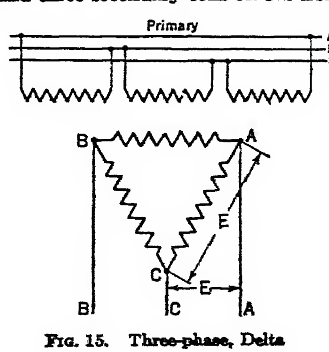

Fig. 15. Three-phase, Delta

is accomplished by connecting the primary either in Y or in Δ and the secondary either in Y or in Δ. With Y or Δ connections there are the following relations between voltage per transformer winding and voltage between lines, and between current in transformer windings and current in lines.

Connection	Volts bet. Lines	Volts per Winding	Current per Line	Current per Winding
Y	E	$0.58\,E$	I	I
Δ	E	E	I	$0.58\,I$

The power in the three transformers in any case is $3 \times 0.58 \times EI = 1.73\,EI$.

There are four combinations of these connections which may be used on any bank of transformers. These connections are given in the following table, and also the ratio of the voltage between lines for the low-tension and high-tension sides for a given ratio (u) of transformation in each individual transformer connection.

Connection		Low-potential, volts bet. lines	High-potential, volts bet. lines
Low Pot.	High Pot.		
Δ	Δ	E	uE
Y	Y	E	uE
Δ	Y	E	$1.73\,uE$
Y	Δ	E	$0.58\,uE$

In a-c secondary distribution networks it is standard practice to use a Y connection on the low-potential secondaries and bring out a conductor from the neutral point, thus making a four-wire system. Between any "outer" and the neutral, 125 volts, single-phase, is available for lamps and small devices; between the three outers there is 208 volts, giving a true three-phase, 208-volt system for larger motors.

PARALLEL CONNECTION OF THREE-PHASE BANKS. If several banks of transformers in the same system are connected in parallel on one side, then to connect the other sides in parallel the connections must be such that the voltage between any two lines on this side will have the same phase in all the banks. From this relation result the following rules:

With ΔΔ on one bank, the other bank must be ΔΔ or YY.
With YY on one bank, the other bank must be ΔΔ or YY.
With ΔY on one bank, the other bank must be ΔY or YΔ.
With YΔ on one bank, the other bank must be YΔ or ΔY.

Even when these relations are satisfied a short circuit will result unless the three phases of each bank are connected in the proper sequence. This can be readily determined by the polarity test described below in Article 9 on Testing.

RELATIVE ADVANTAGES OF Y AND Δ CONNECTIONS. There has been much discussion as to the relative advantages of Y- and Δ-connected transformers for high-tension transmission and as to the value of a grounded neutral. The general and fundamental arguments may be summed up as follows:

With a ΔΔ system the advantages are that if one transformer becomes disabled the system may be operated from the other two, operating on open delta (see below). If the load is unbalanced the voltages do not become unduly unbalanced. Resonance cannot occur. On the other hand, each transformer must be insulated for full line voltage as there is no neutral to ground, and if one line becomes grounded the voltage strain on the rest of the system becomes 1.73 times the normal strain, and this strain may extend to the low-tension winding and the generator which is connected to the transformers.

With YY-connection there is a very unstable neutral and a possible excessive voltage strain on one phase, unless the neutral is grounded.

With a ΔY arrangement for step-up transformers, the neutral on the high-tension side may be grounded. The voltage strain on any transformer is then limited to 58 per cent of the line voltage. There is a possibility of operating the remaining two transformers, if one becomes damaged, by using the neutral as a third conductor. However, there is also the possibility of resonance under certain circumstances and the danger of causing disturbances in nearby telephone and telegraph circuits. Any accidental ground on the system makes a definite short circuit on one phase.

The arrangement of Y Δ for step-up transformers is not desirable on account of the unstable neutral with unbalanced load, but is permissible with a balanced load or with a good connection from neutral of transformers to neutral of generator. This connection, however, is frequently used for step-down transformers particularly when connected to a balanced load.

GROUNDED NEUTRAL VS. UNGROUNDED NEUTRAL. In any system without a grounded neutral there are numerous possibilities of disturbances resulting in a high-voltage strain on the various parts of the insulation of the system. With the high voltages

now in use for transmission systems these disturbances may give a great deal of trouble by breaking down the insulation, as it is not always possible to employ a large margin of safety and lightning arresters do not always protect from these disturbances. On the other hand, if the neutral is grounded, most of these disturbances will merely result in an excessive current, and if the circuit breakers are installed in the proper places they will open the circuit, so that the only adverse result will be a temporary interruption of service.

The choice is then between a system with ungrounded neutral and a large margin of safety in the insulation, and a system with grounded neutral, moderate insulation, and the possibility of occasional interruption of service.

EFFECT OF HIGHER HARMONICS. Many alternators generate an emf whose wave shape contains higher harmonics (see Section 3, Art. 8), and the magnetizing current of transformers operating at high magnetic densities has a distorted wave shape which contains a prominent third harmonic. If these harmonics are present in a Y-connected machine they cause the voltage between each line and the neutral to vary so that there exists an unstable neutral, and the voltage strain on any one phase is indeterminate. If the neutrals of two pieces of apparatus in which these harmonics exist are grounded or joined together, a high-frequency current will flow in the neutral connection. If on the other hand these pieces of apparatus are Δ-connected a third harmonic current will circulate inside the apparatus. This may be measured by connecting an ammeter in the Δ between two phases. This current heats the apparatus, does no profitable work, and is therefore to be avoided. High-frequency current in the line will cause high voltages to occur at certain points if a large amount of capacitance is present, as is the case in any underground line, even of moderate length, and also in long overhead lines. All possible means both in the design of the generators and the connection of of the apparatus should be taken to prevent the occurrence of, or to diminish the effect of, these higher harmonics.

THREE-PHASE OPEN Δ OR V CONNECTION (Fig. 16). This system consists in omitting one transformer from the delta connection, and is used to save expense, particularly in temporary installations or in new installations where the load is not great at first but is expected to increase in time. Thus the purchase and installation of the third transformer are postponed until the load requires it. This connection can only be recommended for low voltages, such as 2300, as it is likely to produce dangerous potentials due to

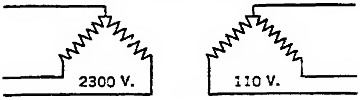

Fig. 16. Three-phase, Open Delta

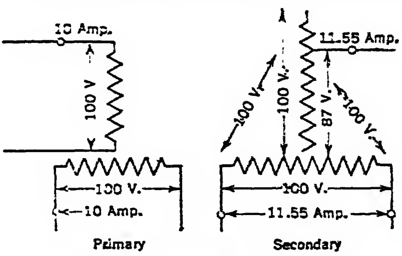

Fig. 17. Two-phase to Three-phase

electrostatic unbalancing. The regulation and efficiency are also poor, as one phase of the load receives its power from two transformers in series. The aggregate capacity of the two transformers should be 15 per cent greater than the load.

TWO-PHASE TO THREE-PHASE TRANSFORMATION. The Scott or T-connection, the standard method of transforming from two-phase to three-phase, consists of two transformers which on the two-phase side may be connected in the normal two-phase manner either independently or interlinked. On the three-phase side one transformer has a tap at the middle point and the other a tap giving 87 per cent of full transformer voltage. Fig. 17 shows the method of connecting and the currents in primary and secondary with balanced loads. Since the total power is $2\,E_2 I_2 = \sqrt{3}\,E_3 I_3$, it follows that $I_3 = \dfrac{2}{\sqrt{3}}\dfrac{E_2}{E_3} I_2$, or the three-phase current is 16 per cent greater than it would be for straight single- or two-phase transformation. Thus one of the windings of one transformer must carry 16 per cent more than its share of the volt-amperes of the load and is overloaded in that proportion.

In commercial practice it is customary for the sake of interchangeability to make the capacity of both transformers 16 per cent greater than the load and to put both a 50 per cent and 87 per cent tap on both transformers. For this connection of transformers each half of the main transformer winding must be distributed over both legs of the core in order to prevent flux (and therefore voltage) unbalancing. If this pre-

caution is taken both the primary and secondary voltages are balanced if the load is balanced. Any unbalancing of the secondary causes a like amount of unbalancing on the primary; thus if this connection is used to transform from three-phase to two-phase and all the load comes on one phase of the secondary it will also come on one phase of the primary.

4. THREE-PHASE TRANSFORMERS

Considerable space, wiring, and first cost may be saved by the use of a three-phase transformer in place of three single-phase transformers. This saving is warranted in large installations, but not in small installations where the convenience of having one interchangeable single-phase transformer as a spare for several banks of three transformers each is an important item.

Core of Three-Phase Transformer. Three-phase transformers may be of the core type as shown in Fig. 1, in which case all the magnetic paths are of the same cross-section, or of the shell type shown in Fig. 2. In the latter type the horizontal cross-pieces and outside vertical pieces may have one-half the cross-section of the central vertical core, providing the coil on the central leg is connected with a definite polarity with respect to the other two coils in order to have the fluxes differ in phase by 60 deg.

Operation of Damaged Three-phase Transformer. In a shell-type three-phase transformer if the primary and secondary are delta-connected it is possible to operate with only two phases in open delta at reduced capacity in case of trouble in the third phase of the system. This is accomplished by separating the third phase entirely from the system and short-circuiting both the primary and secondary windings.

5. DESIGN

(See also Article 7, p. 14 on Cooling of Transformers.) The methods of design for single-phase and polyphase transformers are similar, the chief difference being that of the magnetic circuit. In the design of polyphase transformers each leg is treated as an independent single-phase transformer. The number of turns is adjusted to the voltage per phase, and the cross-section of the conductors to the current per phase. All legs are wound alike, and the phases are connected as described in the preceding section.

The a-c transformer is the most efficient piece of electrical apparatus. Its efficiency at full load is usually better than 95 per cent and frequently better than 98 per cent. For this reason it is very small in volume and light in weight for a given output compared to other pieces of electrical apparatus, and hence the chief difficulty in design is the necessity of providing sufficient surface and a proper means to carry off the heat developed.

The difference in mechanical construction between the core and shell type is that the winding of the core type usually consists of two or more long spools (in which the length is considerably greater than the diameter) surrounding each leg of the transformer. The shell type consists usually of large flat "pancake" coils, laid alongside of each other on the central core with proper separating devices to permit ventilation. See Figs. 1 and 2 (p. 03).

DETERMINATION OF FLUX (ϕ) AND NUMBER OF PRIMARY TURNS (S_1). In order to estimate a desirable value of the flux to be used a factor C is employed which is defined by the relation

$$C = \frac{\phi}{S_1 I_1} \tag{1}$$

The proper value of this factor C depends upon the type, capacity, and voltage of the transformer, and the relative weights of copper and iron.* Usual values are given in the accompanying table.

Values of C

Form of Transformer	Voltage	Core Type Value of C	Shell Type Value of C
Natural draft	0–6000	55–70	500–700
	6000 up	70–75	500–700
Oil-cooled	0–10,000	75–100	
	10,000 up	100–150	
Air-blast or water-cooled	0–10,000	110–160	600–1000
	10,000 up	160–240	600–1000

* A discussion of this factor C will be found in Arnold's Transformers and in S. P. Thompson's Dynamo Electric Machinery, Vol. II.

Volts per Turn. The same criterion may be expressed in a more convenient empyrical form as "volts per turn":

$$e = \text{volts per turn} = 4.44 f \phi\, 10^{-8}$$

Usual values of volts per turn for 60 cycles in commercial practice in the United States are given in the accompanying table.

For 25-cycle transformers the volts per turn are about 50 per cent greater.

By this criterion, reasonable values for the flux and the primary and secondary turns may be readily estimated.

Usual Values of Volts per Turn

Rating in Kva	Volts per Turn	
	Core Type	Shell Type
1	0.5	1.2
10	2.5	3.75
50	5.5	8.5
100	7.0	12.0
500	13.0	26.0
1000	18.0	36.0

CROSS-SECTION OF CORE (A) AND MAGNETIC FLUX DENSITY (B). The core section is determined by the magnetic density which it is desirable to use, which in turn is determined by the core loss. It is found that in average practice a loss of 1 watt per pound of iron can be dissipated without excessive rise in temperature. The corresponding flux densities in iron having a thickness of 14 mils are given in the following table. These values are approximate only, since the quality of the steel used is exceedingly variable. It should also be noted for a transformer intended for supplying a load of low power factor that the iron loss should be less than 1 watt per pound for the best distribution of material.

Values of Flux Density

Size of Transformer	Kind of Steel	Lines per Sq In.	
		25 Cycles	60 Cycles
Small	Ordinary transformer sheet	50,000	40,000
Small	Special; silicon-steel	70,000	60,000
Large	Ordinary transformer sheet	75,000	65,000
Large	Special; silicon-steel	90,000	75,000

Construction. The usual arrangement of the windings and core of a core-type transformer are shown in Fig. 18, and of a shell type in Fig. 19. Usual values for the magnetic densities B in the iron are given above, and for the current density in the copper in the following table.

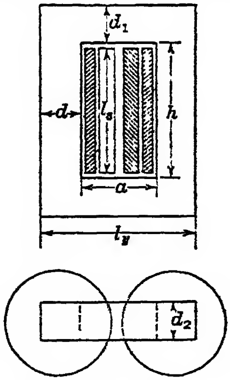

Fig. 18. Core Type

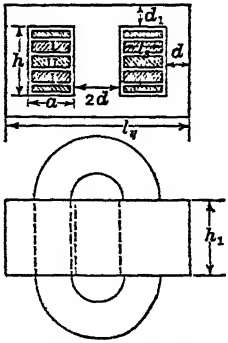

Fig. 19. Shell Type

Current Density

Condition of Transformer	U = Amperes per Sq In.
Poorly cooled....................	850–1200
Ordinary oil-cooled, air blast, etc.....	1100–1600
Large, well-cooled................	1500–1900

INSULATION OF WINDINGS. The insulation of each turn usually consists of the cotton covering if the coils are wound with wire, or mica paper if the coils are wound with strip copper. This is proportioned to withstand the potential between

turns as given above. The voltage between conductors on adjacent layers may be equal to twice the voltage per layer. To prevent breaking down between layers, a layer of Fuller board is used as a separator, and this should project beyond the windings at the ends to prevent creepage. The maximum voltage between layers should be kept below 400, and to accomplish this it is customary to limit the voltage per coil to about 5000 volts. Between the windings and the core a layer of pressboard and sometimes wood is placed, while between primary and secondary windings a layer of pressboard and micanite may be used. For very high voltages the end turns of the high-tension winding for about 75 ft from the terminals is given a special insulation to withstand the sudden high potentials which occur when there is a sudden change in the potential applied to the transformer. These high potentials result from the distributed capacity of the transformer, between the high-tension winding and the core, frame, and other winding.

TERMINAL BUSHINGS. At the point where the high potential leads pass through the case there is a very great dielectric stress which must be taken care of by the use of a proper kind of insulation and a proper disposition of the insulation to prevent a concentration of the dielectric flux at a few points. For voltages below 40,000 a porcelain bushing is customarily used.

For higher voltages it is necessary to supply a large creepage distance and to have the surface submerged in oil to prevent corona effect. This is accomplished in one form of bushing, known as the "condenser type," by surrounding the terminal with layers of insulation and putting sheets of tinfoil between the layers. This arrangement is equivalent to a series of condensers. By properly proportioning the area of the successive layers of tinfoil the drop in potential across the insulation is kept uniform. The whole terminal is enclosed in an oil-filled casing. Another form of bushing known as the "oil-filled type" consists of a long cylinder of composition insulation which surrounds the lead and is filled with oil. The cylinder is divided into compartments to keep the oil properly distributed, and disks or collars project outward from the outside to increase the creepage distance.

END COILS OF SHELL TYPE. With the flat coils customarily used in the shell-type transformer the subdivision of the windings is usually such that there is a half coil of the low-potential winding at each end of the winding space as in Fig. 19. This is to reduce the leakage flux. In order to reduce the leakage flux further all coils may be divided into halves with a ventilating duct between halves. The space between a primary and secondary coil is then reduced to that necessary for the insulation.

6. PREDETERMINATION OF THE PERFORMANCE

From the above calculations a drawing to scale of the transformer may be laid out. The next step is to calculate its performance, i.e., to predetermine the values of the efficiency, regulation, and temperature rise. This last feature is treated in the following article on the Cooling of Transformers.

MAGNETIZING CURRENT (I_M). The final flux density will probably differ a few per cent from the value assumed earlier in the calculation. The cross-section of core is usually proportioned to give the same magnetic density in all parts, as this condition gives minimum core loss for a given weight of iron.

The mean length of path in the iron is measured or calculated. If H (found from the magnetization curve of the iron, see article on Magnetic Properties of Iron) is the ampere-turns per inch for the given density the magnetizing current of the transformer will be

$$I_M = \frac{H \times \text{(length path)}}{\sqrt{2}\, S_1}$$

Sometimes it is desired to allow for the minute air gaps at the joints of the punchings. Arnold finds that under practical conditions each joint represents a gap of 0.002 in. Thus if there are n joints (usually 4) there should be added to I_M an amount

$$\frac{0.313 \times 0.002\, Bn}{\sqrt{2}\, S_1}$$

CORE LOSS. The core loss consists of hysteresis and eddy current losses in the steel punchings. These losses have been considerably reduced in recent years by improvements in the manufacture and quality of the steel (see article on Magnetic Properties of Iron).

$$\text{Core loss} = C_1 f V + C_2 f^2 V \text{ watts}$$

where f = frequency in cycles per second.

V = volume of iron in cubic inches.

C_1 = watts per cu in. per cycle per sec of hysteresis loss for the particular value of B and of the particular material.

C_2 = watts per cu in. for one cycle per sec for eddy current loss for the value of B and the particular material.

Values for C_1 and C_2 are given in the article on Magnetic Materials in Section 2 on pp. 2–41 to 2–47.

COPPER LOSS. The mean length of turn of both primary and secondary windings is obtained from a sketch to scale. The d-c or ohmic resistance of each member at 60 deg cent is obtained by substituting the proper values in the formula

$$R = \frac{0.0093\, lS}{12{,}000\, an}$$

where l = mean length of turn of primary or secondary respectively in inches.
S = number of turns in series.
a = cross-section of conductor in square inches.
n = number of conductors or coils in multiple.

To allow for eddy currents caused by the leakage flux, the above resistance is increased by 15 per cent to give the effective resistances r_1 and r_2. The total copper loss is then $I_1^2 r_1 + I_2^2 r_2$.

TRANSFORMER REACTANCE. As explained in Art. 2 on Transformer Principles, the leakage of flux between the primary and secondary windings of a transformer causes a component of voltage in each member which is out of phase with the current; if the current lags very much this voltage may have a considerable component opposed to the useful voltage and cause a loss of voltage or poor regulation. It is, therefore, necessary in designing to estimate the amount of this flux and calculate the voltage it would produce. In practice empirical formulas are usually used, but a logically deduced formula is desirable as it is more easily adapted to unusual cases.

The phase of the current in the secondary coil is nearly opposed to that in the primary and may be assumed to be exactly opposed without any great error. The result as shown in Fig. 20 is that all these ampere conductors, both primary and secondary, tend to set up a flux in the same direction in the space between the windings and to a lesser degree in the windings themselves. A part of the flux in the intervening space interlinks with the primary turns and another part with the secondary turns. In addition the flux in the windings themselves interlinks with some of the turns. The flux in each part is proportional to the ampere turns producing it and to the permeance of the path. In this case, since the path is in air, the permeance is the area divided by the length, where the length is the average length of the flux lines.

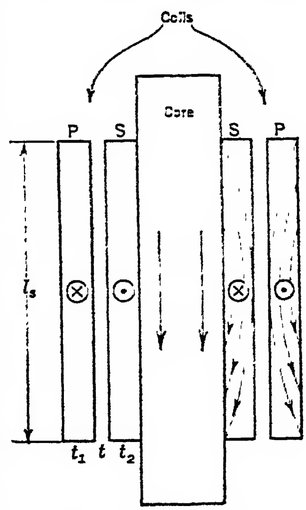

FIG. 20. Leakage Flux

The leakage flux passes between the windings and one part closes its path in the iron inside the inner coil and the other part in air outside the outer coil (in the core type). The reluctance of the path between the two coils is large compared to that of the other two portions, because the inside path has a high permeability and the outside path has a large cross-section. The reluctance of the path between the coils is therefore accurately (and easily) calculated and a constant used to allow for the rest of the path.

In order to calculate the inductance it is necessary to have a cross-section of the windings showing their thickness, length, and arrangement, as in Figs. 18, 19, and 20. Two cases must be considered:

(A) Where there are as many primary coils as secondary coils, and all coils are full size (usual core type).

(B) Where there is a "half" secondary coil at each extremity of the group of windings (the usual arrangement in the shell-type transformers).

Arnold's Method of Calculating Reactance. Arnold calculates the inductance of a single primary coil and its secondary mate or mates, and multiplies this by the number

of primary coils in series or divides by the number in multiple. This gives the total "short-circuit" inductance of the transformer in terms of the primary voltage or turns.

Referring to Figs. 18, 19, and 20 for the core and the shell type, respectively, let the various quantities be represented as follows, all dimensions being in inches:

q = number of primary coils in series.
p = number of primary coils in parallel.
s_1 = number of turns in one primary coil.
s_2 = number of turns in one whole secondary coil.
l_s = height of coils in cylinder type.
l_s = depth of coils in flat type.
t_1 = thickness of a whole primary coil.
t_2 = thickness of a whole secondary coil.
t = distance between coils.
U_1 and U_2 = mean length of primary and secondary turns respectively.
U_m = average of U_1 and U_2.
k = an empirical constant, varying from 0.95 with flat coils to 1.06 with cylinder coils.

Reactance of Core Type. (Fig. 20). In a core-type transformer with cylindrical coils and an equal number of full-sized primary and secondary coils, the permeance of the path of the flux in the duct which interlinks with a primary coil is $\frac{tU_1}{2\,l_s}$ and the permeance of the path in the winding itself is $\frac{t_1 U_1}{3\,l_s}$.

The inductance of one primary coil is

$$L_1 = \frac{3.2\,ks_1^2\,U_1}{l_s}\left(\frac{t_1}{3}+\frac{t}{2}\right)10^{-8}$$

The inductance of one secondary coil is

$$L_2 = \frac{3.2\,ks_2^2\,U_2}{l_s}\left(\frac{t_2}{3}+\frac{t}{2}\right)10^{-8}$$

Reducing the latter to terms of the primary turns by multiplying by $\frac{s_1^2}{s_2^2}$, adding together, and multiplying by $2\,\pi f$, the total reactance of the transformer in terms of the primary is

$$X = 2\,\pi f\,\frac{3.2\,qks_1^2\,U_m}{pl_s}\left(\frac{t_1+t_2}{3}+t\right)10^{-8}$$

Reactance of Shell Type. If, as in the shell-type transformer shown in Fig. 19, there is a half secondary coil at each end to give an increased intermixing, then

$$X = 2\,\pi f\,\frac{3.2\,qks_1^2\,U_m}{2\,pl_s}\left(\frac{t_1+t_2}{6}+t\right)10^{-8}$$

7. COOLING OF TRANSFORMERS

It is necessary to keep the temperature of the various parts of a transformer within such limits that the materials of which it is constructed do not become damaged and deteriorate too rapidly. When subjected to too high a temperature the insulating materials disintegrate and lose their mechanical and dielectric strength, and the iron deteriorates in its magnetic qualities so that the core loss becomes greater for a given density. This so-called aging of the iron may cause an increase of as much as 50 per cent in the loss in the iron. The effect varies with the character of the iron and is practically negligible in silicon steel.

MAXIMUM RISE IN TEMPERATURE. The maximum rise in temperature above a room temperature of 25 deg cent at which the various materials of a transformer should be operated are given in the table.

Material	°C
Iron	70–75
Cotton	60
Paper	70
Mica, asbestos	90

To guard against this possibility of damage the Standardization Rules of the A.I.E.E. recommend that the windings shall not increase in temperature more than 55 deg cent, as measured by resistance, above the surrounding air, and the other parts shall not increase more than 55 deg cent as measured by thermometer.

MEANS OF DISSIPATING HEAT. The problem is to provide a path of low thermal resistance by which the heat energy may pass to the surrounding air. To

accomplish this it is necessary, first, to provide sufficient surface in the subdivided transformer to transfer the heat to the cooling agent, air or oil, without too great a difference in temperature; second, so to subdivide the transformer that no part of the iron is more than 1 in., and no part of the copper more than 3/8 in., from a cooling surface; third, to provide a sufficient quantity of the cooling agent, air, oil, or water, to carry away the heat at the same rate as it is generated; and fourth, to provide sufficient surface on the containing case or tank to transfer the heat from the internal oil to the external air without too great a difference in temperature.

CALCULATION OF EXPOSED SURFACE OF TRANSFORMER. The practical method of estimating the rise in temperature consists in calculating the drop in temperature in the successive media through which the heat must pass to be dissipated. The first step is to calculate the exposed surface of the transformer core and core ducts and of the coils and coil ducts.

For a rise in temperature of 55 deg cent above the surrounding air the allowable watts loss per square inch should be approximately:

	Coil Surface	Core Surface
Oil-immersed self-cooled..	0.40	1.5
Air-blast...............	0.75	1.0
Forced-oil-cooled.......	1.00	1.75
Oil-immersed water-cooled	0.85	1.75

Naturally air-cooled transformers (instrument transformers) should have from 4 to 6 sq in. of surface for each watt of loss.

OIL-COOLED TRANSFORMERS. The transformer is submerged in oil in a tank so that the level of the oil is from 2 to 3 in. above the top of the transformer. The quantity of oil is from 6 to 10 lb per kva rating, or from 250 to 500 lb per kw loss. The oil ducts should be 1/4 in. wide and run vertically. If the tank is smooth there should be from 4 to 8 sq in. of tank surface (not including top or bottom) for each watt loss. For sizes greater than 25 kw it is customary to use fluted or corrugated sides to the tank. In this case there should be from 6 to 10 sq in. of radiating surface per watt loss because the air does not circulate as rapidly in the grooves as over a smooth surface and consequently radiation is poor.

For a rise of 55 deg cent of the transformer there is an average rise of 30 deg of the oil. The maximum rise of the oil is 1.3 to 1.5 times the average.

AIR-BLAST TRANSFORMERS. This type of transformer is usually set over a large air duct in the floor which is supplied by a blower with air at a pressure of 1/2 to 1 oz (3/4 to 1 1/2 in. of water). The air enters the transformer at the bottom and is divided into two streams, one passing vertically through the windings and the other transversely through the iron. There is a damper or valve for each stream, so that the proper amount of air is provided to each part independently. Ducts 1/2 in. wide are provided every 3 to 4 in. A liberal amount of air for 55 deg cent rise is 150 cu ft per min per kw loss The air is expected to rise from 15 to 20 deg cent in its passage through the transformer. The theoretical quantity of air in cubic feet per minute is

$$Q = \frac{1.65 \text{ watts}}{T_a}$$

where T_a is the rise in temperature of the air, which is usually about half as great as the rise of the transformer. See Installation, page 10-19.

WATER-COOLED TRANSFORMERS. The cooling coils are suspended in the tank in the oil near the top, usually above the transformer proper, and carry a continuously circulating stream of water. It is customary to provide a gallon of water per minute for each kilowatt of loss and 1 sq in. of surface of water-coils per watt loss. This assumes a temperature drop of 20 to 25 deg cent in the insulation and oil, 2 to 3 between oil and water, and 20 to 25 in the water.

8. TESTING SINGLE-PHASE TRANSFORMERS

The customary commercial tests on transformers and the best order of making them are: cold resistance, polarity, ratio and checking of taps, impedance, core loss and exciting current, parallel run, heat run, insulation tests. The efficiency and regulation are calculated from the results of these tests.

Oil-cooled transformers should never be tested or subjected to potential unless they have been filled with oil from which all moisture has been removed.

Examples of test results are given below.

COLD-RESISTANCE MEASUREMENT. The cold resistance must be very carefully made as it is used as a basis of calculating the temperature after the heat run. After the transformer has been standing in one place long enough for all its parts to reach

the same temperature as the surrounding air, a direct current of 10 to 15 per cent of the rated current of the coils is sent through the windings and the drop measured with a voltmeter. At the same time the temperature of the windings is measured by a thermometer.

TEST OF POLARITY. This test gives information necessary for connecting several transformers in a bank and have them operate in parallel or on polyphase circuits. Direct current is sent through one winding of a transformer and a d-c voltmeter connected across the other winding. If the current is stopped, the voltmeter will give a deflection either positive or negative. For similar connection and direction of current on all the transformers of a bank the deflection should be of the same sign. A small current should be used as otherwise the throw of the voltmeter needle may be sufficient to bend it.

RATIO OF TURNS. With no load on a transformer the ratio of voltages is the same as the ratio of the turns. Thus, with a known voltage applied to the low-tension winding, the ratio of turns of the two main windings and of the sections between taps can be checked up by connecting across the other terminals another voltmeter of proper range (using a potential transformer if necessary).

IMPEDANCE TEST. This test is important in order to calculate the regulation and in order to determine whether transformers will run in parallel with each other. One winding of a transformer is short-circuited, and a voltmeter, ammeter, and wattmeter are connected in the circuit of the other winding. A voltage of 1 to 8 per cent of the rated voltage of this winding and of the proper frequency is impressed. The voltage is regulated so that readings are taken at values of current from 50 to 125 per cent of the rated current of the winding. The wattmeter reading will be in the neighborhood of 2 per cent of the rating of the transformer. The total impedance of the transformer will be $Z = E/I$. The total effective resistance will be $R = \text{Watts}/I^2$, which will include the effect of eddy currents, and the total reactance will be $X = \sqrt{Z^2 - R^2}$. This reactance cannot be separated into primary and secondary reactance. The results of this test are usually plotted in two curves, one between volts and amperes and the other between volts and watts.

CORE-LOSS AND EXCITING-CURRENT TEST. The alternator supplying the power for this test should give a sinusoidal emf wave, as any distortion in the shape may cause a variation of 5 to 10 per cent in the core loss. A peaked wave gives a lower core loss than a sine wave. For this test the high-tension winding is left open and rated voltage at the proper frequency is impressed on the low-tension winding. A voltmeter, ammeter, and wattmeter are connected in the low-tension circuit, the voltmeter having a range including the rated voltage of the transformer and the ammeter a range of approximately 15 per cent of the rated current of the machine. Readings are taken with a voltage of 50 per cent to 125 per cent of the rated voltage of the transformer. Both ampere-volt and watt-volt curves are then plotted. If extreme accuracy is desired, the RI^2 loss should be substracted to give true core loss.

Separation of Eddy and Hysteresis Losses. In certain special cases it is desired to investigate the iron of a transformer by separating the hysteresis from the eddy-current loss. Let

W_1 = the core loss at normal voltage and frequency.
W_2 = the core loss at half voltage and half frequency.
W_e = eddy-current loss at normal voltage and frequency.
W_h = hysteresis loss at normal voltage and frequency.

Then
$$W_e = 2\,W_1 - 4\,W_2$$
$$W_h = 4\,W_2 - W_1$$

PARALLEL RUN TEST. The test for polarity and ratio having shown nothing wrong in the transformers, they are connected two at a time, the low-tension windings being connected in parallel to a generator and the high-tension windings in parallel with each other with an ammeter of about 10 per cent the capacity of the transformer connected in one lead between them. The voltage of the alternator is gradually increased from zero and the current in the ammeter noted. This current should not be greater than 5 per cent of the rated current of that winding at rated voltage. If a transformer has double windings in either member the same test should be made on these windings in parallel.

HEAT RUN. The heat run is made at the rated load of the transformer and sometimes at an overload of 25 or 50 per cent, depending upon the guarantees. The run may be made by connecting the transformer to a load such as a water rheostat (q.v.), but as there are other equally good methods, avoiding the waste of so much energy, this dead load is seldom used. The other methods require two or three transformers to be tested simultaneously.

Two Transformers "Bucking" (Fig. 21). The low-tension windings of two transformers are connected in multiple to a voltage of rated value and frequency. The high-tension windings are connected up so that their emf's oppose or "buck" each other, and are in series with an adjustable source of emf, of rated frequency, having a value of 2 to 5 per cent of the rated voltage of the windings. This "loss-supply" may be either an alternator and transformer, or a potential regulator. The voltage of this source is adjusted so that full-load current circulates in the high-tension windings and thereby induces full-load current in the low-tension windings. It should be realized that, although only 2 to 5 per cent of the rated voltage is needed to send the current through the primaries, yet each primary is generating its rated voltage and if there should be a ground anywhere a dangerous potential strain or shock might result.

Three-transformer Arrangement (Fig. 22). Three single-phase transformers may

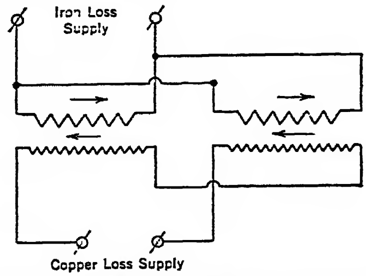

FIG. 21. Connection for Heat Run by Bucking

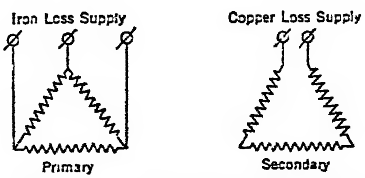

FIG. 22. Heat Run by Open Delta Method

be connected with their low-tension windings in delta to a three-phase source of supply of proper voltage and with the high-tension windings also connected in delta with one corner open into which the "loss supply" is connected preferably by means of an auxiliary transformer to isolate the dangerous potential of the primaries. The "loss-supply" voltage must be adjusted so that the desired current flows in the primary winding.

Time for Heat Run. The time required for a heat run may be considerably shortened by operating at an overload for a short while, or, if the transformer is an air-blast transformer, by operating without the blast until a reasonably high temperature has been attained. Then the proper load is adjusted and the run continued until all temperatures remain practically constant, that is, do not rise more than 1 deg cent in 2 hours. The voltage should be cut off once every hour and a resistance measurement quickly made to determine the temperature of the windings.

Temperature Rise by Resistance is calculated from the formula

$$T = (234.5 + t)\left(\frac{R_h}{R_c} - 1\right)$$

where T = temperature rise in degrees centigrade.

t = temperature in degress centigrade, by thermometer, at which the cold resistance is measured.

R_c = resistance in ohms at temperature t.

R_h = "hot" resistance in ohms at end of heat run.

The number 234.5 is the reciprocal of the resistivity temperature coefficient (referred to 0 deg cent), of copper, i.e., the reciprocal of 0.00427.

Temperature Rise by Thermometer. In an air-blast transformer it is desirable to measure by thermometer the temperature of the incoming air, of the outgoing air (from iron and coils), of the primary windings, and of the secondary windings. Spirit thermometers and not mercury thermometers should always be used for measuring the temperature of transformer windings.

In an oil-cooled transformer the temperature, by the thermometer, of the tank at top and bottom and of the oil in two or three places near the top should be taken.

INSULATION TESTS. To test the insulation between turns and sections of coils double the rated voltage per section is impressed on each section for 1 minute. This test should be made at a high frequency, preferably at double the rated frequency. After this one and a half times normal voltage at rated frequency is applied for 5 minutes to discover the effects of the double voltage test. These voltages should be applied and removed gradually.

High-potential Test on Complete Transformer. To test the dielectric strength of the insulation as a whole the following high-potential test is made. Connect both terminals of the high-tension winding to one terminal of the high-potential transformer. Ground both ends of the secondary winding to the core and frame, and connect to the other terminal of the high-potential transformer. Adjust a needle gap to arc at the desired test voltage and increase the voltage gradually until the gap arcs over. Decrease the voltage till the arcing ceases, and hold the voltage as near as possible to the arcing point for 1 minute. The voltage should then be decreased gradually. The proper testing voltages and spark-gap adjustments are given in the Standardization Rules of the A.I.E.E. (q.v.).

EFFICIENCY AND REGULATION. The efficiency and regulation may be calculated as described above under Equivalent Circuit of Transformer, page 10–06 but it is the more usual practice to determine the efficiency by means of the separate losses:

Let P_2 = secondary output in watts.
A = core loss in watts for that voltage on primary which gives rated voltage on secondary with load.
B = I^2R in both windings as obtained in the impedance test and for the current corresponding to P_2

Then
$$\text{Efficiency} = 1 - \frac{A + B}{P_2 + A + B}$$

9. TESTING OF THREE-PHASE TRANSFORMERS

In testing three-phase transformers the same methods are followed as with single-phase units. The only difference is in testing for polarity; owing to the mixing of the magnetic circuits special care must be exercised. The direct current must be sent in one direction through one primary phase and in the opposite direction through the other two, so that they will not neutralize one another. With a voltmeter similarly connected on the primary and secondary of each phase in turn, break the direct current; if the connections are right the voltmeter on the secondary will deflect in the same direction as the steady deflection on the primary.

PARALLEL RUN. For the parallel run of two three-phase transformers, connect their low-potential sides in multiple to a source of three-phase potential. Connect together the primary terminals No. 1 of both transformers and bring the pairs of terminals No. 2 close together so they may be connected by a small fuse wire. If no spark is noticeable when the fuse wire spans the connection, then the No. 2 terminals may be permanently connected. The same procedure is followed with the No. 3 terminals.

10. EXAMPLES OF PERFORMANCE

Usual values of the performance characteristics of transformers are given below.

Exciting Current ranges from 2 to 6 per cent of full-load current in lighting transformers of the core type and from 5 to 10 per cent in power transformers.

Core loss ranges from 0.5 to 1.25 per cent of the rated output.

Total I^2R ranges from 0.75 per cent of the rated output in large sizes to 2 per cent in small sizes.

Total Reactance drop ranges from 1.25 to 5 per cent of the voltage, being less for the shell type than for the core type. The value depends largely on the purpose of the transformer, methods of construction, and opinion of the designer.

Efficiency and Regulation. The variation of the efficiency with the load of two small 60-cycle transformers for lighting purposes is shown in Fig. 23. The efficiency and regulation at full load of a line of these transformers are shown in Fig. 24. These

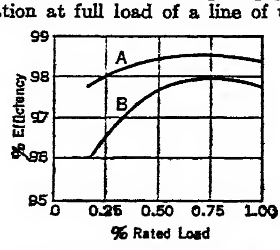

FIG. 23. Efficiency of 60-Cycle Transformers
A = 50 kva; B = 10 kva

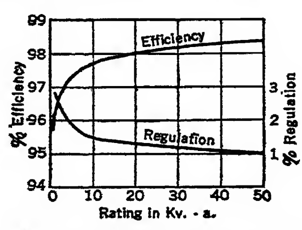

FIG. 24. Efficiency of a Line of 60-Cycle Transformers

transformers are small and of the core type. Larger transformers would have even better characteristics.

11. SPECIFICATIONS FOR TRANSFORMERS *

The following memoranda are intended to assist in writing specifications.

Principal Characteristics and Conditions of Service. Service for which transformer is to be used, e.g., operating synchronous converters, induction motors, lights, etc. High- and low-tension voltages at normal load. Taps for obtaining different voltages. Rating in kilovolt-amperes and in kilowatts at stated power factor. Frequency.

Style and Description: Details of Construction. Whether oil-, air-, or water-cooled. Style and location of terminals. Where line surges are likely to occur, it is usual to specify, for large transformers, that the end turns, say 10 per cent of the total turns at each end, shall have extra heavy insulation.

Work to be Done by Other Contractors. Who is to supply and install floor framing and supports; high- and low-tension wiring, wiring and supports for delta- or star-connections, if to be used three-phase.

Performance and Tests. (See Standardization Rules of the A.I.E.E.) Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load with stated transformation ratio. High-potential tests of insulation. Requirements regarding effect of moisture and heat on insulation, such as the following: The transformers shall contain no material which will be permanently injured by moisture or by an occasional temperature of 95 deg cent, provided that this temperature is not maintained at any one time for a period greater than 3 hours. The transformers shall be capable of operating continuously at 80 deg cent, without the insulation being damaged thereby. Regulation with rated non-inductive load. Regulation with load of rated kilovolt-amperes at stated power factors, say 100 per cent and 90 per cent. State formula by which regulation is to be calculated. Reactance between primary bus and secondary terminals when transformers are to operate compound-wound synchronous converters. (The required reactance is usually specified by the manufacturers of the synchronous converter.) Amount of air or water for cooling, in cubic feet per minute at stated pressure. After the transformer has been in service for 1 year, its efficiency at full load shall be not lower than the above guaranteed amount by more than a stated percentage and after 2 years its efficiency shall be not lower than the guaranteed amount by not more than a stated percentage.

12. INSTALLATION OF TRANSFORMERS

Transformers require no special foundations but merely a level floor of sufficient strength to carry the weight. Provision should be made for an electrical connection from the tank of the transformer to the ground.

OIL- AND WATER-COOLED TRANSFORMERS. The greatest enemy to successful operation of transformers in general, and high-voltage transformers in particular, is moisture, in that 0.1 per cent of moisture in oil renders it unfit for use. This may result either from rain or dripping water falling into the transformer or onto some of the parts, or from the condensation of the moisture in the atmosphere on the various parts. For this reason all parts of a transformer must be very carefully inspected, cleaned, and dried before the transformer is put into service. If the operating potential is 15,000 volts or less an inspection will tell whether the transformer should be dried, but for voltages greater than 15,000 the drying operation should be carried out in every case.

Methods of Drying. The best method of drying is to send a current of dry air at 90 deg cent through and around the transformer. This should continue for 24 hours in all transformers, for 72 hours in high-voltage transformers of reasonable capacity, and longer in special cases. Another method of drying is to short-circuit one winding of the transformer and to apply to the other member a voltage of 1 to 2 per cent of the rated voltage of that winding so that a current of $^1/_5$ to $^1/_3$ of the rated value flows through the winding. This current should be adjusted so that a spirit thermometer placed on the low-tension coils shows a temperature of 80 deg cent and not greater.

Preparation of Oil. No potential should be applied to any oil-cooled transformer unless it is supplied with a proper amount of oil as the oil forms the essential insulating medium as well as cooling medium. The oil should be tested before using. Oil is considered in good condition when it will withstand 22,000 volts between disks 1 in. in diameter and 0.1 in. apart. Transformers for 40,000 volts or less will operate satisfactorily

* By W. A. Del Mar.

when this dielectric strength has dropped to 16,500 volts, but when this condition has been reached the oil should be dried, purified, and strained. Transformers for a voltage greater than 40,000 should not be used with oil which breaks down under 20,000 volts in the above-described test apparatus. A special apparatus for drying and purifying the oil is on the market (see *Gen. Elec. Bulletin* 4134).

The transformer tanks should be filled by pouring the oil through a fine cloth strainer and allowing the oil to settle 12 hours before using. Rubber tubing should not be used for carrying the oil as the sulfur in the rubber will eventually cause trouble. The cover of the transformer should prevent any water dripping into the transformer but there should be a free exit allowed for gases which may gather. If the transformer stands in a moist atmosphere a special "breather" containing calcium chloride should be employed. In all transformers the level of the oil should be well above the top of the transformer proper and this should be noted 2 or 3 days after the original filling to see whether the transformer windings have absorbed sufficient of the oil to lower the level a dangerous amount.

As the oil used for insulation in transformers undergoes a slow chemical deterioration in the presence of oxygen many oil-cooled transformers are sealed tight or closed with a special device which prevents the entrance of fresh air as the tank "breathes" owing to the expansion and contraction of the oil with change of temperature. Some transformers have the space above the oil filled with an inert gas such as nitrogen. In all events there should be some device to prevent the entrance of moisture.

Certain small sizes of oil-cooled transformers are designed to be suspended from cross-arms on poles or the sides of buildings or to be installed in manholes in a subway. These transformers are especially protected against the weather.

Precaution Against Overheating. It is most important to be assured of the proper circulation of the cooling medium as the temperature of the transformer will rise quickly to an excessive value in case of a failure of the cooling medium. In this case the load must be reduced and kept at such a value that the temperature of the oil at the top does not exceed 80 deg cent. If at any time the oil reaches an excessive temperature there will be a tendency for a deposit to form on the transformer and coils, which will interfere with the proper cooling. An inspection should be made occasionally for this purpose and the deposit removed. The oil should be sampled and tested each week for the first month and every 6 months thereafter. In taking samples of the oil great care should be exercised that the vessel in which the sample is contained is perfectly dried. The temperature of the oil in a self-cooled transformer should never exceed 80 deg cent, and in a water-cooled transformer 65 deg cent. Oil-cooled transformers must be in a well-ventilated compartment in which the air should not be more than 5 deg above the outside atmosphere. An inspection should be made from time to time to see that there is no condensation on the inside walls of the tank.

Precaution for Multiple Operation. Transformers should never be connected in multiple on both the primary and secondary sides unless it is known that the polarity is correct and that the ratio and regulation of the two transformers are the same.

AIR-BLAST TRANSFORMERS; DUCTS AND BLOWER SET. Air-blast transformers should be placed over an air duct of sufficient size to permit the required current of air to flow at a velocity of less than 500 ft per min. The duct should be of non-combustible material and should have smooth sides in order to offer very little resistance to the current of air. Air is supplied to this duct by means of motor-driven blowers of capacity to supply the proper quantity of air for a group of transformers at pressures from $1/2$ to $1\frac{1}{2}$ oz. Roughly the rating of the blower motor in horsepower is equal to

$$\frac{\text{(Cubic feet of air per minute)} \times \text{(pressure in ounces)}}{1200}$$

The air enters the transformer at the bottom, flows vertically through the coils, and passes out at the top, and also flows transversely through the iron, passing out at the side. Separate dampers at each outlet are provided in order to regulate the two currents independently. The dampers are regulated so that the outgoing air has a temperature 20 deg above the incoming air.

Since the transformers are so dependent on the air blast for their operation and safety, it is customary to provide a reserve blower set.

Location. Care must be exercised to protect the transformers from moisture and dirt and particularly, since they are open at the top, to place them where water and dirt cannot drop in the open top. All terminals of the air-blast type of transformer are usually brought out below so that the primary and secondary cables may be laid in the air duct and all connections and inspection may be made from below. It is therefore desirable that the air duct be sufficiently large to enable a man to move about therein.

Drying and Cleaning. In putting the transformer in operation all moisture must be removed before applying potential. This may be accomplished by running the blower set and forcing air through the transformers, which will be sufficient if the air is dry. Another method is to short-circuit one winding of the transformer and apply a low voltage of from 1 to 2 per cent of the rated voltage to the other winding, so that 75 per cent of full-load current flows through the windings. This is maintained for 24 to 36 hours. All transformers of this type should be cleaned once a month by means of compressed air at 20 lb pressure.

Measurement of Temperature. In determining the temperature of the windings only that calculated from a resistance measurement is dependable, as the coils are so thickly wrapped in insulation that a thermometer will not show the true temperature.

13. OPERATION OF TRANSFORMERS

Single-phase transformers may be used singly or in parallel on single-phase circuits, and in various combinations on polyphase circuits as described above. The polarity should be determined before making the connections.

PARALLEL OPERATION ON SINGLE-PHASE CIRCUITS. Single-phase transformers are very generally operated with the primaries in parallel on the supply circuit and their secondaries in parallel on the load circuit. In order successfully to operate in this manner two or more transformers, the transformers must have: (1) the same ratio of transformation; (2) the same regulation; and (3) the same value of X/R, where R and X are the total resistance and reactance respectively of any one of the transformers. Transformers divide the load inversely proportional to their reactances, provided the ratio of reactance to resistance is the same in both cases. If transformers are purchased to operate in parallel with others, proper provision must be made in the design of the transformers, and this fact should be stated in the specifications.

In general, a 50-kw transformer will have about twice the resistance and twice the reactance of a 100-kw transformer of the same commercial line, and therefore these transformers will divide the load in proportion to their capacity. But this is not likely to be true of transformers of different lines or made at widely different times.

If transformers not satisfying the above conditions are to be run in parallel, an impedance coil having a proper resistance and reactance may be connected in the circuit of one of them, thus establishing the necessary conditions for the proper distribution of load, provided the ratios of transformation are the same.

TRANSFORMERS ON POLYPHASE CIRCUITS. See Art. 3 on Transformer Connections.

14. AUTO-TRANSFORMERS AND COMPENSATORS

An auto-transformer or single-circuit transformer, also called a "compensator," consists of a transformer having the usual iron core but only one electrical circuit instead of two. This circuit is tapped at various points as shown in Fig. 25, and the primary and secondary circuits, while independent outside the transformer, unite in the same winding in the transformer. If an alternating voltage is impressed across the points ab, a magnetizing current will flow in the winding setting up an alternating flux which will link every turn and induce therein an alternating voltage. The voltage between any two taps, as ac, is proportional to the number of turns between the taps; thus any ratio of voltages may be obtained. If the secondary ac is loaded a current will flow in the primary and the primary and secondary currents will flow in the two parts of the winding as indicated in the figure.

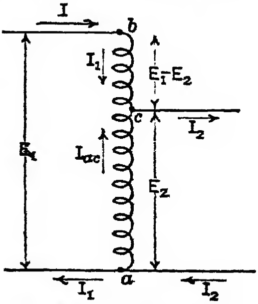

FIG. 25. Auto-transformer

VOLTAGE AND CURRENT RELATIONS. Let N_1 be the total number of turns between a and b, N_2 the turns between a and c, E_1 the voltage across the terminals a and b, and E_2 the voltage across the terminals a and c. Then, neglecting the resistance and reactance of the winding,

$$E_2 = \frac{N_2}{N_1} E_1$$

Let I_1 be the current entering the terminal b, I_2 the current in the *external* circuit connecting a and c, and I_{ac} the current *in the transformer winding* between a and c. Then, neglecting the resistance and reactance of the winding and the magnetizing current,

$$I_2 = \frac{N_1}{N_2} I_1$$

$$I_{ac} = I_2 - I_1 = \frac{N_1 - N_2}{N_2} I_1$$

The current in the turns between b and c is

$$I_{bc} = I_1$$

Auto-transformer Versus the Two-circuit Transformer. For $N_2 = {}^1/_2 N_1$ the current in the turns between a and c would be just equal, neglecting the exciting current, to the current in the turns from b to c (but opposite in direction). Consequently for a 2 to 1 transformation but one winding of an ordinary two-circuit transformer could be used, provided a tap was available at the middle point of this winding, and the rated output of the transformer could be obtained without the current in this winding exceeding its rated value. Since under these conditions there would be no current in the second winding, the heating of the transformer would be less than it would be were the transformer used as an ordinary two-circuit transformer, and therefore a greater output could be obtained without exceeding the nominal temperature rise.

In general, for the same power input into the connected load an auto-transformer requires but $\frac{E_1 - E_2}{E_1}$ of the copper required for a two-circuit transformer, where E_1 is the high-tension and E_2 the low-tension voltage. The higher the ratio of transformation the less the saving in copper. There is also a serious objection to an auto-transformer of high ratio of transformation, in that an accidental ground on the high-tension lead, b in Fig. 25, would establish a high voltage between the low-tension leads and the ground, which may cause a dangerous shock to a person touching either low-tension lead or may cause other damage. This may be partially prevented by grounding the common point of the high- and low-tension circuits, the point a in Fig. 25, in which case an accidental ground on the high-tension side would produce a short circuit, which would open the circuit breaker in the primary circuit, *provided the resistance between the two grounds is low and the circuit breaker operates properly.* These two provisions, however, may not always be realized even though reasonable care is taken, and it is therefore not considered good practice to use an auto-transformer of high ratio of transformation, except in special cases where economy of space is an important factor and danger from shock can be guarded against, e.g., on a-c locomotives.

RATING OF AN AUTO-TRANSFORMER. In commercial practice the rating of an auto-transformer in volt-amperes is taken equal to the difference between the high- and low-tension voltages multiplied by the rated current in that part of the winding, bc in Fig. 25, across which this voltage exists. The capacity of an auto-transformer for a given work bears to the capacity of a two-circuit transformer for the same purpose the ratio $\frac{E_1 - E_2}{E_1}$. For example, to step down the voltage of the supply mains from 500 to 400 volts and supply a load of 100 kva would require an auto-transformer having a rating of $\frac{500 - 400}{500} \times 100 = 20$ kva as against a two-circuit transformer having a rating of 100 kva. The weight, dimensions and cost of an auto-transformer are very nearly the same as for an ordinary two-circuit transformer having the same voltage and kva rating.

APPLICATIONS. Auto-transformers are used chiefly where the required change in voltage is small, e.g., for motor starters and for balancing the voltage between two or more circuits. The smaller the ratio of transformation the greater is the gain in cost and efficiency resulting from the use of an auto-transformer instead of a two-circuit transformer. Auto-transformers are also used to provide a neutral for the Edison three-wire system; see Distribution Circuits. In single-phase railway work single-phase auto-transformers are used on the locomotives for transforming the trolley voltage (from 3000 to 6000 volts) to the motor voltage (about 500). This is a rather high ratio of transformation for an auto-transformer, but as the saving in weight is very important and as one terminal is grounded, it has proved satisfactory for this service; see Electric Locomotives.

Auto-transformers are frequently constructed three-phase (and occasionally two-phase). These are generally used for starting polyphase motors by providing a lower voltage for the starting period. They are also occasionally used in high-tension distri-

bution. If the voltage applied to an a-c motor is reduced to one-half, the motor starting current will be one-half and the volt-amperes one-quarter. Thus the starting current in the line will be one-quarter. A three-phase auto-transformer may be either Y- or delta-connected. (See Section 3, Art. 35). The delta connection cannot be made to give a balanced voltage less than half that of the higher voltage, as may be readily seen from an inspection of Fig. 26.

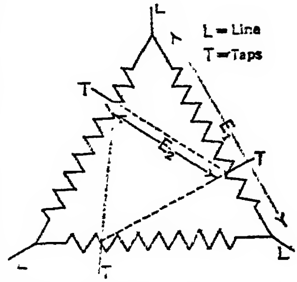

FIG. 26. Delta-connected Auto-transformer

DESIGN. The design of an auto-transformer is quite similar to that of a two-circuit transformer (q.v.), and the leakage reactance is calculated in the same way. For low-leakage reactance the primary and secondary coils must not be entirely separated, but each must be divided into sections and intermixed to as great an extent as possible. Having found the magnetizing current, core loss, resistance and reactance in the usual manner, the calculations follow the same methods as for power transformers. In general, the efficiency at unity power factor is given by the equation

$$\text{Efficiency} = \frac{E_2 I_2}{E_2 I_2 + (r_1 - r_2) I_1^2 + r_2 (I_2 - I_1)^2 + \text{Core loss}}$$

where r_1 is the total resistance of the winding measured between the high-tension terminals and r_2 the resistance measured between the low-tension terminals. The efficiency is better than that of a two-circuit transformer of the same kva rating.

CONVERTERS AND RECTIFIERS

By Walter I. Slichter

ENERGY CONVERTERS

1. MOTOR-GENERATORS

A motor-generator set is a combination of a motor and a generator having separate fields and armatures but mounted on the same shaft with common base and bearings. Combinations of various types of motors and generators are used; some of the more important combinations and their applications are described below.

Direct-current Motor Driving Direct-current Generator. These sets are used when it is desired to convert low-voltage direct current into high-voltage direct current, or vice versa; they are used in preference to a dynamotor (q.v.) when good regulation is desired in the secondary circuit.

Direct-current Motor Driving Alternating-current Generator. These sets are used for converting direct into alternating current. See also Art. 3 on Synchronous Converters.

Induction Motor Driving Direct-current Generator. The induction motor may be wound for potentials as high as 13,000 volts, and the transformation from alternating current at this voltage to direct current may be made without the use of transformers. Since the induction motor has a decreasing speed with increasing load the d-c generator must be compounded to give good regulation; with proper compounding excellent regulation may be obtained. The induction-motor-generator set is sometimes used in preference to a synchronous converter when the service requires specially good regulation. However, the efficiency of such a set (about 85 per cent at rated load) is less than that of a synchronous converter, even if no transformers are required by the motor-generator set. The motor-generator set also occupies from 50 to 80 per cent more floor space, weighs from 30 to 50 per cent more, and costs from 25 to 50 per cent more than a synchronous converter, in spite of the fact that they are designed to operate at the highest practicable speeds.

Synchronous Motor Driving Direct-current Generator. This combination is preferable in many instances to the preceding, because it operates at constant speed and because the field of the synchronous motor may be adjusted to make use of line compounding or to compensate for low power factor in other apparatus on the circuit. Provision must be made for the d-c excitation for the synchronous motor. If the d-c generator is wound for too high a potential a special exciter must be provided. Since there is no load on the set at starting the synchronous motor may be started in the usual manner.

2. DYNAMOTORS

A dynamotor is a d-c device combining both motor and generator action in one magnetic field. It has an armature having two separate windings and two separate commutators, one at each end of the armature. Either winding may be used as the motor winding, and the other as the generator winding. Such a machine performs the same function in a d-c circuit that a power transformer does in an a-c circuit, i.e., serves as a means of transforming high-voltage direct current into low-voltage direct current, or vice versa.

PERFORMANCE CHARACTERISTICS. The device corresponds to two machines in which there is only one core loss, one friction loss, one excitation loss, but two losses due to rI^2 in the two armature circuits. It is therefore more efficient than a motor-generator set, but less efficient than one machine. Since the currents in the two windings flow in opposite directions their resultant magnetic effect is zero. The machine has therefore no armature reaction (except for the slight amount due to the current to overcome the losses in the machine). It is not subject to the troubles of field distortion and bad commutation that occur in either motors or generators. It is impossible to compound a dynamotor, since any increase in field strength intended to increase the voltage of the generator would decrease the speed of the motor by the same amount and no change would result. The

ratio of the two voltages is therefore fixed by the number of turns, and only varies from this by the loss due to rI drop in both windings. These two drops are additive, and therefore the regulation of such a machine is not very good.

APPLICATIONS. Dynamotors are used largely to give large currents to start other motors, or to give low voltages or a fractional voltage in a multivoltage system for speed control. The motor of the combination may be wound for the line voltage and the generator for any fraction of the line voltage. Thus the combination supplies a large current at a low voltage, which will give a good starting torque in motors connected to it with a reasonable consumption of power. They are used as equalizers or " balancers " in three or multiwire circuits, but are not as desirable for this work as motor-generator sets with compound-wound machines, on account of their poor regulation. They are also used to supply a low voltage for such purposes as telephone and telegraph systems and the low voltage and large currents for electrolytic work.

3. SYNCHRONOUS OR ROTARY CONVERTERS

Since in general it is more economical to transmit electrical energy in the form of alternating currents and in many cases more convenient to utilize it in the form of direct currents, some means of converting from one form of electrical energy to the other is desirable. For this purpose synchronous converters and motor-generator sets (q.v.) are available. Synchronous converters are also called " rotary converters."

A synchronous converter is a machine very similar to a d-c generator in which certain commutator segments, or the conductors connected to them, are connected to 2, 3, 4 or 6 collector rings, as the case may be. When the movable member is caused to rotate, the voltage between any two collector rings is alternating. Such a machine, when driven by an engine or motor, may be operated as an a-c generator or as a " double-current " generator giving alternating current from its collector rings and direct current from its commutator. If the collector rings are connected to a source of alternating currents the machine will run as a synchronous motor and direct current may be obtained from the brushes on the commutator; i.e., the machine, with but one set of windings, acts simultaneously as an a-c motor and a d-c generator. It has therefore the friction, core loss, and excitation loss of one machine instead of two, and since the motor and generator currents flow in the same winding and during at least the major part of each cycle are in opposite directions, they more or less balance each other and the armature rI^2 loss is much less than in either a motor or generator alone.

Synchronous Converter vs. Motor Generator. A converter is much more efficient and weighs and costs less than a motor-generator set of the same capacity. It also occupies less space. However, since only one winding is used, there is a definite relation between the emf's of the a-c and d-c terminals. The maximum value of the alternating wave bears a definite relation to the direct emf (see below). It is therefore necessary to supply the converter with a voltage of the same order as the direct voltage, and this involves the use of transformers, if a high-voltage transmission line is used to supply the converter. Motors operating at voltages as high as 13,000 volts can be used in motor-generator sets.

Relative Efficiencies. The efficiency of a converter is in the neighborhood of 93 per cent and of the transformers 97 per cent, thus the efficiency of the combination is about 90 per cent. The efficiency of a synchronous motor is in the neighborhood of 93 per cent and of a d-c generator 92 per cent, thus the combination motor-generator set has an efficiency of 85.5 per cent. If the supply voltage is greater than 13,000 volts, transformers will also be needed for the motor-generator set and the net efficiency would then be 83 per cent.

Synchronous Converter vs. Rectifiers. A converter differs from a rectifier (q.v.), since the former gives a direct emf of constant and uniform value and the latter gives a pulsating unidirectional voltage and current. In the former the energy is stored in the form of magnetism for an instant whereas in the latter there is no magnetic field and no storage of energy. A rectifier will not work satisfactorily on an inductive d-c circuit, but a converter will.

APPLICATION OF CONVERTERS. The most common application of synchronous converters is in electric railway work. The great majority of motors for electric traction are d-c series type, operating at 500 to 600 volts. The energy for these motors must be transmitted over long distances, which requires a high-voltage a-c transmission line and converters to link the d-c distribution with the a-c transmission. Converters have also been developed for high-voltage d-c traction systems, these converters giving 1500 volts direct current. Two such converters may be connected in series for 3000-volt d-c distribution (*Elect. J.*, 12, p. 154, Apr. 1915). Synchronous converters are also used for lighting and power service and for electrolytic work.

TERMINOLOGY. The following terms are used to describe certain characteristic features of the various kinds of synchronous converters.

Phases and Rings. A single-phase converter has two collector rings, and each ring is connected to the windings by as many equally spaced taps as there are pairs of poles. The taps for the two rings alternate at equal spaces. A single-phase converter is therefore a two-ring converter.

A three-phase converter has three rings and three equally spaced taps (one for each ring) for every pair of poles. A four-phase or quarter-phase converter has four rings and four taps for every pair of poles. A six-phase converter has six rings and six taps per pair of poles.

Shunt and Compound-wound Converters. A converter may be shunt or compound wound, depending upon the service for which it is intended. The series winding is intended to make the converter take leading current when the load increases and thus automatically increase the voltage at the a-c terminals, but the ratio of the a-c *terminal* voltage to the d-c voltage remains unaltered.

Converter with Series A-c Booster. A synchronous converter with series booster is frequently used when exact hand regulation of the d-c voltage is required, as for lighting circuits. It is merely a converter with a separately excited a-c generator on the same shaft, and each phase of the armature of this booster is in series with one phase of the converter and the line. This generator acts as a booster and raises the voltage impressed upon the armature of the converter.

Inverted Converter. Sometimes a converter is operated to convert from direct to alternating current. It is then called an "inverted converter." The machine will operate satisfactorily in this manner, but its speed depends upon the nature of the a-c load. An inductive load in the a-c circuit causes the armature to demagnetize the fields, with a resultant increase in speed. It is therefore dangerous to operate an inverted converter on an inductive load unless it is provided with a speed-limit device. This effect does not occur when the machine is operating as an a-c motor, since its speed is fixed by the frequency of the supply circuit.

Cascade Converter or Motor Converter. This is a combination of an induction motor and converter connected in series or concatenation (see Motor-converters p. 11–12). The converter receives half the power in mechanical form from the shaft and half the power inductively, in the form of alternating current at half frequency, from the secondary of the induction motor. By this means the steadiness of a 30-cycle converter is obtained in a 60-cycle unit.

Split-pole Converter. The "split-pole" or "regulating-pole" converter is designed to give a variable ratio of alternating emf to direct emf for operation in parallel with storage batteries and similar purposes. The field poles are divided into sections the excitation of which may be controlled independently. The effect of the split pole is primarily to produce a third harmonic in the flux distribution curve, which increases or decreases the *total* flux per pole and therefore the d-c voltage, but does not change the a-c counter emf between slip rings, since these rings are connected to the armature winding at points 120 electrical degrees apart. Split pole converters give a voltage variation of about 20 per cent.

Commutating-pole Type. In most large converters, 500 kw and above, particularly for 60 cycles and high voltage, 600 volts, it is customary to provide commutating poles to improve commutation and reduce the cost by making it possible to run with a higher value of "volts per bar." See D-c Generators.

RATING AND PERFORMANCE. The standards of the A.I.E.E. specify a maximum rise of 50 deg cent on any part of the windings and 60 deg on the commutator for continuous operation. Twenty-five-cycle converters will give momentarily an output of three times their normal rating without damage or injurious sparking at the commutator, but 60-cycle converters are more sensitive to overloads.

4. PRINCIPLES OF CONVERTER ACTION

In this section are briefly treated those features of a synchronous converter, in which the converter differs in action from an a-c or d-c generator; see table on page 11–07 for a summary of the voltage, current, and capacity relations.

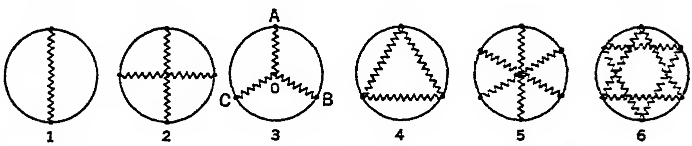
CONNECTIONS AND VOLTAGE RATIOS. The ratio of voltage on the a-c side to that on the d-c side depends upon the number of rings and type of connection employed.

Two-ring Converter. The two collector rings are connected by taps to the same winding as the commutator; hence the alternating emf has the same values as the direct emf at the instant that the taps pass the brushes. As this is also the maximum value of the

alternating emf, the effective value (i.e., the value to be indicated by a voltmeter) will be 0.707 times the maximum, or 0.707 times the direct emf. Fig. 1 shows in a simple manner the connection of a single-phase converter. The external circle represents a two-pole armature winding and inside is shown the supply transformer connected to two taps diametrically opposite each other. The voltage across this transformer would be 0.707 E, where E is the voltage between the positive and negative brushes on the d-c side.

Four-ring Converter. If two additional collector rings are connected to conductors spaced half way between the former taps, there results the quarter-phase converter shown in Fig. 2. The voltage across each supply circuit or transformer is the same as before, but the two voltages will differ in phase by 90 deg.

Three-ring Converter. If three collector rings are connected to taps spaced 120 deg apart the emf between adjacent collector rings will be the vector sum of AO and OB in Fig. 3. Since AO and OB each equal $0.5 \times 0.707\ E$ the voltage AB will be $\sqrt{3} \times 0.5$



FIGS. 1–6. Transformer Connections and Vector Relation of Voltages in Synchronous Converter

$\times\ 0.707\ E = 0.612\ E$. Thus in a three-ring or three-phase converter the voltage between adjacent taps is 0.612 times the direct voltage, and the connections of transformer are as in Figs. 3 and 4.

Six-ring Converter, Diametrical and Double Delta Connections. A six-ring converter may be connected diametrical as in Fig. 5 in which case the voltage of each transformer will be $0.707 \times E$ and the result will be like the combination of three single-phase groups. A six-ring or six-phase converter may also be connected " double delta " as shown in Fig. 6, which is similar to the combination of two groups of three-phase delta transformers. In both cases the voltage between adjacent taps of a six-phase converter is 0.355 E.

***n*-Ring Converter.** In general the voltage between taps of any converter having n equally spaced taps per pair of poles is

$$E_{ac} = \frac{E \sin \frac{\pi}{n}}{\sqrt{2}}$$

CURRENT RATIOS. To determine the ratio of the continuous current I to the alternating current I_3 per collector ring in a three-phase converter, for example, assume the d-c output equal to the a-c input with unity power factor; then

$$\sqrt{3}\ E_3 I_3 = EI$$

and, from preceding paragraph, $E_3 = 0.612\ E$

where E_3 = a-c voltage between lines; I_3 = alternating current per line; E = direct voltage; I = direct current. From these two relations

$$I_3 = 0.94\ I$$

The ratios of currents for other converters are obtained similarly, and are given in the table on page 11–07.

In actual practice the current on the input side must be greater than that given by these relations, in order to supply the losses in the converter, and the alternating current will also vary inversely as the power factor, which is taken as unity in the table.

RESULTANT COIL-CURRENT. In any machine acting simultaneously as a motor and a generator the two currents must flow in opposite directions, and the current in any particular conductor will be the difference between the two. In any particular coil the direct current is constant in amount and direction from the instant the commutator segment connected to this coil passes the positive brush to the instant it passes the negative brush, and conversely from negative to positive brush. In any coil midway between the a-c taps the alternating current is a maximum when this coil is half way between brushes (for unity power factor), and the current falls to zero as the coil reaches the interpolar position. Therefore, for the period of time that the direct current in a coil remains constant in amount and direction there is also in it a variable current changing from zero to a maximum and back to zero again. The net or resultant current will therefore have a wave shape

and frequency somewhat as shown at R in Fig. 7. The heating in this particular coil will therefore be proportional to the product of the resistance of the coil by the square of this current, and it is readily seen that the power lost is less than that due to either the direct or alternating current alone.

A coil situated very near one of the a-c taps will carry a direct current subject to the same law as before mentioned, but the alternating current in this coil is the same as that in the middle coil and has its maximum value when the middle coil is at the middle of the poles and not when this particular end coil is at the middle of the pole. The alternating

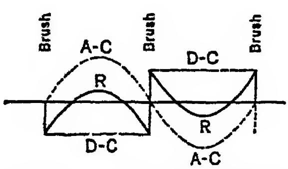


Fig. 7. Current in Coil Midway between Taps

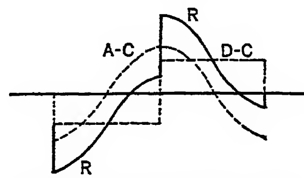

Fig. 8. Current in Coil at Tap in Two-ring Converter

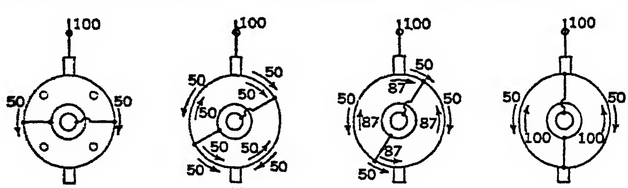
current in this coil may therefore reach its maximum value soon after the coil has passed a brush, as shown in Fig. 8, and the resultant of the two currents is greater than that in the middle coil. The farther a coil is situated from the middle coil of a group, the greater is the phase displacement of its alternating current, the greater is the value of the resultant current, and the greater is the heating effect. Thus although the heating effect in a rotary converter winding is less than that of a d-c machine having the same output it is different in each and every coil, is minimum in the central coil (when the power factor is unity), and is maximum at the coil nearest the tap, and the greater the angle between taps the greater is the total heating effect.

Distribution of Heat Losses in Armature Winding. In Figs. 9 to 12 inclusive, representing a two-ring converter, the numbers outside the circles represent the direct current in the winding (corresponding to 100 amp in the external d-c circuit and unit power factor on a-c side) and the numbers inside the circles the instantaneous alternating current in the winding. It will be seen that the resultant current in a coil midway between taps, Figs. 9 and 12, never exceeds 50 amp. A coil 30 deg from the middle, Fig. 10, has a maximum



Figs. 9–12. Component Currents in a Two-ring Converter

current of 100 amp. A coil 60 deg from the middle, Fig. 11, has a maximum current of $50 + 87 = 137$ amp, and a coil 90 deg from the middle (tap coil) may have a current of $100 + 50 = 150$ amp. The heating of the armature winding is therefore not uniformly distributed, though the conduction of heat from one part of the winding to another tends to equalize the temperature rise.

If the converter operates at a power factor different from unity, the position of minimum resultant current is no longer at the middle coil, but is moved one way with leading current and the opposite way with lagging current. Thus one end coil has improved heating conditions, and the middle coil and the other end coil have much worse heating conditions, the result being that the heating as a whole has increased and is more non-uniformly distributed than with unity power factor.

The power lost in each individual coil of a converter and the effect of the power factor on this loss is very well shown in Figs. 13 and 14, taken from a paper by J. E. Woodbridge (*A.I.E.E.*, 1908). In Fig. 13 the curved line shows the relative rI^2 loss in a coil having any position throughout 120 deg of one phase of a three-phase converter when the power factor is unity. The curve shows the ratio of the loss compared to the loss in the same machine acting as a d-c generator of the same capacity. It will be noted that the middle coil has a loss of 22 per cent of that of the generator and the end coils 120 per cent, and

that the average loss is 57 per cent. For a power factor of 0.966, representing a phase displacement of current of 15 deg, the loss in individual coils ranges from a maximum value of 180 per cent at one tap to a minimum value of 22 per cent in the coil shifted 15 deg to one side of the middle coil. The other end coil has a loss of a little over 80 per cent of the generator loss. The average value has been increased to 65 per cent.

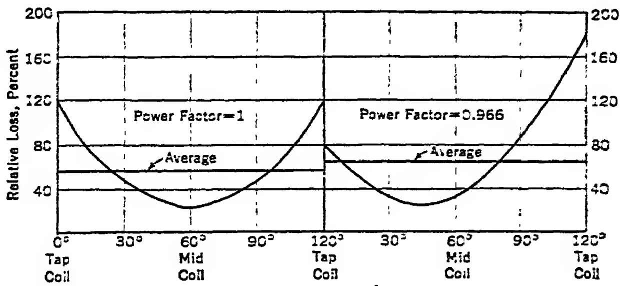


FIG. 13. Relative rI^2 in Individual Coils of Three-ring Converter

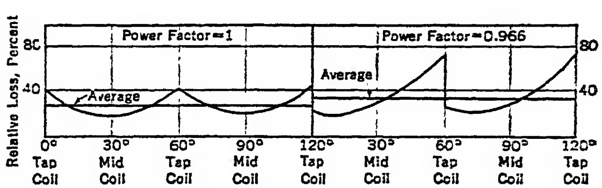

FIG. 14. Relative rI^2 in Individual Coils of Six-ring Converter

In Fig. 14 the same ratios are shown for a six-phase converter, in which the winding of one phase is distributed over only 60 deg. Consequently the conditions are better and the maximum loss due to low power factor is less.

DEPENDENCE OF OUTPUT UPON NUMBER OF PHASES. As a result of these conditions we have the following relations of the capacitance of a given armature with various numbers and connections of taps, the capacitance being based on an equal total amount of rI^2 loss.

It should be remembered that there are other losses besides coil losses in the converter, and that therefore practical figures are slightly different from those given in Table 1.

FIELD EXCITATION. The variation of the field excitation of a synchronous converter has much the same effect as in the case of a synchronous motor (see Synchronous Motors); that is, if its field is underexcited the armature will draw a lagging current which assists the field and sets up the necessary flux, whereas if the field is overexcited the armature will draw a leading current which opposes the field and reduces the flux. By this means the converter may be made to take either a leading or lagging current. A leading current flowing over a line having inductance tends to raise the voltage at the receiving end of the line.

Table 1.—Voltage, Current, and Output Ratios

	D-c Generator	Converters					
		2-ring	3-ring	4-ring	6-ring diametrical	6-ring double delta	12-ring
D-c volts	100	100	100	100	100	100	100
A-c volts between lines	...	71	61.2	71	71	61.2	71
A-c volts between rings	...	71	61.2	50	35	35	18
D-c amperes	100	100	100	100	100	100	100
A-c amperes in line	...	141	94	71	47	47	24
A-c amperes in winding	...	71	55	50	47	47	45
Relative RI^2 loss	100	137	55	37	26	26	20
Relative output:							
Unity power factor	100	85	134	165	197	197	224
87 per cent power factor	. .	...	99	115	129	129	135

Line Compounding. If there is sufficient leading current and sufficient inductance in the line, the voltage at the receiving end may be greater than at the sending end in spite of the resistance of the line. This is sometimes called "line compounding." The relation between the voltages at the two ends of the line may be expressed as follows:

Let E = voltage to neutral at sending end.
V = voltage to neutral at receiving end.
I_1 = component of line current in phase with V, i.e., the power component of the line current.
I_2 = component of line current at 90 deg to V, i.e., the *leading* reactive component of the line current.
r = resistance of one line.*
x = inductive reactance of one line.*

Then, noting that I_2 is to be taken positive when leading,

$$E^2 = (V + rI_1 - xI_2)^2 + (xI_1 + rI_2)^2$$

Use of Series Field. In practice a series field is added to the converter and the shunt excitation is adjusted so that the armature current is lagging at no load. As the load increases the series field increases, the adjustment being such that at about $^3/_4$ load the proper excitation for unity power factor is given. Hence at all loads over $^3/_4$ the field will be overexcited, the current will be leading, and the voltage will be raised or compounded.

5. DESIGN OF SYNCHRONOUS CONVERTERS

DESIGN. The design of a synchronous converter is very similar to the design of a d-c generator (q.v.), except for certain special conditions due to the fact that the frequency is fixed by the frequency of the supply system, and that greater latitude is allowed in the choice of the nominal value of the d-c armature reaction and copper density, because the real value of these quantities is the difference between their nominal d-c values and their a-c values.

SPEED AND NUMBER OF POLES. The revolutions per minute and the number of poles are definitely related to the frequency of the supply circuit, in cycles per second, in accordance with the formula:

$$120 \times (\text{Frequency}) = (\text{Number of poles}) \times (\text{rpm})$$

The choice of the number of poles usually depends upon the commutator.

COMMUTATOR. The design of the commutator is usually the limiting feature and therefore the first to be considered. This is particularly true of either high-frequency (60-cycle) machines or of those in which the d-c voltage is 600 or over. Three factors must be considered in the design to secure successful commutation and life of the commutator, namely, peripheral speed, voltage between bars, thickness of bars. If the peripheral speed or the voltage between bars is too high commutation will be bad. If the commutator bars are too thin the commutator will not retain its shape and commutation will be bad. These three limiting factors are very closely related and in a high-voltage machine give very little choice. The diameter of the commutator depends upon the voltage and frequency, and its minimum value is given by the three following relations. Let

s = pitch of commutator bars in inches. This ranges from 0.15 in small machines to 0.20 in high-voltage or high-frequency machines, to 0.40 in liberally designed machines. These values include the width of bar and about 0.03 in. insulation between bars.
V = peripheral speed of commutator in feet per minute. This ranges from 3500 in liberally designed low-voltage, 25-cycle machines to 5000 in 60-cycle machines, and is extended to 6000 under compulsion.
e = average volts per bar = machine voltage divided by the number of bars between brush studs. Normal values are from 8 to 16. The maximum voltage between bars is about 1.57 times this.
f = frequency in cycles per second.
E = voltage between d-c terminals.
p = number of poles.
n = total number of commutator bars.
d = diameter of commutator in inches.

Then $$s = \frac{Ve}{10Ef}, \qquad n = \frac{pE}{e}, \qquad d = \frac{sn}{\pi}$$

* r and x should include respectively the resistance and reactance not only of the line wire, but also of the transformers and reactance coils through which the line current passes.

ARMATURE AMPERE-TURNS AND CURRENT DENSITY. Since the d-c and a-c armature reactions are opposed to each other the nominal value of the d-c armature reaction ampere-turns may be chosen much higher than in generators, and values of 4000 to 8000 ampere-turns per pole are in common practice. The nominal or apparent value of the ampere conductors per inch of periphery varies from 500 to 900, and the apparent current density (d-c) in the armature copper from 2500 to 5000 amp per sq in.

DIAMETER OF ARMATURE. The diameter of the armature per pole varies from 3.5 to 6 in., and the diameter is usually from 6 to 8 in. greater than the diameter of the commutator, the difference depending upon the possibility of making a good mechanical construction of the end connections. The number of slots in the armature and the number of segments in the commutator must be a multiple of both the number of phases and the number of poles.

ARMATURE WINDING. The winding of the armature is usually of the multiple drum type, although the series winding may be used. The turns per pair of poles are divided by equally spaced taps (to the slip rings) into as many groups as there are phases. The number of turns in series between brushes is adjusted for the proper direct emf and a reasonable value of flux per pole. The alternating emf bears a definite relation to the direct emf, depending upon the type of connection (see above), and also to some extent upon the shape and length of pole arc.

FLUX DENSITY IN AIR GAP. The air gap or pole-face flux density usually has a value ranging from 40 to 60 kilolines per square inch as in generators.

DAMPING COPPER IN POLE FACE. In the pole face of every converter a squirrel-cage winding should be provided to assist in starting and to prevent hunting. The total cross-section of copper per pole ranges approximately from 1/10 to 1/5 of the armature copper per pole, and the end rings must be of reasonable cross-section compared to the bars. The joints between bars and end rings must be carefully made.

SHUNT AND SERIES FIELDS. The determination of the length of armature and length of commutator, and the design of the field, follow the same laws as the design of these parts for a d-c generator. The proportioning of the series field results from the considerations given above under Field Excitation, the problem being that a certain amount of leading current is required at a given load and to make the armature take this leading current the field excitation must be increased by a certain number of ampere-turns, from which the number of turns in the series field can be determined.

EQUALIZER CONNECTION. In large multipolar machines it is customary to connect to a common ring all commutator bars which are at the same potential; these "equalizer connections" avoid local cross-currents in the armature from flowing through the brushes and causing bad commutation. These cross-currents are caused by unequal or uneven air gap.

SHAFT, BEARINGS, ETC. Since the transfer of energy is in the conductors themselves, there is no mechanical torque other than that to overcome friction and core loss.

Table 2.—Efficiency and Losses of Converters

Kw rating	500	300
Frequency	25	60
Core loss	1.00	1.75
Armature rI^2	0.55	0.60
Shunt field rI^2	0.70	0.60
Brush rI^2	0.40	0.40
Bearing friction	0.55	1.50
Brush friction	0.30	0.65
Efficiency	96.50	94.50

Therefore the shaft, bearings, and mechanical housing of a rotary converter are quite light and present no particular mechanical difficulties in mechanical design. For the same reason converters do not require very elaborate foundations. Machines of less than 1000-kw capacity are usually supplied with a base and are complete in one piece; larger sizes are supplied with foundation plates.

EFFICIENCY AND LOSSES. The efficiency and distribution of losses of a typical 25-cycle and 60-cycle converter are shown in the Table 2. All values are in per cent of input at full load.

EXAMPLES OF DESIGN. In Table 3 are given design data on four representative converters of different capacities.

Table 3—Synchronous Converters

Design Data

Item	Unit	1	2	3	4
Poles		4	6	6	6
Rating	kw	500	500	100	300
Speed	rpm	750	500	1000	1200
D-c volts	volts	600	600	440	600
Frequency	cyc per sec	25	25	50	60
Number of phases		6	6	3	3
Armature reaction	amp-turns	15,000	6720	7400	3500
Nominal σ*	amp cond	1500	710	675	475
Flux density in gap	kilolines	58	52	23	53
Armature diameter	inches	25.6	36	21	28
Slots per pole		24	24	65/6	21
Armature length	inches	11	17.25	7.1	10.5
Commutator diameter	inches	19.7	28	16.5	20
Number of segments		288	288	194	252
Periph. speed of commutator	feet per minute	3800	3650	4300	6280
Volts per bar	volts	8.3	12.5	13.6	14.3
Pitch segments	inches	0.17	0.306	0.266	0.25
Armature diameter per pole	inches	6.4	6	3.5	4.75
Nominal U†	amperes	6000	3600	2630	3400

* σ = ampere conductors (d-c) per inch periphery.
† U = amperes (d-c) per square inch.

6. TESTS AND OPERATION OF CONVERTERS

TESTS. The following are the usual tests made on converters to determine the efficiency, regulation, and heating and to show any defects in construction.

1. Resistance of Armature, Shunt Field, and Series Field. The armature resistance is usually measured between points on the commutator diametrically opposite and the equivalent resistance calculated from this value by the equation

$$\text{Equiv. resistance} = \frac{4 \times (\text{Diametrical resistance})}{(\text{Number of poles})^2}$$

To obtain the true rI^2 in a converter armature this equivalent resistance is multiplied by the square of the external direct current and by a constant as given in Table 4.

Table 4.—Loss Factors

	Theoretical	Commercial
Single-phase	1.39	1.47
Three-phase	0.56	0.59
Quarter-phase	0.37	0.39
Six-phase	0.26	0.27

These values hold only if the converter is operating at unity power factor. For any other power factor the reactive component of the alternating current per phase must be found and the square of this component times the resistance per phase of the armature gives the additional rI^2 loss due to the lesser power factor.

2. No-load Saturation Curve. The no-load saturation curve, as in a-c generators and d-c generators (q.v.) is usually plotted between commutator voltage and ampere-turns of shunt field.

3. Core loss as in a-c and d-c generators (q.v.).

4. Phase Characteristic at no load and at full load as in synchronous motors (q.v.).

5. Synchronous Impedance as in a-c generators (q.v.).

6. Starting Tests to determine current and voltage necessary to start the converter on a-c time to reach full speed, and voltage induced in field windings as in synchronous motors (q.v.).

7. Heat Run. This may be made either with a resistance for load or two similar converters may be tested in parallel by the Hopkinson or "pump back" method; see Transformers. In addition to a source of d-c power of the rated voltage of the converter to supply the losses, either a d-c booster or an a-c potential regulator is needed to adjust the load.

8. Insulation Tests. See Alternating-current Generators and Standardization Rules of the A.I.E.E.

9. Pulsation Test. A synchronous converter is very sensitive to any change in impressed voltage or frequency. A sudden change in either of these factors will cause a pulsation which will start the machine hunting, as discussed in the article on Synchronous Motors. This hunting may increase until the machine falls out of step or flashes over. To

determine whether a converter has a dangerous tendency of this kind, a test is made in which two similar machines are supplied with power from a common generator. Between each converter and the common connection a resistance is placed in each a-c line, having a value that will give with full-load current a drop in voltage of 15 per cent of the rated voltage of the machine. Thus there is 15 per cent rI drop between each converter and the generator and 30 per cent between the two converters. The two machines are operated at no load and at rated voltage with the shunt fields adjusted for minimum input. The voltage across the commutators is observed for any periodic variation. Then the field of one machine at a time is varied from half normal to twice the normal value, and any indications of periodic variations of the direct voltage noted. If the machines have a proper damper winding in the pole faces, they should not develop any dangerous hunting, even under the above unfavorable conditions.

SPECIFICATIONS. The following memoranda are intended to assist in writing specifications.

Principal Characteristics and Conditions of Service. Use to which converter is to be put, such as railway, lighting, motor driving, or battery charging. Whether it is to convert from alternating to direct current, or vice versa. Voltages and number of phases. Nominal rating in kilowatts or institute rating in kilowatts. Frequency and speed.

Style and Description; Details of Construction. Whether interpole; whether shunt or compound wound, or whether there is a split-pole field winding; whether rheostat is to be supplied for shunt field; if so, its characteristics. Proposed method of starting, and whether starting apparatus is to be supplied. Whether a speed-limit device is required; if so, the shunt field rheostat shall have sufficient resistance to speed the machine for testing the speed-limit device, the latter being set at 15 per cent over rated speed. Whether an end play device (or oscillator) is desired, and if so, what type or types are acceptable.

Work to be Done by Other Contractors. Whether the synchronous converter contractor is to furnish and install the following: Main wiring, field wiring, field-rheostat grids, dial plate and chains, starting panels, starting rheostat or motor generator, foundations.

Performance and Tests. Temperature rises upon which nominal and Institute ratings are to be based. Overload capacity (see Standardization Rules of the A.I.E.E.). Commutation limits. Efficiency at 25, 50, 75, 100, 125, and 150 per cent nominal load. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation. Converters shall operate in parallel without "hunting" from no load to stated (say 200 per cent) overload, provided drop in high-tension lines due to resistance between any converter and any other synchronous apparatus in the system does not exceed a stated value (say 20 per cent), and provided that the phase variation does not exceed a stated value (say 2.5 deg). What voltage regulation is required, how it is to be obtained, and whether it is to be hand or automatic. If the converter is shunt wound, state voltage-regulation requirements. What per cent reactance between a-c bus and converter is required?

OPERATION. In the operation of synchronous converters the points mentioned below should receive special attention.

Transformer Connections. The usual methods of connecting transformers to supply converters are shown diagrammatically in Figs. 1 to 6 and are discussed above in the section on Voltage Ratios and also in the article on Transformer Connections. Of the three-phase to six-phase connections the choice must be made with some care, as all connections are not equally good for each specific use of the converter.

Methods of Starting. The several methods of starting converters are as follows:

Alternating-current Starting, which is the same as the starting of motors; see Synchronous Motors.

Direct-current Starting. The machine is started as a d-c shunt motor and synchronized on the a-c side after it is up to speed. This requires less power, but takes more time and more skill in order to synchronize. To secure maximum starting torque, the a-c side should be disconnected from the transformers, which otherwise act as a shunt to a part of the starting current (Newburg and Smith, *Elec. J.*, 15, p. 24, January, 1918).

Starting with Auxiliary Motor. This involves the extra cost and extra continuous loss of the auxiliary induction motor. It is no more efficient than starting by direct current and requires the same amount of time. By the use of suitable relays the starting and synchronizing may be made entirely automatic (Wensley, R. J., *El. Ry. J.*, 53, p. 948, May 17, 1919).

Combination Alternating- and Direct-current Starting. The machine is started up with direct current, then disconnected from the d-c mains and connected to a low-voltage tap of the a-c supply, and brought up to full speed. This method is more economical of power and time but requires more starting apparatus than either the a-c or d-c methods.

Field Break-up Switch. All converters are supplied with a switch to open the field in

several places to avoid the strain of the high potential induced in the field during starting and to reverse the direction of current in the field after the machine is up to speed in order to reverse the polarity if it should not be right. This is usually a double-throw switch with several poles.

End-play Device. In order to prevent the brushes from wearing grooves in the commutator and collector rings a device is mounted upon one end of the shaft to move the shaft endwise back and forth periodically. In small machines this is a mechanical device consisting of a ball running between two warped surfaces. In large machines it consists of an electromagnet which periodically pulls out the armature a short distance. The magnetic pull of the main field poles pulls the armature back.

Speed-limiting Device. In case a converter should be disconnected from the main a-c generating circuit and still remain connected so that it would tend to operate from the d-c side there is danger of its speed becoming dangerously high. To avoid this a centrifugal governor is placed on the shaft and arranged to operate the main d-c switches of the converter electrically.

VOLTAGE REGULATION. There are several methods of regulating the voltage delivered by the commutator of a converter.

Compound-wound Converter with External Reactance. This method is automatic and will give about 10 per cent variation in voltage. It is standard practice for railway work; see also Railway Substations.

Shunt-wound Converter with Synchronous Booster. A synchronous generator is carried on the same shaft as the converter and connected in series between the transformers and the collector rings of the converter. The method is good but expensive. G. A. Juhlin (*Inst. El. Eng. J.*, 55, p. 241, April, 1917) gives a detailed discussion of the relative advantages of reactance and booster regulation.

Shunt-wound Converter with Induction Regulator. A large variation in voltage is possible, but this method does not respond to quick changes. It is quite generally used in lighting work.

Shunt-wound Converter and Taps on the Transformers. The voltage ratio of the transformers may be varied. This is usually accomplished by connecting the line to different taps on the primaries, which involves opening the circuit or short-circuiting a portion of the transformer at each change.

Regulating or Split-pole Converter. With this type of converter the voltage regulation is gradual and normally accomplished by hand, but by the addition of an automatic voltage regulator may be made automatic.

WEIGHTS AND SPEEDS. The weights and speeds of a commercial line of 60-cycle compound-wound converters for 250 volts direct current are given in Table 5. All have commutating poles.

Table 5.—Typical Rotary Converters

Poles	Kw	Rpm	Phases	Weight, pounds
6	100	1200	3	3700
6	150	1200	6	4370
6	200	1200	6	5650
6	300	1200	6	6800

7. MOTOR-CONVERTERS

A motor-converter is a combination of an induction motor and synchronous converter, with the secondary of the motor and the armature of the converter mounted upon the same shaft and connected together electrically without slip rings. The induction motor receives all the a-c power, transforms a part of it into mechanical power delivered to the shaft, and also acts as a transformer delivering the rest of the power in electrical form at a lower frequency from its secondary to the armature of the converter. It operates like two induction motors in " concatenation " or " cascade." The object is to obtain the steadiness of a 30-cycle converter on a 60-cycle circuit.

The speed of a motor converter depends upon the supply frequency and varies inversely as the sum of the number of poles in both machines. Thus if a combination of a 6-pole motor and 6-pole converter be operated from a 60-cycle circuit the speed of the armature will be 600 rpm. The primary of the induction motor will operate at 60 cycles, but the secondary will supply the armature of the converter with 30 cycles. Thus the converter may be built with the good design constants of a 30-cycle machine.

This combination is larger than a converter but smaller than a motor-generator set, and its efficiency is lower than that of a converter. It is used somewhat in Europe but not much in the United States.

FREQUENCY CONVERTERS

Frequency converters are motor-generator sets in which both machines are designed for operation with alternating current, but for two different frequencies, thus a 25-cycle motor may drive a 60-cycle generator. They are used for three general classes of work which may be typified as follows:

(*a*) To supply 60-cycle current for lighting from a 25-cycle power circuit. The 60-cycle current is much more satisfactory for lighting than the 25-cycle current.

(*b*) To supply 25- or 15-cycle current for single-phase railway from a 50- or 60-cycle power system.

(*c*) To tie together two large power stations which started independently with different frequencies and, as a result of growth and changed economic conditions or ownership, find it desirable to be able to exchange energy either for purposes of evening up the demand or to meet the emergency of an accident to the generators of one of them. Most of the large power stations in a given neighborhood, even when owned by different corporations, are tied together to help each other out in case of trouble in one of them. For this type of service it is desirable that the frequency converters be "reversible," that is, either machine may be the driving motor.

Although several types have been proposed and discussed on paper, only two types have attained, or are likely to attain, any great commercial importance. These are the induction-synchronous and the synchronous-synchronous types. The former is not ordinarily reversible; the latter is.

8. INDUCTION-SYNCHRONOUS TYPE

An induction motor direct connected to a synchronous a-c generator (either single-, two-, or three-phase at either end or any combination thereof) may be designed, by choosing a suitable relation between the number of poles on each machine, to receive power at any frequency and deliver power at any other frequency. Thus a 10-pole motor operating on a 25-cycle circuit driving a 24-pole generator at 300 rpm will deliver approximately 60 cycles. This combination has the disadvantage that an increasing load causes decreasing speed and therefore decreasing frequency in the load circuit. This can be taken care of in some cases by choosing a ratio of poles which will give a nominal ratio of 25 to 62.5 cycles, for instance, and by added resistance in the secondary of the induction motor, regulate the speed at all loads so that the generator gives 60 cycles. Where the secondary system or load is an independent circuit without other generators there is no objection to allowing the frequency to vary slightly from the nominal value.

If there are to be two frequency converters in parallel supplying the load the adjustment of the division of load may be accomplished either by suitably designing the resistances of the secondary of the two induction motors so that they have the same slip, or by having an adjustable resistance connected in these secondary circuits of the motors. The great advantage of the induction-synchronous type is that, owing to the characteristics of the induction motor, a variation of 1 or 2 per cent in the frequency of either of the two systems will not cause a serious overload on the set, as is the case with the synchronous-synchronous type.

9. SYNCHRONOUS-SYNCHRONOUS TYPE

This consists of a synchronous motor driving a synchronous a-c generator. The constant-speed characteristic of a synchronous motor makes it particularly suited as the driving motor of a frequency converter, as this insures a constant ratio of frequencies irrespective of the load on the set.

Such sets are more generally used than any other type, particularly for linking together two systems whose frequencies are fixed by the presence of other generators. However, any considerable variation in the frequency of one system will place a considerable overload on the set and may cause it to pull out of step. Consequently, it is advisable that the capacity of the set be not too small in proportion to the capacity of the system. The synchronous motor usually has an amortisseur or squirrel-cage winding in its pole faces in order to assure good starting ability and to reduce hunting (see Synchronous Motors). This type of set is reversible, that is, will transfer energy either way between the systems which it ties together. The reversal of the flow of energy is accomplished by moving one of the stationary armatures in its cradle as described below.

In order that a synchronous-synchronous set may operate properly in parallel and divide the load proportionately with other synchronous apparatus on the two systems to which the motor and generator are respectively connected, the number of poles of both motor and generator must be carefully chosen. Thus to change from 25 to 60 cycles per second, the highest speed which allows an exact transformation of frequency is 300 rpm, and this requires 10 poles on the 25-cycle machine and 24 poles on the 60-cycle machine.

DIVISION OF LOAD ON SYNCHRONOUS SETS. The parallel operation of two or more sets of this type involves certain complicated considerations. In the first place the division of the load depends not only upon the voltage regulation of the individual machines constituting a set, but upon the mechanical position of the armatures on the shaft. Two sets built apparently the same may not divide the load equally because of inaccuracy in the placing of the keyways, etc. To avoid this trouble it is customary to mount the stationary member of one machine of each set movable in a cradle, so that the angular phase position of this member (usually the stationary armature) with respect to the base, may be adjusted. The two sets to be operated in parallel are loaded, and the stationary armature of one machine is rotated in the cradle until the load on the two machines divides properly.

SYNCHRONIZING FREQUENCY CONVERTERS. The synchronizing of such sets is difficult, and several complicated conditions must be satisfied. The theory is quite involved and is discussed at length in a paper by J. B. Taylor on Parallel Operation, *Trans. A.I.E.E.*, Vol. 25, p. 113, from which the attached table is taken. The essential requirement is that it is necessary to synchronize not only the motor with its supply circuit, but also the generator with its load circuit. Thus, when the motor has been synchronized properly, it may be found that the generator is 180 deg out of phase with the load circuit. To bring the generator into phase it is necessary to cause the motor to "slip" one or more poles successively until the generator comes into proper phase; this can be done by reversing the field of the motor one or more times, depending upon the number of poles on the generator and on the motor. The necessity for more than one reversal is due to the fact that with a large number of poles on both motor and generator there are only a few combinations in which the poles of the motor and the generator of one set match up with the poles of motor and generator of another set. Thus with a 10-pole motor and 24-pole generator (the most common arrangement) when the motor slips one pole or 180 electrical degrees of its circuit, the generator slips $24/10 \times 180$ or 432 electrical degrees of its circuit. It is necessary to make the motor slip 5 poles or 5×180 deg to make the generator slip the first even multiple of 360, that is, $5 \times 432 = 2160$ or 6×360 deg. In this case it might be necessary to make the motor slip 4 poles before getting the right combination. Five reversals would reproduce the original conditions, and, after that, more reversals would repeat the cycle of possible combinations. Table 1 shows the possible combinations for various commonly used sets.

In practice, this difficulty is overcome by the use of a special synchronizing indicator

(see Synchronizers) having two hands on the same dial; one hand shows the phase relation of each member of the set with respect to its particular external circuit. It is necessary to synchronize the set when both hands are not only stationary but point to the zero position. If only the motor were properly synchronized it would be found that both hands were stationary, the motor hand pointing to zero but the generator hand pointing to some other position.

Table 1.—Possible Combinations for Synchronous-synchronous Frequency Converters

Cycles		Poles		Speed	Kw	Chances of Correct Synch.	Field Reversing Switches	
Motor	Gen.	Motor	Gen.	Rpm	Capacity		Motor	Gen.
25	60	10	24	300	Max	1 in 5	Yes	Yes
25	62.5	4	10	750	600	1 in 2	....	Yes
25	62.5	8	20	375	Max	1 in 2	....	Yes
40	60	4	6	1200	150	1 in 2	....	Yes
40	60	8	12	600	3000	1 in 2	....	Yes
40	60	12	18	400	Max	1 in 2	....	Yes
25	50	4	8	750	600	Certain	....	....
25	50	8	16	375	Max	Certain	....	....
33.3	60	10	18	400	Max	1 in 10	Yes	Yes
30	60	6	12	600	1000	Certain	....	....
30	60	8	16	450	Max	Certain	....	....

Explanation of Table. The first two columns show the frequencies of the two circuits to be tied together; the third and fourth columns, the number of poles on motor and generator, respectively; the fifth column, the speed of the set. The sixth column, the maximum capacity in kilowatts in which such sets are available in commercial practice ("max" means as large as desired). The seventh column states the chances of the set coming in right the first time, and indicates the maximum number of trials that might be necessary before the right combination is found: thus in the first line, four trials might have to be made to secure proper synchronizing. The last two columns tell whether it is necessary to have field reversing switches on each member. These are used to make the motor slip a pole and to reverse the polarity of the generator. The use of reversing switches on both members of a set reduces the number of trials necessary to get proper synchronizing.

Synchronous-synchronous sets are started by means of a squirrel-cage winding in the field poles which makes the motor start (at a reduced voltage) as an induction motor and pull into step without synchronizing.

By providing ample capacity in the motor, particularly in field copper, these sets may be used for power-factor correction of the motor circuit by overexcitation of the motor.

The efficiency of these sets is quite high, but is of course the product of the efficiencies of the two machines. The machines may be wound for high voltage, thus eliminating the need of transformers for voltages of 13,000 or less. Two-bearing enclosed sets are quite popular in order to economize in space and in friction loss.

APPLICATION. For the supply of power to single-phase railways at 25 cycles from a 60-cycle three-phase transmission network it is customary to use a 24-pole, three-phase synchronous motor running at 300 rpm at 60 cycles, driving a 10-pole single-phase synchronous generator giving 25 cycles. Several of these are in use in Philadelphia, notably a 30,000-kw single-phase generator driven by a 36,000-kva three-phase motor. The stator of the 60-cycle machine may be shifted through 24 mechanical degrees, equivalent to 288 electrical degrees. A shift of 90 deg is used in load control, and the balance, 188 deg, is reserved for synchronizing. A 70-hp motor is used to do the shifting. The single-phase generator would rate at 61,000 kva if operated three-phase. This is the price paid to minimize the effects of the pulsating single-phase armature reaction.

A special type of frequency converter makes use of the principle of "frequency splitting" by splitting the 60 cycles into $25 + 35 = 60$. The fraction $^{25}/_{60}$ of the power is transformed electrically, and $^{35}/_{60}$ is transformed mechanically. This makes possible a reduction in the rating and size of one of the machines to $^{35}/_{60}$ of the total power transformed.

A typical set, of which many are in use (Hell Gate, New York), consists of a 14-pole, 35,000-kw, 60-cycle induction motor which would tend to run at 514 rpm. The rotor is phase wound with collector rings. The other machine is a 10-pole 20,400-kw, 25-cycle synchronous machine for 300 rpm. The two are on one shaft and forced to run at 300 rpm by the synchronous machine (see Fig. 1). At 300 rpm the induction motor has a slip of 214 rpm which gives a voltage at 25 cycles in the secondary, and this is fed to the 25-cycle

system. In addition the induction motor delivers power to the shaft and thus drives the synchronous machine. The power converted electrically is 35,000 × 214/514 = 14,600 kw, and the power converted mechanically is 35,000 × 300/514 = 20,400 kw, which is the rating necessary for the synchronous machine (neglecting losses).

Because it is difficult to design the winding of the induction motor rotor for high voltage, transformers are interposed between it and the 25-cycle system. The flow of energy is reversible, depending upon the relative phase angles of the two machines, and the transfer of power may be controlled by moving the stator of the synchronous machine in its cradle. The set is started by an auxiliary induction motor, synchronized with one system, and then, by moving the stator of the adjustable machine through a small angle, it is synchronized

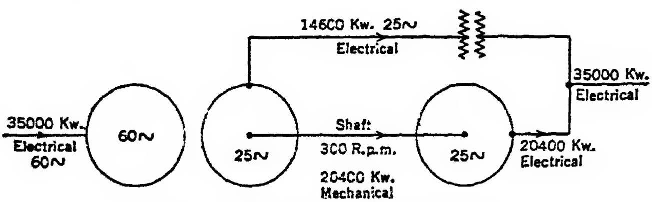

Fig. 1. Induction Frequency Converter

with the other system and the load adjusted as desired. The synchronous machine may be used for power-factor correction. Such sets must be of large capacity as they tie the two systems together rigidly and any shock on one is transferred to the other and the set is greatly overloaded in trying to hold the two systems together.

10. INDUCTION TYPE

When the stator of an induction motor is excited from a supply circuit having a frequency of f_1 cycles per second and the rotor of this motor is driven by another motor in the *opposite* direction to that in which it would rotate owing to the currents in its stator winding, the frequency of the current induced in the rotor winding is

$$f_2 = \frac{N_0 + N}{N_0} \cdot f_1$$

where N_0 = synchronous speed of the motor and N = actual speed at which its rotor is driven. This combination of two motors (the driven motor really acts also as a generator) may therefore be used as a frequency changer.

Neglecting the losses in the driven motor, the electrical input into its stator is

$$\frac{f_1}{f_2} \times \text{(Output of set at frequency } f_2\text{)}$$

and the mechanical output of the driving motor is

$$\frac{f - f_1}{f_2} \times \text{(Output of set at frequency } f_2\text{)}.$$

This combination is less expensive than the usual motor-generator set, but it has the disadvantage of poor regulation, as every change in the potential of the supply circuit is transmitted to the receiving circuit; it is therefore but seldom used.

PHASE CONVERTERS AND BALANCERS

A phase converter is a machine for converting single-phase power into polyphase power, or vice versa. A phase balancer is a machine for balancing the load on one or more polyphase generators when these generators are supplying an unbalanced load to the circuit to which they are connected.

11. PHASE CONVERTER

The phase converter is a single-unit two-phase induction motor, or a two-phase synchronous motor with an extra heavy squirrel cage.

SINGLE-PHASE TO POLYPHASE CONVERSION. The Norfolk and Western Electric Locomotives receive single-phase power through a single trolley. Three-phase induction motors are used to drive these locomotives. The connecting link between the single-phase and polyphase system is a two-phase induction motor operated as a phase converter. The connections to change from single-phase to an approximately balanced three-phase system are shown in Fig. 1.

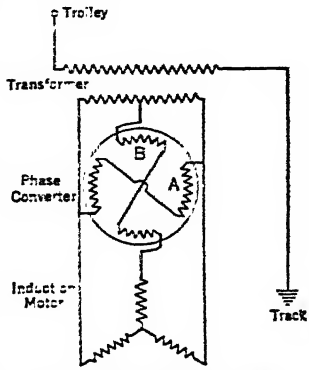

Fig. 1. Connections of Phase Converter

The machine is driven by power supplied to phase *A*. Phase *B* corresponds to the teaser coil of a transformer T-connection. This phase has an emf induced in it of the proper magnitude and phase position to make the voltages across the three phases approximately balanced.

The phase converters on the Norfolk and Western are started by single-phase commutator motors. The operating speed of the converter is high, permitting a design of minimum weight for a given output. The converter in addition to furnishing power to polyphase motors may be used to drive auxiliary apparatus. Polyphase motors receiving their power from phase converters may be used for regenerative braking. The rated capacity of a two-phase balancer should be one-half of the usual polyphase power required.

POLYPHASE TO SINGLE-PHASE CONVERSION. It is quite common to supply the single-phase power for railways from existing three-phase systems, and a phase converter may be used for this purpose; but so many difficulties arise from any electrical interconnection between a single and a polyphase system that experience has shown the superiority of a motor-generator set for this purpose. The set consists of a three-phase synchronous motor driving a specially designed single-phase generator. As in most commercial uses a conversion of frequency from 60 to 25 is also necessary, a frequency converter (q.v.) is the usual solution.

12. PHASE BALANCER

In many three-phase distribution circuits the loads are not balanced on the three phases because small single-phase loads are connected on the various phases. The unbalance changes from time to time so a simple segregation of the single-phase load is not possible. The phase balancer was introduced about 1915 to correct this condition but, as the problem of unbalancing has become less with the increase in size of generating systems, no new ones have been put in service for some time and the device is only of theoretical interest. It makes use of the principle of symmetrical components, according to which any unbalanced three-phase system of currents may be resolved into two balanced three-phase systems of opposite phase rotation or sequence (see Section 3, Art. 37).

The phase balancer puts into the system the small balanced three-phase currents of opposite or negative phase sequence to those of the generators, leaving the generators to supply the other and larger balanced system or component. The shunt balancer is the more usual as it may be made to take care of changing conditions automatically. It consists of a large and a small synchronous machine on the same shaft with their respective phases in series but reversed in phase connection.

For details the reader is referred to the bibliography and particularly to the article by Heningsen.

13. PHASE SHIFTER

This is officially known as a three-phase transformer for phase angle control. It consists of a three-phase static transformer with shunt and series coils in one member, usually the secondary, the series coils being arranged to give voltages in quadrature to the respective shunt coils. The series coils have taps so that the amount of quadrature voltage may be varied in steps from about -10 to $+10$ per cent. This gives a variation in phase angle of -6 to $+6$ deg. Its purpose is to shift the phase angle of the secondary with respect to the primary. It is used as a tie between two systems operating from independent generating stations, and its purpose is to regulate and control the power and direction of energy flow through it, thus dividing the load on two systems.

RECTIFIERS

The term rectifier is applied to any piece of apparatus for transforming alternating into direct current, or vice versa, by electric conduction alone without the storage of energy in a magnetic field. There are many types which, in order of practical importance, are:

1. Mercury arc with a cold (pool type) cathode and gaseous conduction.
2. Mercury vapor with a hot cathode and gaseous conduction ("Phanotron").
3. Mercury vapor with a hot cathode and gaseous conduction with a grid for control, three electrode ("Thyratron").
4. Thermionic, with a hot cathode and pure electron conduction in a high vacuum ("Fleming Valve").
5. Copper oxide.
6. Electrolytic.
7. Crystal.
8. Vibrating reed.
9. Rotating commutator.

The first three are used in power work, the fourth to eighth inclusive are used only in communication, particularly in radio. The last is not very satisfactory.

APPLICATIONS. Mercury-arc rectifiers find their chief use in the supply of direct current to railways at 600, 1500, or 3000 volts. To a lesser degree they are used in charging storage batteries. They are at their best at high voltages, where their efficiency is much higher. The other rectifiers are used to supply direct current to the plates of the tubes used in radio transmitting and receiving sets which usually take power from an a-c supply system.

14. MERCURY-ARC RECTIFIER

The operation of this rectifier depends upon the fact that a tube containing mercury vapor under a low pressure and having one electrode of mercury, and the other of some other conductor, graphite, offers a very high resistance to a current tending to flow through the tube from the mercury to the other electrode, but has a very low resistance to a current flowing in the opposite direction, provided the current is once started by forming an arc in the tube.

CONNECTIONS FOR SINGLE-PHASE OPERATION. The connections employed in practice are shown in Fig. 1. The complete equipment consists of a source of alternating current *HG*, the rectifier tube *AA′*, two reactances *E* and *F*, and the load represented as a storage battery *J*. The rectifier tube is an exhausted glass vessel in which are two graphite electrodes (anodes *AA′*) and one mercury cathode *B*. Each anode is connected to a separate side of the a-c supply, and also through one-half of the main reactance to the negative side of the load. The cathode *B* is connected to the positive side. There is also a small

starting electrode *C* connected to one side of the a-c circuit through a resistance and used for starting the arc. When the rectifier tube is rocked so as to form and break a bridge of mercury between the cathode *B* and starting anode *C* a small arc is formed. This produces mercury vapor in the tube, and the arc immediately jumps to one or the other of the main anodes and alternates on these during regular operation.

MODE OF OPERATION. To analyze the operation, assume an instant when the terminal *G* is positive and *H* negative. The positive current will then flow from anode *A′* to cathode *B*, through the load *J* to *D*, and through reactance *F* back to *H*. The current cannot jump from *A′* to *A* on account of the high counter emf of the arc. The small arrows surrounded by circles show the path of the current during this half cycle. During the next half cycle the terminal *H* is positive and the current flows to *A* through the tube to *B*, through the load *J*, reactance *E*, and back to *G*. The small arrows show the path of the current during this half cycle. Hence during a whole cycle the cathode *B* is continuously negative, but first one anode is active and then the other. If the voltage and current should become zero coincidentally the arc would become extinguished and operation cease. Hence the reactances *E* and *F* are introduced. At the end of the first half cycle described, when the line voltage drops to zero, the inductance of *F* maintains the current and a local circuit is formed through *A*, *B*, and *F*, which maintains the arc until the voltage at *G* has risen to a value which is sufficiently high to maintain the arc.

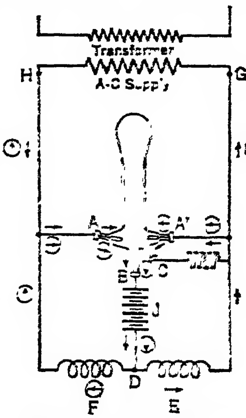

FIG. 1. Mercury Vapor Rectifier

The rectifier thus makes use of both half waves, or the entire alternating current, and the result is a uniform pulsating unidirectional current. On account of the reactance in the circuit, this current in the load never falls to zero and, in fact, with sufficient reactance, may be made very nearly constant. But this extreme is not always desirable, as it distorts the current wave in the a-c supply circuit.

ARC RECTIFIERS ON POLYPHASE CIRCUITS. All rectifiers of real power rating are operated from a three-phase supply and the transformers are connected to impress six-phase voltages on the rectifier and, in the case of great power, twelve-phase. The six-phase rectifier has six working, or power, anodes (graphite) and one cathode, a pool of mercury insulated from the tank. There are also usually a "starting" anode and an auxiliary "exciting" anode. The connections for such a rectifier are shown in Fig. 2 on the following page.

The tank is of steel, insulated from the ground, and with the electrical connections to the several electrodes carried through the tank walls by special "insulating seals," in some cases of porcelain and in others of a special glass (see Bibliography) in which the different materials have the same heat-expansion coefficient. This tank is surrounded by another tank, and between them circulates the water for cooling purposes. The inner tank is maintained at a vacuum of 1 to 5 microns, and the upper limit of successful operation is 10 microns (0.010 mm). The vacuum is maintained by two pumps in series, a mercury-condensation pump for fine adjustment and a mechanical rotary pump for coarse work. The latter runs only occasionlly.

The rectifier is started by closing the switches and causing the starting electrode to dip into the mercury pool and then immediately be withdrawn. This starts an arc which ionizes the mercury and causes the arc to spread to the exciting anodes and then to the six power anodes. The exciting electrodes are small electrodes placed near the cathode and connected to the supply through a limiting reactance so that they will not take much current but will maintain the arc at times of light load. The voltage on the d-c side is theoretically equal to the maximum instantaneous value of the a-c voltage from anode to cathode, but in practice there is a drop of 15 to 25 volts lost in the arc itself which with the loss in the transformers and reactors means a total loss of voltage of 18 to 30 volts irrespective of the rated voltage and almost irrespective of the current. This voltage has a ripple in it which becomes less and less marked as the number of anodes is increased, being almost negligible except to telephone practice with 12 anodes. Reactances in series with the d-c load are used, and sometimes these are fitted with wave filters to avoid telephone interference. The secondaries of the transformers are always connected in Y, and with the six-phase type a double Y is used with the two neutrals joined by a reactance which sometimes is in the form of an "interphase transformer" which can be designed to prevent an excessive rise in voltage at very light loads and thus give the device a better regulation.

In a simple rectifier there is a considerable drop in voltage between no load and 10 per cent of rated load, above which load the voltage does not drop off very much. There are three ways of overcoming this: (a) holding a false resistance load on the rectifier; (b) using saturation in the interphase transformer; and (c) using grids or third electrodes to control the voltage (see below).

Parallel operation on the a-c side offers no difficulties whatever, but proper division of the d-c load depends upon using one of the three expedients just mentioned.

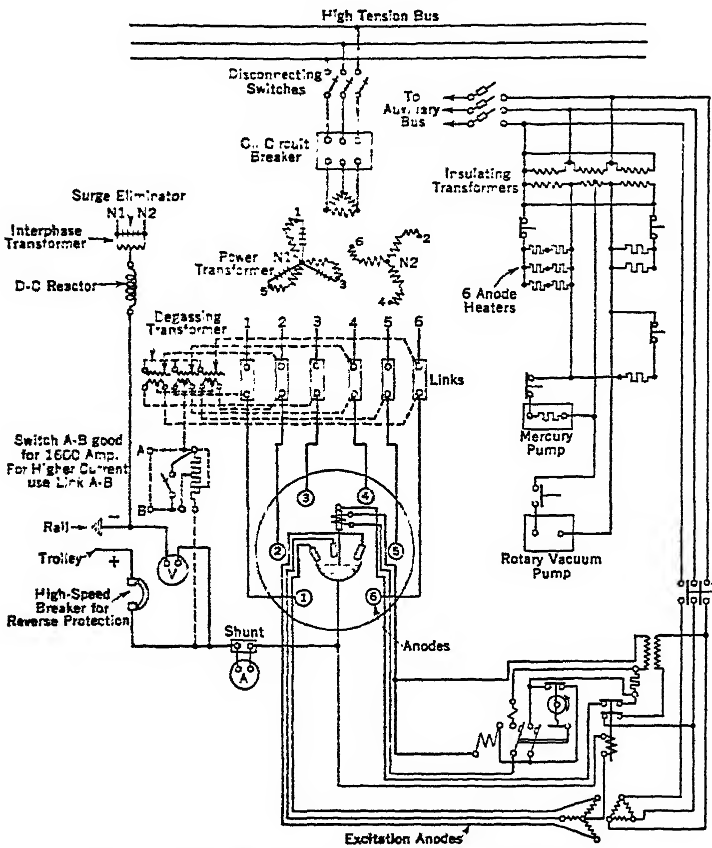

FIG. 2. Connections for 6-phase, 600 volt Rectifier (G. E.)

EFFICIENCY. The efficiency of a 600-volt rectifier ranges from 93 to 94 per cent from 25 per cent load to 150 per cent load, and of a 1500-volt rectifier from 95 to 96 per cent.

This is the overall efficiency including the losses in all the auxiliaries, transformers, pumps, reactors, and excitation. The efficiency of the rectifier alone depends only upon the delivered voltage and the arc drop thus: Eff. = 600/600 + 25 = 0.96 at all loads.

POWER FACTOR. This ranges from 92 to 95 per cent; it is caused by wave distortion and by the reactive power of the transformers. It cannot be regulated as in converters.

CAPACITIES AND OVERLOADS. Ratings up to 3000 kw at 625 volts are in common use. Rectifiers will stand very great overloads for short periods of time. For instance, guarantees are: 150 per cent load for 2 hr, 200 per cent for 5 min, and 300 per cent for 1 min. If a short circuit, known as an "arc back," does occur inside the rectifier, it is not

likely to cause any permanent damage; the rectifier may be started up again and immediately put back into service.

COMPARISONS. A complete rectifier outfit costs about 10 per cent more than a converter outfit and takes about 50 per cent more floor space, but it requires very modest foundations, gives no trouble from vibration, and operates as well on 60 cycles as on 25, which is not true of a high-voltage converter. Many are in operation, unattended, in automatic substations as 60 on the Independent Subway System of New York City.

15. RECTIFIER WITH GRID CONTROL

The addition of a grid in front of each anode and the application of a voltage of the proper value and phase give the rectifier some of the characteristics of the " three-electrode tube " (see Communication) in that the magnitude of the output voltage and current may be controlled. Also it is possible to reverse the flow of energy and change from direct to alternating current, thus making an " inverter." These have been proposed for railways on which the locomotives are designed for regeneration on down grades.

In a gaseous tube the grid can prevent the current at its anode from starting until such time as the grid is properly excited, but, after the current has started, the grid cannot stop it because so much ionized gas is present, and so the current will continue till the end of the half cycle or wave. Thus the output can be limited but not increased.

16. HOT-CATHODE MERCURY RECTIFIERS

In these the cathode is caused to emit electrons by heat applied to a suitable metal, and the tube contains a very small amount of mercury in the form of vapor. This will operate as a rectifier with smaller values of current than the pool type but with about one-half the voltage drop, therefore with a much higher efficiency at low voltages such as 125 and 250. They are available in sizes for 100 amp continuously. They are known under the trade name of Phanotron and have been applied to supplying 125–250 volts direct current on the Edison three-wire distribution.

17. THREE-ELECTRODE HOT-CATHODE MERCURY RECTIFIERS

These have a hot cathode, a cold anode, a grid, and a small amount of mercury vapor like the preceding, and though restricted to smaller currents than the pool-type rectifier are susceptible to more accurate control of the voltage and current by the grid. They are known by the trade name of Thyratron and may be used for converting from alternating to direct current at any frequency and from direct to alternating current. They may thus be used to convert from one frequency to another. It has been proposed to convert a-c power at the power station to d-c power at high voltage, transmit at high-voltage direct current and then convert back to alternating current at any desired frequency at the receiving end, thus obviating the difficulties of power system instability (see Bibliography).

18. TUNGAR RECTIFIER

This rectifier acts on the principle of the Fleming valve (see Communication), and consists of a heated tungsten filament for one electrode, and a tungsten plate for the other, both placed in a glass bulb containing argon gas. If the plate is made positive to the filament a thermionic current will flow across the intervening space in the vacuum, but if the filament is positive to the plate no current will flow. By combining two tungar rectifiers with an auto-transformer, as is done with the two halves of the mercury-vapor rectifier, both half waves may be rectified. This rectifier is limited to small current (15 amp) and is used chiefly for charging small groups of storage batteries at 60 volts or less. The voltage drop in the arc is about 15 volts for a valve in good condition.

The other rectifiers available, Fleming valve (hot cathode and high vacuum), copper oxide, electrolytic, crystal and vibrating types are used only in radio and communication and are treated in that volume.

SWITCHING, CONTROL, AND PROTECTION

By Stephen Q. Hayes

CIRCUIT ELEMENTS

1. DEFINITIONS

The subjects of switching, control, and protection are very closely related in that they all are concerned with the opening and closing of circuits and employ the same equipment in so doing. The distinctions between them arise from the types of circuits dealt with and the reason for changing the condition of the circuit.

Switching is usually employed in connection with the operation of circuits involved in the development and distribution of electric light and power.

Control is the term applied to describe the operation of equipment to open or close circuits of industrial motors, furnaces, and similar devices for converting electrical power to mechanical motion, or for heating and similar purposes.

Protection is the term applied to opening a circuit for the purpose of preventing harm to any of the component parts.

Switchgear is an assembly of coordinated individual apparatus employed for the rendering of electrical service, namely, for the control and distribution of electrical energy. It comprises switchboards and switching equipment.

Switchboards are usually understood to be the panels, control desks, pedestals, or similar supports on which the meters, relays, control handles, instrument switches, etc., are mounted.

Switching Equipment is usually interpreted to mean the circuit breakers, switches, and similar devices in the main circuit together with their related current and potential transformers, bus-bars, connectors, etc. The term "switchgear" is often used as an alternative expression.

2. FUNDAMENTAL IDEAS

Switching operations are a necessary element in any system of electrical circuits. One of the important parts of switching is the opening and closing of the circuit which is generally called "circuit-breaking." Apparatus for accomplishing this varies from a very simple device to open low-voltage circuits and small currents, to complicated large breakers to interrupt large power circuits connected to immense sources of power. The problems involved are correspondingly varied. In most cases both the closing and opening of the circuit are performed by the same devices, and the requirements of each function must be considered in the design of the apparatus.

Circuit Breaking may be defined as the interruption of the continuity of an electrical circuit in which energy is flowing. In general, the same apparatus—whether it be switch, controller, contactor, air breaker, or oil breaker—is used not only to "break" the circuit but, when desired, to restore the continuity of the circuit or to "make" the circuit.

INTERRUPTION OF DIRECT CURRENT. The initial effect of attempting to interrupt the flow of direct current by a circuit breaker is an arc when the contacts begin to open. This arc persists until it is interrupted by the further opening of the circuit breaker to a point where the voltage required for the maintenance of the arc is greater than the available voltage. The current then reduces to zero and the arc is extinguished. This completes the opening of the circuit.

The type of d-c load is important, since some kinds of load are more difficult to open than others. Incandescent lamps, heating equipment, and similar resistances, having little or no self-induction, may be switched off easily. Batteries on charge and shunt wound motors, owing to their counter electromotive force, give an opposing voltage independent of the current so that the switch when opening has to break only the small actual

voltage needed to force the current to flow through the internal resistance of the battery or motor. While the shunt field winding of such motors has a high self-induction, the field circuit remains closed on the armature circuit so that its energy does not discharge back into the switch or breaker. Series motors, however, lose their counter electromotive force on the opening of the switch or breaker, and their full energy discharges back into the switch. This partly accounts for the vicious arcing that usually occurs when opening a d-c railway circuit, where the load is largely made up of series motors.

INTERRUPTION OF ALTERNATING CURRENT. This operation is similar to that for direct current, but there is this fundamental difference, that the current has a zero value with each alternation which facilitates the breaking. When opening an alternating current of unity power factor, such as lighting or heating load, the current passes through zero simultaneously with the voltage and the arc is extinguished as the current passes through zero. When the dielectric strength across the gap exceeds the arc voltage, current must cease to flow.

Theory and experiment indicate that, in a very short interval of time, embracing this moment of zero current, the medium containing the arc returns from its *momentary* condition of a comparatively good conductor carrying current with a low voltage drop to its *normal* condition of a comparatively good insulator, supporting the full generated voltage of the circuit, with passage of little current. It is this rapid transition, at the moment of zero current, from the state of a highly conducting arc to the state of an insulating non-ionized gas which is important for the extinction of the arc in an alternating-current switching device.

If the system voltage is high and the contact separation of the circuit-breaking device is small, the arc re-establishes itself. If, at the next passage of current and voltage through zero, the contact separation has increased sufficiently, the arc will not re-establish itself and remains extinguished, thus definitely interrupting the circuit.

An ideal breaker is one which always extinguishes the arc at the first zero point of the current wave and at the same time introduces a sufficient insulating gap to prevent re-establishment of the arc.

OIL. Submerging the circuit-breaker contacts in oil does not entirely prevent an arc at the contacts, but it cools the contact and the arc so that the extinction and re-establishment voltages in oil may reach a value many times that in air. The switching energy liberates heat, decomposing and carbonizing the oil and causing a gas bubble at the contact. Drops of carbonized-oil residues float in the arc space and act as de-ionizing centers for the ions. These de-ionizing centers or nuclei consist of volumes of relatively cool un-ionized gas arising from the decomposition of the oil and mixed turbulently into the arc space. It seems to certain engineers that the principal cause of the arc-interrupting capacity of the oil circuit breaker is its action as a gas blast switch, the gas blast arising from the decomposing oil. If the arc is not submerged deep enough in the oil the hot gases in rising to the surface are not sufficiently cooled and may ignite the oil at the surface and explode the arc gases that may have accumulated above the oil. An alternative theory developed by other engineers suggests that the successful operation of an oil circuit breaker is due to the scavenging action of an oil blast that sweeps away the arc products.

3. SWITCHES

A switch is a device for making or changing connections in an electric circuit. It must, when closed, carry its rated current without excessive drop, or excessive heating; it must take care of overloads met in practice; it must be designed to prevent, or render harmless, any arcs that are formed when being opened; it must, when open, insulate all live parts for the maximum potential of the circuit.

KNIFE SWITCHES. The use of knife switches is rather limited in circuit-breaking, as an arc will occur between the switch blade and the break jaw. Permissible arcing, without affecting the performance of the switch, determines its arc-breaking capacity. The more rapidly the switch is opened, the less the damage from the arc. Also the arc is more vicious and difficult to control on d-c circuits than on a-c circuits of the same voltage and class of service. For this reason, it has been found that a knife switch with dimensions satisfactory for opening a 250-volt d-c circuit can be safely used to open the circuit on a 550-a-c line. Hand-operated switches in d-c circuits are usually limited to 600 volts. When used to break current, quick break attachments are *recommended* for all switches rated for over 250 volts d-c; they *must be* provided for those rated at or above 200 amp and 500 volts d-c, or 800 amp and 250 volts a-c.

The current-carrying capacity of a switch or circuit breaker is determined by its permissible temperature rise. The capacities usually assigned for such devices are based

on the current which they can carry continuously, the temperature rise not exceeding 30 deg cent in the current-carrying parts.

The non-uniformity of current distribution in conductors of a-c circuits increases as the currents become larger and also increases with the frequency. For 25-cycle circuits a lesser amount of current would cause a given temperature rise than on direct current and on 60-cycle circuits a still smaller current would cause the same temperature rise, so that, for the larger capacities, current ratings are frequently given for d-c, 25-cycle, and 60-cycle service. The following table of amperes for 30-deg rise is characteristic of knife-switch ratings for different conditions.

D-c	25-cycle	60-cycle	D-c	25-cycle	60-cycle
1200	1100	1100	3000	2500	2200
1600	1400	1200	4000	3400	2800
2000	1800	1600	6000	4400	4000

Fig. 1 shows some of the features of a two-pole single-throw 200-amp rear-connected switch typical of the normal American design of knife switches.

Various modifications in the standard knife switch are made to allow for starting of d-c motors, to provide auxiliary contacts for the discharge resistance in the field circuit, and to take care of other special conditions.

STARTING SWITCH. Where it is necessary to start a synchronous converter from the d-c end or to start a d-c motor of large capacity under relatively easy starting conditions, a multipoint knife switch of the type indicated in Fig. 2 can be utilized to advantage for cutting out steps of a starting resistance. The switch illustrated has four sets of contact jaws of such length that the switch blades make contact with each set in succession. Each switch has four blades, a construction that allows ample ventilation and reduces the depth of the switch from the switchboard. A ratchet device, with pushbutton in the handle, has been provided on the larger sizes, to prevent large machines being started too quickly by throwing the switch through all the positions without stopping at any one.

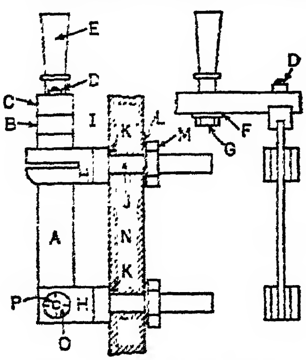

FIG. 1. 200-ampere Low-jaw Knife Switch

A, copper blade, hard drawn, 98% conductivity; *B*, blade block pinned and sweated to *A*; *C*, Micarta cross bar with milled slots; *D*, screw fastening cross bar to blade block; *E*, handle bolted to cross bar; *F*, washer for handle bolt; *G*, nut for handle bolt; *H*, jaw blades pinned and sweated in blade block; *I*, blade block with milled slots; *J*, studs electrobrazed to blade blocks; *K*, dowel pins locating switch studs; *L*, washer for switch stud; *M*, nut for switch stud; *N*, base for switch; *O*, slotted spring washer; *P*, hinge bolt.

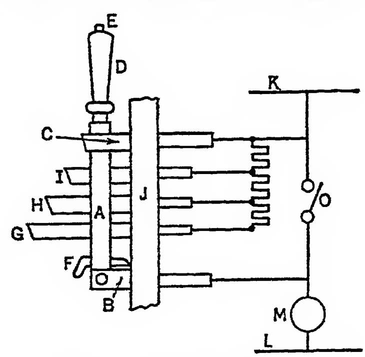

FIG. 2. Typical Starting Switch

A, switch blades; *B*, hinge jaw; *C*, main break jaw; *D*, handle; *E*, push button to operate ratchet; *F*, ratchet operated by push button; *G*, *H*, *I*, intermediate break jaws; *J*, switch base; *K*, positive bus; *L*, negative bus; *M*, armature of d-c machine; *O*, short circuiting switch.

FIELD SWITCH. Another modification of the knife switch that is frequently employed in opening and closing field circuits is the field discharge switch, Fig. 3. This is usually a two-pole switch with an auxiliary jaw and blade for cutting in a discharge resistance across the field terminals before the circuit is opened by the switch. By connecting this discharge resistance across the field, the electromagnetic energy in the winding is dissipated in the resistor instead of causing undue strain on the insulation of

the field, as would be occasioned by attempting to open the field circuit suddenly without any protective resistance.

FIELD TRANSFER. Where it is necessary to transfer the field circuit of a machine with its rheostat without opening the circuit, a transfer switch can be utilized to advantage. This switch usually has blades of the rocker type and makes connection from the middle contacts with the upper set of contacts before opening on the lower set, thus transferring the circuit through the rheostat and field between excitation buses without opening the field circuit, with but a momentary paralleling of the excitation buses.

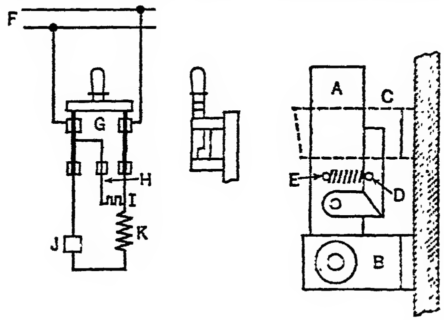

Fig. 3. Field Switch—Quick Break Attachment

A, switch blade; *B*, hinge jaw; *C*, break jaw; *D*, quick-break attachment; *E*, spring to actuate quick-break attachment; *F*, excitation bus bars; *G*, auxiliary switch blade; *H*, auxiliary switch jaw; *I*, discharge resistance; *J*, field rheostat; *K*, field of generator.

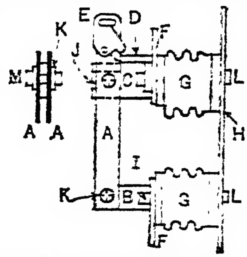

Fig. 4. Disconnecting Switch, Standard Duty

A, double blade embracing switch posts *B* and *C*; *B*, hinge post, sweated and pinned, or riveted, in block *F*; *C*, break post, slotted at *J*, attached at *B*; *D*, stationary part of latch; *E*, movable part of latch, pivoted on blade *A*; *F*, switch blocks bolted to inserts in porcelain insulators *G*; *G*, corrugated porcelain pillars with cemented-in inserts; *H*, steel base for switch; *I*, bolts for attaching blade blocks *F* to inserts in insulators *G*; *J*, slot in break post *C* for cross bolt *M* of switch blades *A*; *K*, slotted spring washers; *L*, bolts for attaching steel base *N* to inserts in insulators *G*; *M*, cross bolt for switch blades *A*.

Where there is a possibility that there may be a considerable difference in voltage between the two sources of d-c supply to the rheostat and field circuit, field transfer switches are provided with auxiliary jaws and limiting resistors so that, in the middle position, when the field circuit with its rheostat is connected to both sources of excitation, a certain amount of resistance is placed between these two sources to limit the interchange of power.

DISCONNECTING SWITCHES. Another frequent use for knife switches is to employ them as disconnecting switches for the purpose of isolating oil circuit breakers, lightning arresters, and other devices in the high-tension circuit to permit the more ready inspection of such equipment. These disconnecting switches are not supposed to open the circuit when any appreciable amount of current is flowing, although certain modifications, provided with a suitable arcing horn, can open the charging current in the transmission line, the magnetizing current of transformers, or a relatively moderate amount of power at high voltage.

For indoor use up to 2500 volts, the disconnecting switches are usually mounted on bases of ebony asbestos, marble, or similar material; for higher voltages it becomes necessary to use porcelain pillars which usually are mounted on metal supports. A typical switch is illustrated in Fig. 4. Many of the earlier disconnecting switches were made without latches and depended solely on friction to maintain their blades in the closed position, but it was found that the repulsion effect due to very heavy short circuits frequently caused such switches to blow open, and latches are now usually provided for the more important installations.

OUTDOOR DISCONNECTING SWITCHES. These differ from the indoor principally in the use of shell-type insulators instead of the pillar type, the use of non-rusting bolts and fittings, and frequently the provision of a sleet hood for the outdoor switch jaws or some special form of contact designed to crush the ice formation as the switch closes. Most disconnecting switches are operated by means of hook sticks, where single-pole operation is satisfactory and the switches can be mounted within ready reach of the attendant. Gang operation, either manual or electrical, is used in many installations, particularly at higher voltages.

For outdoor service, the disconnecting switch can be supplied for inverted mounting, upright mounting, or sidewall mounting. Arcing horns are provided when the air-break

switches are required to open an appreciable amount of current. If gang operation of the outdoor disconnecting switches is desired, disconnecting switches of the type shown in Fig. 5 can be utilized to advantage as plain disconnects for isolating the apparatus, opening all phases at one time. This switch comprises several complete poles all operated by a single mechanism, the tilting insulators on all phases being mounted on a common square shaft. Modifications of the tilting switch are made for voltages up to 73 kv by employing the multi-unit type of built-up porcelain supports with base, mechanism, contacts, and other features suitable for the clearance needed at such a voltage.

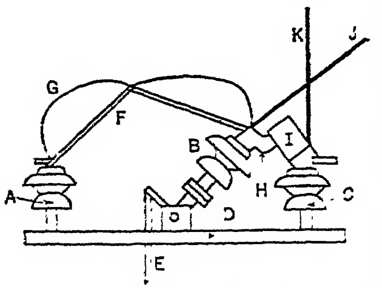

Fig. 5. Gang-operated Disconnect Switch

A, hinge-jaw insulator; *B*, moving insulator; *C*, break-jaw insulator; *D*, base; *E*, operating mechanism; *F*, Hinged-switch mechanism; *G*, shunt to hinge-mechanism; *H*, movable main contact; *I*, stationary main contact; *J*, movable arcing horn; *K*, stationary arcing horn.

INSTRUMENT SWITCHES. Switches of the drum type (see page 12–33) have practically superseded all other types for use in connecting one instrument to any of several circuits and for making the multipoint connection required in synchronizing generators. These switches are so arranged that the turning of the switch handle operates a shaft on which are mounted various contact-making segments. These segments make or break contacts with stationary fingers mounted on an insulated base.

CONTROL SWITCHES. Drum-type switches are designed for the control of electrically operated switches and circuit breakers, rheostats, engine and turbine governors, feeder potential regulators, etc. In general, control relays are operated directly from such control switches in order to handle such heavy operating currents as may be met with in the case of switches and circuit breakers (see Arts. 11 and 12). These control switches are essentially multicircuit double-throw switches. They are usually provided with large pistol-grip handles, and have a spring return mechanism which causes the switch to return automatically to the off position when released from the operating position. They usually have a mechanical marker to indicate the last operation of the switch. Suitable indicating lamps can be used in conjunction with control switches to obtain electrical indication of the position of circuit breakers or other devices.

Very compact control switches, occupying a panel space 2 $^3/_8$ in. square have been developed primarily for miniature switchboards. Indicating lamps $^3/_4$ in. diameter outside of fittings are also available, and very compact instruments are used to round out the design which permits controlling circuits 6000 ft. away over telephone cables.

4. FUSES

Metal strips or wires which open electric circuits by melting or fusing when the current reaches a predetermined value are called fuses. They were used in the earliest electric plants to furnish automatic protection for feeder and generator circuits. Their use is now confined largely to low-voltage distribution circuits and to the protection of small pieces of apparatus such as motors and small-capacity transformers.

All fuses have an inherent time element feature owing to the fact that the current must heat the fuse metal up to its melting temperature. This time varies with the size and type of fuse, the large ones in general taking longer to reach their fusing temperature than the smaller ones, on account of their thermal capacities. There are three designs of fuses in general use, namely, the open or link, the expulsion, and the enclosed types. Enclosed fuses were developed to replace the open fuse; they comprise, in the broad sense, types using links enclosed in an insulating container for safety. Enclosed fuses include various types of expulsion fuses, De-ion fuses, powder-filled fuses, oil-immersed fuses, liquid spring-operated fuses, etc.

OUTDOOR EXPULSION FUSES. Fuses of the type indicated in Fig. 6 are available for voltages up to 115 kv and currents up to 200 amp. The interrupting capacity of this line of fuses range from 7000 amp at 4500 volts to 400 amp at 115,000 volts. These fuses are so placed, in open-end tubes, that the fuse, when melting, generates arc gases. It was originally thought that the gas expansion caused a strong blast through the tube, blowing out the arc and so clearing the circuit. Later investigation seems to prove that the arc suppression is due to de-ionizing action similar to that described in connection with the De-ion circuit breaker (see Art. 8).

In applying such fuses, care must be taken to fuse them to such capacity that they will blow on short circuits but not on overloads, as gradually increasing overloads do not volatilize the metal fast enough to secure the proper explosive action.

De-ion power fuses are now available in current ratings up to 200 amp, for voltages of 7500, 15,000, and 23,000 volts with a three-phase interrupting capacity of 325,000 kva at 7500 volts, 500,000 kva at 15,000 volts, and 600,000 kva at 23,000 volts. This fuse is

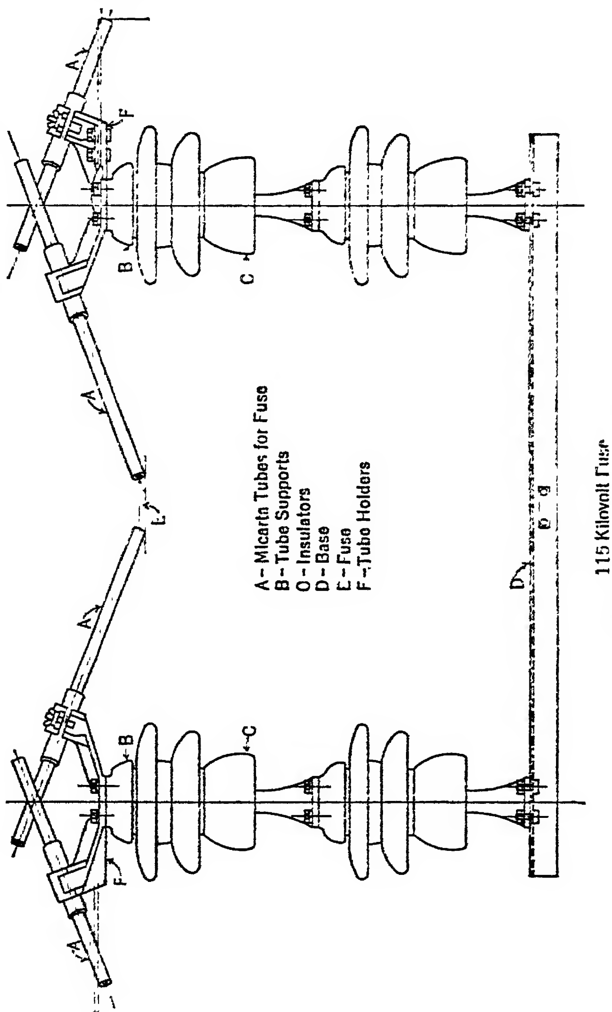

FIG. 6. 115 Kilovolt Fuse

arranged for outdoor service but may be used indoors without change. It is equally effective at rupturing high or low current, and its speed of operation is very fast. The fuse can be renewed at the installation; it is of the dry type, the de-ion chamber being lined with inert boric acid in molded dry form. The material of the wall of any fuse determines the nature of the gases expelled from the tube into the atmosphere, and the boric acid lining gives off an inert boric oxide and water vapor; the water in the form of vapor provides one of the most efficient de-ionizing media known.

CARTRIDGE-TYPE ENCLOSED FUSES. These fuses were so made at first that it was necessary to return them to the manufacturer to have the cartridge refilled after the fuse had blown, and this practice is still followed on ratings of 200 amp or larger. Certain standard dimensions and types of contacts have been adopted for various sizes up to 600 amp at 250 and 600 volts. Up to 60 amp the ferrule type of contact is used as shown in Fig. 7, and blade contacts shown in Fig. 8 are used for fuses from 61 to 600 amp.

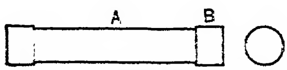

Fig. 7. Enclosed Fuse with Ferrule Contacts

A, fuse tube, fiber; *B*, metal ferrule contacts.

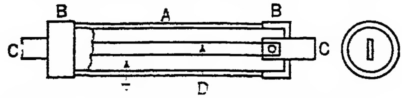

Fig. 8. Enclosed Fuse with Blade Contacts

A, fuse tube, fiber; *B*, metal ferrules; *C*, blade contacts; *D*, fuse strip; *E*, filler, gas-absorbing material.

Rupturing capacity up to 250-volt and 600-volt cartridge fuses, as determined by test, shows that on large systems the circuit characteristics should be such as to limit the maximum overload current passing through the fuse to approximately 10,000 amp at the rated d-c voltage.

REFILLABLE FUSES. These were developed to permit the user to place a new fuse in the old cartridge. Two general classes of renewable fuses have been developed, one in which the renewal element is a bare link without any powder filling, and one that has the fusible element enclosed in a powder-filled tube. Some of the features of one type of enclosed fuse are shown in Fig. 9, employing the drop-out type of bare link fuse.

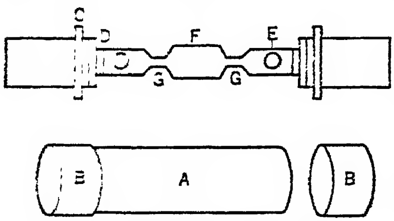

Fig. 9. Renewable Cartridge Fuses

A, hard fibre tube with threaded ends; *B*, removable metal caps vented; *C*, removable washers arranged for venting; *D*, fixed washers arranged for venting; *E*, fuse attachment bolt; *F*, drop out link of fuse; *G*, melting points of fuse.

High-voltage cartridge fuses have been applied successfully for several years, giving excellent protection for power circuits of low capacity. They are particularly useful for opening short circuits within their rupturing capacity, but it has been found that the fuses of this type for 4500 volts and above will not open low overloads at their rated voltage, as the gradual heating of the fuse material tends to reduce the de-ionizing effect of the powder filler, and the arc-gas pressure, as a result, is not sufficiently high. This effect somewhat limits their field of usefulness, but they can be employed satisfactorily on potential-transformer circuits where low-voltage fuses will take care of usual overload conditions. The high-voltage cartridge fuse has a current rating of two or three times full load of the potential transformer, and will blow only on a transformer breakdown or a defect in the wiring, giving essentially short-circuit conditions. Although these fuses have inherently a relatively high interrupting capacity

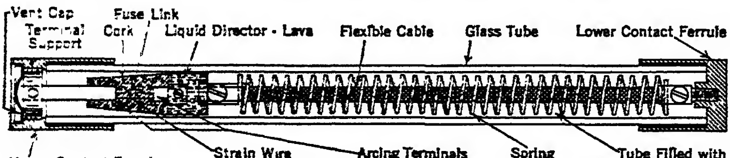

Fig. 10. Schweitzer–Conrad Fuse Construction

they are frequently used in stations where the short-circuit current would exceed the fuses' rupturing capacity. For such cases, current-limiting resistors are employed, these being designed to be placed in series with the potential-transformer fuses where the short-circuit amperes in the station or power source exceed the interrupting capacity of the fuses.

LIQUID FUSES. Liquid fuses, such as the so-called carbon tetrachloride and oil-immersed fuses, have a relatively high first cost but meet a demand for overload and

short-circuit protection, on the higher-power circuits, better than the cartridge type. In the first type of fuses (cf. Fig. 10), available from 7500 to 132,000 volts, a glass tube is used and the fuse is immersed in a liquid having a freezing point of —65 deg fahr. Carbon tetrachloride is non-inflammable and one of the best fire-extinguishing mediums known, with a very high dielectric strength. The fusible element is in two parts: one is of low resistance and low mechanical strength to carry the normal current: the other is a high-resistance element of high tensile strength attached to a spiral spring. When the low-resistance element melts, the current is shunted to the high-resistance element, and its melting permits the spring to separate the contacts rapidly and open the circuit. These fuses are not refillable in the field, and this drawback and their higher price frequently lead to the use of other types such as the cartridge or the expulsion type.

OIL-IMMERSED FUSES. These are made at present only up to 15,000 volts, but they meet a demand for a fuse with relatively high rupturing capacity and refillable features. Owing to the necessity for an oil tank, oil terminals, and bushings, their cost is comparable to that of an oil breaker. They are usually arranged with the equivalent of a movable cover carrying the fuse in suitable clips so that the fuse can be safely handled. When the cover is closed the fuse is automatically connected to the main terminals under oil. This device is particularly suitable for subway applications, but most people prefer to pay a little more to obtain an oil circuit breaker, or are satisfied with a cheaper type of fuse.

5. RESISTORS

Resistors (see also Section 4, Arts. 1–4) are used for starting and regulating the speed of series-, shunt-, and compound-wound d-c motors, and wound rotor a-c motors with either manual or magnetic controllers. Starting and speed regulation are obtained on the d-c motors by varying the resistance in series with the motor armature and on the a-c service by varying the resistance in series with the motor secondary. Resistors are also used for grounding the neutrals of generators or transformer banks. They are designed to pass enough current, if a line wire becomes grounded, to trip out the highest set circuit breaker. Where a number of generators or transformer banks are operated in parallel it is customary to ground only one generator neutral at a time to avoid circulating currents. Resistors are designed to comply with the A.E.S. and when correctly applied will operate with an average temperature rise not exceeding 350 deg cent.

Resistors for d-c motors have one or more frames usually connected in series. All standard a-c wound rotor motors whether for two- or three-phase circuits have their secondaries wound for three phase. The resistors for each phase usually consist of 1, 2, 3, or multiples of 3, frames of tubes or grids. Secondary resistors for a-c motors are designed *for star connection. Resistors for manual controllers may be connected with all three* secondary phases closed or one secondary phase open on the first point of the controller. A lower value of torque is obtained with the single-phase connection. Resistors for magnetic controllers are connected with all three phases closed in the secondary on the first point.

TYPES OF RESISTORS. For motor control service, resistors are made of various classifications, depending on percentage of full-load current and the length of time that they are to be maintained in service, and are built in various forms.

Flat Units for resistance elements consist of a molded flat core of vitreous material on which the resistance wire is wound; the surface is then coated with a special cement and baked. Thus the resistance material is protected from injury and made proof against moisture. This type is frequently used in connection with small field rheostats.

The plate-type resistance element utilizes coils attached to a circular base of insulating material. The coils are either covered with insulating, heat-conducting cement and baked, or are enclosed in a ventilated iron case. Suitable contacts and a switch arm are provided.

Cylindrical Units usually have a core of asbestos tubing or sometimes a metal tube coated with an insulating material such as enamel. A wire of low temperature coefficient is used. The tube with the winding is covered with an insulating compound, and porcelain bushings or metal rings are placed on the end. The units are then thoroughly baked and mounted rigidly on a frame or in a suitable case. The coating protects the resistance material from mechanical injury, forms a good conductor of heat, and in case of a burnout prevents appreciable arcing and unwinding of the wire.

Edgewound Resistors like that in Fig. 11 consist of a special non-corrodible alloy ribbon wound edgewise around a porcelain insulator which in turn is reinforced by a flat steel support fastened through it. Both ends of the steel support are notched so that any unit can be removed from the frame without disturbing any others. Because of its unique

construction the resistor tube is almost unbreakable. Shattering of any section of the porcelain tube has no effect whatever upon its operation as the ribbon requires only a fractional part of the support which it receives. The construction of the edgewound resistor provides excellent radiation, eliminating the possibility of localized heating.

Cast Grids are available in the different types indicated in Fig. 12. The L type is designed especially for panel and wall mounting; the 5-in., 8-in., and 14-in. grid plates are intended for floor or angle iron mounting. If the current-carrying capacity required is known, the grid having the proper cross-sectional area can be selected from standard designs. This line of grids covers a range of capacity of 18 to 346 amp per grid. By paralleling units any desired current rating can be obtained.

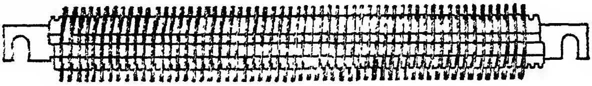

FIG. 11. Edgewound Resistor

Before being assembled the grids are dipped in aluminum paint, which serves as a protective coating against corrosion both during storage and after the grids have been placed in service.

The grids are mounted on three mica-insulated tie rods which are suspended between end frames that may be tightened without disturbing the length of the resistor. The end frames for the L-type, 5-in., and 8-in. grids are galvanized bent sheet steel; the 14-in. grids are of cast iron. The general construction is indicated in Fig. 13.

Where cast grids are used to ground the neutral of a high-tension transformer bank on an outdoor installation it is desirable to have the grids suitable for use without any covering. Various schemes have been tried, but the heating of the resistance tends to crack off the weatherproofing. It is quite possible that some nickel-iron alloy or stainless-steel compound will be found capable of standing the weather without deterioration, even when the grids are heated by the passage of ground current to a fault.

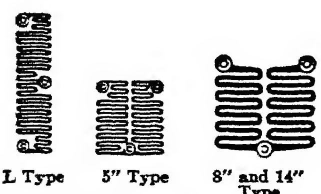

FIG. 12. Cast Grid Resistor Construction

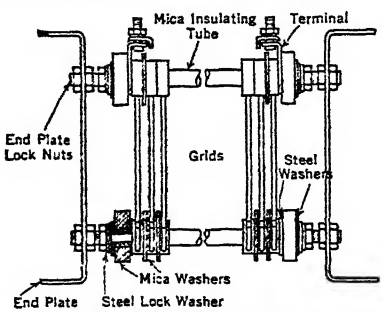

FIG. 13. Grid Resistor Assembly

CAPACITY OF RESISTORS. Wire wound resistors mounted directly on the stationary contact studs are used for the smaller sizes of rheostats; edgewound non-breakable and non-corrodible resistors are used on the intermediate size, and grid resistors on the largest size.

Capacity of grid resistors depends largely upon the ventilating space. The frames should never be stacked more than 4 ft high, and, when space is available, each frame should be separated from the next by approximately the width of the end frame. Frames may be mounted on the floor, platform, or wall, but the grids in all cases must be in a vertical position.

For high voltages, particularly for temporary testing in connection with generating equipment, water rheostats of different types have been evolved, consisting of two or more electrodes dipping down into the water by varying amounts. In some a continuous flow of water is provided; in others the water is maintained in a barrel or other container.

FIELD DISCHARGE RESISTORS. Resistors are used for protecting the field windings of large motors and generators. When the field switch is opened, the voltage induced in the winding may be sufficient to puncture the insulation, and to avoid this a discharge resistor is connected in parallel with the field at the time the circuit is opened. This resistor allows the energy to be dissipated without increasing the voltage to a dangerous

degree. A suitable field switch with a discharge clip should be provided. The resistance of the resistor should usually be slightly greater than that of the field with which it is to be used.

CURRENT-LIMITING RESISTORS. Resistors are used in series with potential transformer fuses to limit the current, in case of short circuit, to such values as the fuses can interrupt safely. This means that potential transformer fuses when in series with the current-limiting resistor can be applied to any system, irrespective of kva rating, as long as the voltage rating is not more than that of the fuses or resistors. The resistors are of the wire type and consist of coiled nickel-chromium wire wound in grooves on a heavy wet-process porcelain tube. An iron casting is the means of support for these resistors and is cemented to each end of the porcelain tube. There is no covering surrounding this resistor, thus allowing easy inspection and radiation of the heat without the danger of burning or charring covers. These resistors are frequently mounted in connection with the potential transformer fuses (Fig. 14), and they have resistances varying from 4.5 ohms for 2500-volt service to 225 ohms for 25,000-volt service.

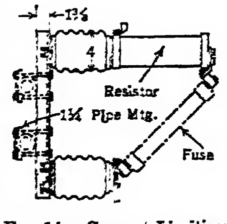

FIG. 14. Current-Limiting Resistor and Fuse

CIRCUIT BREAKERS

Circuit breakers are devices used to open electric circuits by the mechanical separation of contacts that are normally held closed by a latch, toggle, or similar mechanism. Usually they are built to operate automatically under predetermined conditions. Two main types of circuit breaker are in use in the United States: one in which the circuit is opened in air, known generally as the air-break circuit breaker; and the other where the circuit is opened in oil, known as the oil-break circuit breaker. These two terms are usually shortened to "air breaker" and "oil breaker."

6. CARBON BREAKERS

The majority of air breakers protect their main contacts from burning by the use of auxiliary carbon contacts which take the final arc so that an air breaker is usually a carbon circuit breaker. Supplementing the pair of copper contacts, which carry the current when the breaker is closed, a pair of carbon contacts is provided in parallel with the copper ones, and the circuit is transferred from the copper to the carbon by having the copper contacts open first, leaving the carbons to take the final arc. Carbon is used for the final contacts because, under the action of the arc, it burns clean whereas copper contacts will either pit or form globules which would adhere to the surface. Also the comparatively high resistance of the carbon is advantageous.

The *main elements* in the normal carbon breaker comprise the two stationary contacts, to which the leading-in and leading-out terminals are attached, and the movable contacts, which bridge between the two stationary ones. The stationary contacts consist of blocks of copper against which the moving contacts are pressed, when the breaker is closed. For the smaller sizes of breakers, the round studs are electro-brazed to this copper block, the size of stud depending upon the capacity of the breaker. The movable-contact elements of air circuit breakers and many oil circuit breakers are laminated brushes in a U-shape built up from thin strips of copper. The ends of each lamination make direct contact with the stationary blocks.

The main features of a carbon-break circuit breaker are shown in Fig. 1. The main brush is laminated and is made by giving the extra-hard copper-strip laminations a set to a smaller radius than they have in the finished brush. This causes the innermost lamination of the brush to press by spring action against the inside block, and each of the other laminations in a similar manner presses against the lamination in front of it. Each lamination therefore makes an independent contact at each end on the stationary contact blocks. Owing to the elliptical form of the brush, the ends of the laminations bear with heavy contact pressure against the contact blocks. The laminations have a substantial

sliding motion relative to the contact blocks during the opening and closing of the breaker. This sliding contact breaks up the oxide film that may have accumulated.

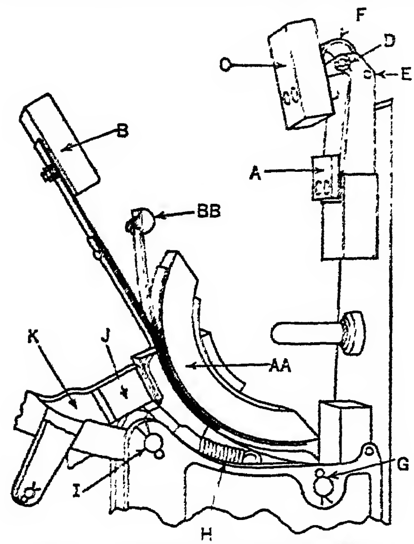

Fig. 1. Main Features of Air Breaker

AA, main brush; *BB*, arcing tip; *A*, copper arcing plate; *B*, moving carbon; *C*, stationary carbon; *D*, pin; *E*, carbon holder; *F*, copper shunt; *G*, pivot rod; *H*, springs; *I*, phosphor-bronze pin; *J*, phosphor-bronze clip; *K*, projection on toggle mechanism for large breakers.

The *magnetic blowout* is used in some circuit breakers to assist in rupturing the arc by blowing it out into a much longer path (cf. Fig. 2). When the contact pieces *A* and *B* are separated, the arc that is drawn is extended by the magnetic field *C* into some such shape as *D*. For heavy d-c railway work the magnetic blowout breaker has been used extensively. In such a breaker the final arc occurs on auxiliary contacts, usually placed in an intense magnetic field. For the higher voltages, such as 3000 volts direct current, and for heavy currents, the plain carbon breaker becomes impractical because of the tremendous short-circuit arcs, and some sort of blowout device or De-ion structure is necessary.

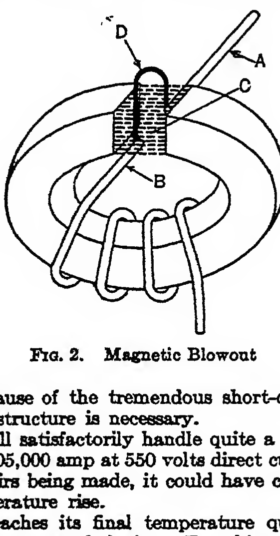

Fig. 2. Magnetic Blowout

Carbon breakers without a magnetic blowout will satisfactorily handle quite a range in load. In a test, a 4000-amp breaker interrupted 105,000 amp at 550 volts direct current and was in such good shape that, without any repairs being made, it could have carried full-load current continuously under normal temperature rise.

RATING. Inasmuch as the circuit breaker reaches its final temperature quickly with steady current load, it is necessarily a maximum rated device. For this reason, current ratings given in manufacturers' publications for all carbon circuit breakers are maximum rated, based on the allowable temperature rise that is reached after a continuous run of approximately one hour or more at the rated current.

Air circuit breakers are suitable for service in either d-c or a-c circuits, but the question of heating and the difficulty of handling heavy a-c currents particularly on 60 cycles, without a high inductive drop, places a natural limitation on the a-c equipment. For circuits of 3000 amp and above it becomes almost essential to interleave the conductors of various phases to reduce the inductive drop to a minimum, and an effort is usually made to keep the current in a-c circuits below this figure. For the few cases where this current limit must be exceeded, carbon breakers are available with several sets of brushes spaced well apart for ventilation. For 25-cycle service air breakers are available up to 10,000 amp, and for 60-cycle service up to 7000 amp, this last breaker having a d-c rating of 14,000 amp.

RANGE. A typical calibration range for automatic overload trip is approximately 80 to 160 per cent of the 30-deg cent rise ampere rating. Breakers can readily be set to trip at any point within this range. There are often special conditions in circuits which require certain features of functioning on the part of the breakers in addition to their normal action of opening at a predetermined load. These features can usually be added as attachments. The following are some of the more important ones, their function being practically denoted by their name: shunt trip, inverse time limit, undervoltage trip, reverse-current trip, field-discharge attachment, lock-out, and signal lights.

OPERATING MECHANISM. As a rule, carbon breakers are held closed automatically by a toggle, trigger or latch. Various trip mechanisms are constructed to dis-

engage the holding device and to permit the breaker to open. Manual closing is the ordinary method employed, but electrical operation is used where power operation is required. Ordinarily a cylindrical solenoid magnet as shown in Fig. 3 is furnished, located beneath the breaker, or a motor is employed. The solenoid with d-c excitation is standard with most companies because it is simpler in construction, more reliable in operation, and more easily kept in repair; the d-c solenoid is much lower in cost than the a-c solenoid so that alternating current is used only when no direct current is available. The adaptation of the Rectox rectifier to circuit-breaker control has permitted the furnishing of a rectifier at each solenoid and the employment of an a-c control circuit running to the breaker, rectification by means of the Rectox device and supplying direct current to the solenoid.

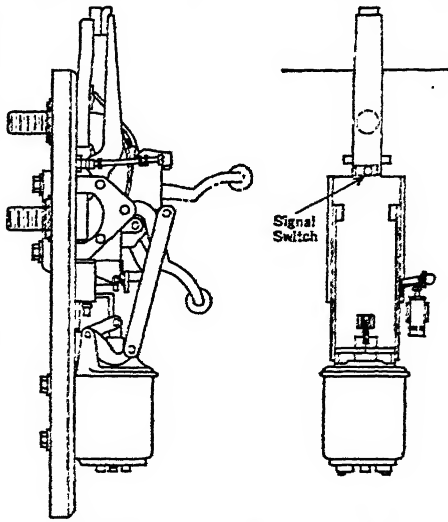

Fig. 3. Solenoid-operated Air Breaker

MOUNTING. Carbon breakers are mounted on panels, walls, or pedestals. The smaller breakers are usually placed on panels with combinations of other equipment needed on the switchboard. Medium-sized breakers are also panel mounted, but the larger ones are often pedestal mounted. The pedestal mounting is used particularly where heavy service conditions are encountered; it is especially desirable for high-speed breakers on account of the vibration caused by their quick trip action.

7. HIGH-SPEED AIR BREAKERS

High-speed breakers were developed for use in connection with heavy d-c railway electrification, particularly at 1200, 1500, and 3000 volts, in order to have a breaker that

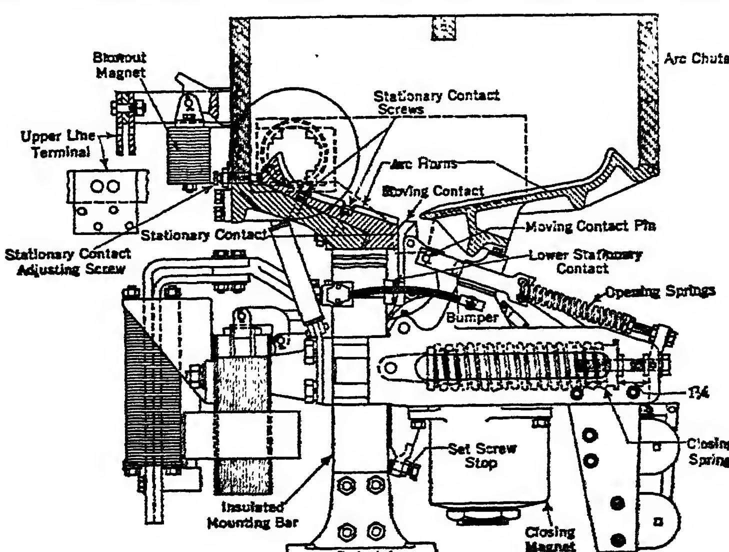

Fig. 4. Sectional Elevation of a High-speed Breaker, Showing Arrangement of Parts

would open the circuit in a few thousandths of a second to prevent a flashover on the commutators of d-c machines. The main idea of the high-speed breaker is to interrupt high-value, fast-rising current in the minimum time. To assist in obtaining a high-speed action, the usual auxiliary arcing contact is omitted and the arc is drawn on the main current-carrying contact. As shown in Fig. 4 the design of the breaker utilizes a movable contact, made of solid copper, bridging two stationary contacts, and held closed by the action of the electromagnet. Inside of the breaker the path of the line current, as indicated in the schematic diagram, Fig. 5, is divided into two parallel circuits, *A* and *B*. Circuit *A* is stacked with iron punchings. Circuit *B* is comparatively non-inductive and passes through the magnetic circuit of the breaker holding-in coil in such a manner that the flux due to the load current neutralizes the flux of the holding magnet.

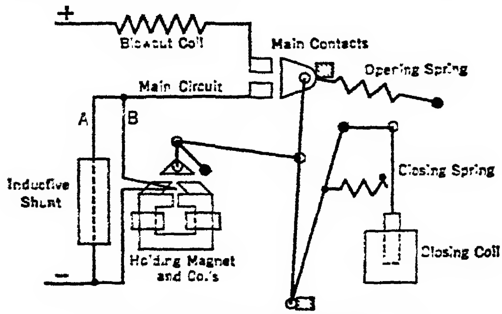

FIG. 5. Diagram of High-speed Breaker

Under normal-load conditions, the holding-coil flux predominates, and the breaker is held closed against the action of strong springs. The currents in the two parallel paths vary inversely as the resistance of the paths. Under short-circuit conditions, one path being inductive, the current divides inversely as the impedance of the paths. Therefore the non-inductive path *B* will carry a much larger proportion of the short-circuit current, and the holding coil flux will be reduced, allowing the breaker to be opened instantly at the high rate of acceleration caused by the action of the powerful springs, which were kept in tension by the holding magnet. Tests on the high-speed breaker indicate that its speed of action depends somewhat upon the characteristics of the machine with which it is being used, owing to the difference in rate of current rise, under short-circuit conditions. For short-circuit current values of 4000 amp upward and with current rises at the rate of 3,000,000 amp per sec and upwards, this breaker may be expected to limit the current rise in 10/1000 sec. This type of breaker has also been adapted for trolley wire protection in 12,000-volt 25-cycle railway electrification.

8. DE-ION BREAKERS

For several years, research work has been carried on in the development of an oilless circuit breaker suitable for a-c service indoors in order to eliminate the hazards incident to oil fires, gas explosions, etc. This has resulted in the De-ion circuit breaker which replaces a single long arc by a large number of short arcs in series and provides a means of extinguishing the short arcs.

The fundamental principle of this breaker is based on the laws of conduction of electrical energy in a gas, such as air, where, under certain conditions, the air may change in a very short space of time from a momentary condition of being a comparatively good conductor carrying current at a low voltage, to its normal condition of a comparatively good insulator supporting the full generated voltage of the circuit with the passage of very little current. It has been found that the thin layer of air immediately adjacent to the cathode regains its insulating qualities almost instantly after the current reaches zero, while the remainder of the arc path builds up its dielectric strength at a much slower rate. As the current wave in an a-c arc approaches zero, and for a short time immediately following zero, the factors producing new ions in the arc paths have practically ceased their activity. Electrons are expelled from that portion of the air space immediately adjacent to the cathode so that a thin layer of air immediately adjacent to the cathode becomes de-ionized in an exceedingly short space of time. The first 250 volts, peak value, or about 175 volts, root mean square value, are borne almost entirely by this cathode layer, and the ability to withstand this voltage is attained in a fraction of a microsecond.

Fig. 6 shows, in a diagrammatic manner, the main features of the De-ion circuit breaker. There are two main stationary contacts supported in, but insulated from, the supporting framework. There is a main moving brush contact controlled through the operating mechanism linkage which is insulated, and which is operated from the solenoid and has

all the usual attachments for electrical closing and tripping. Mechanically and electrically connected to the main moving brush by means of the supporting conductor is the moving arcing contact provided with a horn which, in the closed position, makes contact against the stationary arc-tip. This stationary arcing contact is connected through the main current blow-in coil and the lead to the upper stationary contact. In the upper part of the breaker are de-ionizing plates and certain magnets.

When the De-ion breaker is opened while carrying current, the main moving brush leaves the main contact slightly before the moving arcing contact parts from the stationary contact, so that momentarily all the current that has previously been flowing from the main contacts flows from the lower main contact through a flexible shunt to the moving brush, through the connections to the moving arcing contact, through the stationary arcing contact, and through the main blow-in coil and the lead to the upper main terminal. The arc is immediately transferred by the action of the blow-in coil to the main arcing horns and up the inclined surface of these into the de-ionizing chamber immediately above. This single long arc between terminals, when blown into the de-ionizing chamber, is immediately broken up into a number of small arcs between the de-ionizing plates. At about a dozen places the radial field coils are in shunt connection across gaps and draw currents proportional to the drop across these gaps. With the reactance of the coils in shunt with the arcs across the short plates, these arcs become unstable and are extinguished. The radial coils are then in series with the arcs in the adjacent main de-ionizing chambers and carry the full series current. The radial field coils are so connected that they will cause the arc to be driven in a rotating manner rapidly around inside the chamber. This de-ionizing chamber comprises a series of de-ionizing plates, magnetic plates, and radial field coils suitably mounted.

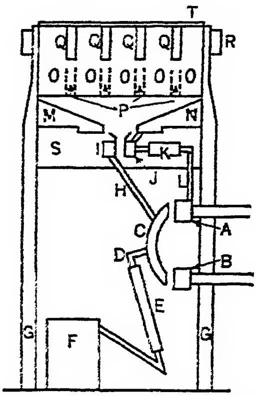

FIG. 6. Diagrammatic Sketch of De-ion Breaker

A and *B*, main stationary contacts; *C*, main moving contact; *D*, operating mechanism linkage; *E*, operating mechanism insulation; *F*, operating solenoid with attachments; *G*, supporting framework; *H*, connection of main moving contact to arcing contact; *I*, moving arcing contact with horn; *J*, stationary arcing contact with horn; *K*, blow-in current coil; *L*, connection from *K* to *A*; *M*, front main arcing horn; *N*, rear main arcing horn; *O*, de-ionizing plates; *P*, guide plates; *Q*, radial field coils; *R*, steel cylinder; *S*, steel plates in magnetic blow-in circuit; *T*, magnetic blow-in return circuit.

The stator plates clamped together give the effect of a larger number of very short gaps in series, each of these having its own cathode and anode and each gap having theoretically an insulating value of about 175 volts root mean square.

The De-ion circuit breaker is most effective as an a-c device. The de-ionizing chamber is applicable to d-c circuits up to a certain voltage limitation, and the advantages to be gained by such applications are not at the present time outstanding ones. The de-ionizing principle has been extended into several different classes of a-c circuit interrupters. Industrial contactors operating on this principle on voltages up to 550 volts have been in continuous service, and the de-ionizing principle has been made applicable to breakers up to 25,000 volts.

Small De-Ion Circuit Breakers are now available in ratings up to 600 amp at 250 volts direct current and 600 volts alternating current. They are made as one-, two-, or three-pole units in sizes from 15 amp up, corresponding to the ratings of the wires they are to protect. The trip mechanism is actuated by a thermal device calibrated to trip at 25 per cent overload. On the larger breakers an additional trip of the magnetic type is available. These breakers will trip satisfactorily in a circuit capable of developing 10,000 amp on short circuit. With the small breakers, the circuit voltage cannot actually force this amount of current through the breaker, but with the larger ratings the current can actually reach this figure. These breakers are more compact than the usual air-break type, they are completely enclosed, they cannot be held closed on overload, and they will stand repeated short-circuit tests within their rating of 10,000 amp.

9. MISCELLANEOUS AIR BREAKERS

The use of compressed gas for interrupting high-voltage circuits has been experimented with for many years, but it was not until adequate testing facilities were available in the larger manufacturing works that real progress was made.

The A.E.G. of Germany developed breakers, suitable for voltages up to 100 kv, that depended on a blast of air for blowing out the arc. The high-voltage circuit was made at the top of a tube through a terminal connected by the moving contact to the lower terminals of the bottom end of the tube. Operation was generally secured by an air cylinder fed from the same source of air pressure which gives arc rupture, and the mechanical operation of the device was so arranged that the movement of contact parts and valve actions assured air pressure simultaneously with or just previous to the parting of the contacts, so that there was no possibility of drawing a high-voltage arc without the necessary pressure for rupture being present. Air pressures up to about 225 lb per sq in. were usually available from the air reservoir.

For small stations involving only a few breakers carbon dioxide obtained from bottles of carbonic acid was used, in this way eliminating the special air compressor. The carbon dioxide was better as an arc-extinguishing means than the compressed air. A number of breakers with an arc kva rupturing capacity up to 500,000 were put in service for different voltages.

A live pot circuit interrupter using water was developed by the Siemens Schuckert Company of Germany, and breakers for service up to 500,000 kva rupturing capacity have been built. This breaker is provided with a fluid chamber divided into two parts, the inner chamber being filled with water or other liquid and the outer chamber being a water-storage space and air space to allow expansion of the gas when it passes through the throat bushing of the inner chamber. Thus pipes in the outer chamber are provided for leading the expanded moist gases safely away from the vicinity of the arc rupturing space. Arc interruption is secured by adiabatic expansion of the gases through the throat bushings into the outer chamber. This action causes a decrease in temperature and corresponding moisture condensation in the arc stream which reduce the movement of the electrons and increase the dielectric strength of the arc path. In accordance with one possible theory offered in explanation of the arc extinction this decrease in temperature is accompanied by corresponding condensation of moisture on the electrons thereby increasing their inertia and making breakdown of the space between the contacts impossible.

Various types of vacuum breakers have been built by different makers. In theory a vacuum breaker relies on absence of air or gas pressure and so is dielectrically opposed to other switching devices which use a blast of gas either generated by the arc itself or supplied from an outside source for arc rupture.

The Siemens Schuckert Company have done some development work on a circuit breaker using tanks full of resistance liquids. The contacts within these tanks are normally held together when the circuit is closed and are drawn apart when the breaker is open, introducing resistance progressively until the current is reduced to a minute value which is opened by the moving contact rising above the top of the liquid.

10. ELEMENTS OF OIL CIRCUIT BREAKERS

An oil circuit breaker may be defined as a device, other than a fuse, constructed primarily for interruption in oil of a circuit under infrequent and abnormal conditions. This definition excludes oil motor-starting devices with low interrupting capacities intended for frequent service. A description of a typical oil circuit breaker may be summarized by stating that it usually comprises one or more metal tanks, practically filled with insulating oil, having metal tops with insulating bushings through which pass conductors of copper rods which are attached to stationary contacts located below the surface of the oil. Movable contacts, operated from an external or internal mechanism, bridge the stationary contacts and complete the circuit when the breaker is closed, and are displaced from the bridging position when the breaker is opened, thus interrupting the circuit. Auxiliary contacts, readily renewable, are usually provided to take the final arc when opening, and to protect the main contact from burning.

Oil quenches the arc, when the contacts are drawn apart, by its cooling effect, and this quenching is most effective when the current passes through zero. The use of oil also permits smaller distances between live parts, and between live parts and ground, owing to its high dielectric strength. For this reason, an oil circuit breaker is usually of smaller dimensions than a corresponding air circuit breaker.

CONTACTS. Contacts of oil circuit breakers have two very important duties. When closed, they must carry the full-load current of the breaker with a small temperature rise, and they must carry for a few seconds, without deterioration, whatever amount of short-circuit current the system can pass through them. When opening or closing under load or short-circuit conditions, the main current-carrying parts must be so protected that they will not be burned or scarred sufficiently to prevent carrying full-load current again

with low temperature rise when the breaker is reclosed. On small circuit breakers the necessary protection is obtained by the special shape of the contact. On large circuit breakers the arcing contacts are separate from the main contacts.

Main Contacts of three kinds are in general use in American oil circuit breakers, namely, the solid butt type, the wedge and finger type, and the laminated butt type. Arcing contacts are generally provided to protect the main contacts from burning. They are mostly of the wedge and finger type, a lever roll-in type, and the bayonet type with plain break or quick break action. To insure arc extinction, five different schemes are in general use, namely, plain break, multibreak, explosion chamber, high speed, and De-ion grid. The General Electric Co. uses the plain break, oil blast or impulse, and explosion-chamber form. The Condit Co. uses the plain break and the multibreak form. The Pacific Electric Co. and the Kellman Co. use the multibreak contact. The Westinghouse Co. uses plain break and high-speed contacts and the De-ion grid.

Butt Contacts may be plain or laminated. Plain butt contacts consist of properly shaped stationary members engaging moving members, one of the members being resiliently supported by means of springs. This type is adaptable to low current breakers and is most frequently found on the high-voltage breakers. The laminated butt contacts are made in several forms, the elliptical form being the earliest and utilizing copper strip laminations. The application of the semi-elliptic brush is now limited to breakers of relatively low current-interrupting capacity or short-time rating because of the tendency of the magnetic forces to deform the brush. Various types of reverse brush contacts have been designed to overcome this difficulty. For heavier currents, non-welding alloys, plated on or inset, are used.

Wedge and Finger Contacts are shown in Fig. 7; they comprise one or more wedges,

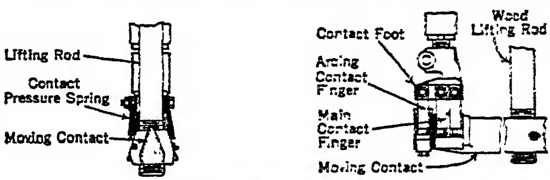

Fig. 7. Wedge and Finger Contact

usually on the movable element, which enter between the contact fingers when the breaker is closed. These contact fingers, which are arranged in pairs, are so constructed that they conform themselves to the wedge surfaces and present at all times a uniform contact pressure over the contact area.

Magnetic Blowout Effect in circuit breakers at voltages of 15,000, and below, has been found by experience and test to be very pronounced with heavy currents. Full advantage is taken of the magnetic loop (comprising the studs and moving contacts at each pole) for the maximum blowout action in all plain break breakers.

De-ion Grids, introduced in 1929 by the Westinghouse Co. for use on high-voltage breakers, furnish a method for keeping the oil in contact with the arc. The schematic relationship of the arc and the elements of the grid structure is shown in Fig. 8. The interrupting element or stack of grid plates, from which its name is derived, is attached at the end of the high-tension bushing. The grid is made up of a number of similar units, each unit in turn being made up of plate elements of insulating and magnetic material. Each individual grid plate carries a slotted opening, all of these registering in the complete grid to form a single deep and relatively narrow groove extending throughout its length. This groove is closed at one end of the grid but open for its entire length at the other end. As the contacts part on opening, the movable element passes downward through the groove and on to the end of the stroke well out of the grids, leaving an ample space for a layer of clean oil between the contact surfaces and the bottom of the grids to insure adequate insulation in the open position. The arc produced by parting of the contact is drawn and extinguished in this narrow groove, closed on all sides except for the opening at the inner end necessary to permit contact movement and the openings at the top and bottom of the grid. As the contact moves downward, towards the open position, the arc is drawn down through the air gap of the iron plate giving rise to a magnetomotive force, in the iron circuit and across the air gap, of one turn times the current in the arc. As the contact continues downward the same effect is produced in the next succeeding iron plate, and so on until the arc is extinguished. The arc is drawn between the parting contacts in the vertical, relatively narrow, deep groove formed by slots in the several plate elements of the grid and closed at the outer end. Plates of magnetic material are spaced at intervals through-

out the grid and so arranged as to form a partial return circuit and to provide a magnetic field when the arc is drawn through the air gap. This magnetic field operates to move the arc quickly toward the closed end of the groove. The grid being submerged in oil, the groove is filled with oil which cannot escape except through small openings at top or bottom, and which, for the short interval of time the arc exists, is for all practical purposes solidly entrapped. The arc moving towards the closed end of the slot is in effect being forced against a solid wall of oil throughout its entire length, resulting in a high rate of decomposition of the oil with an accompanying continuous and adequate supply of fresh un-ionized gas. This gas cannot escape, except through the arc stream, since the arc fills the open end of the groove. The driving power behind the arc forces the gas back through the arc stream, diluting it with un-ionized gas while current is flowing; the fresh gas acts as the de-ionizing surface after the current zero is reached. Numbers of tests

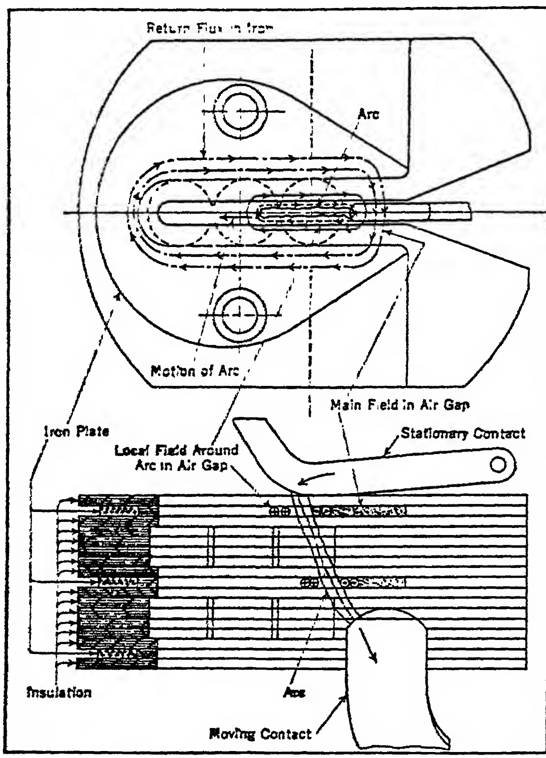

FIG. 8. Di-ion Grid Structure

have been made on large power systems which verify in actual practice the functioning of these breakers.

A porcelain tank breaker with greatly reduced oil volume is one of the promising lines of development for high-voltage breakers.

TANKS. The main purpose of breaker tanks is to hold the oil that submerges the contacts. Incidentally they dissipate the heat and enclose the working parts of the breaker. The type of tank is governed by considerations of the duty to be performed and of cost. Rectangular tanks are used for small breakers of moderate rupturing capacity. Circular tanks with dome-shaped bottoms are used for the largest-capacity low-tension oil circuit breakers, as this construction gives the strongest type of tank capable of withstanding the stresses frequently encountered when interrupting large amounts of power.

Mounting. Breakers of smaller size are built for mounting on pipe or angle iron frames. The frames are attached to the tops, and the tanks are supported by the tops to

which they are fastened. Tanks can be lowered for inspection or adjustment by special devices. Tanks of the largest sizes, principally for high-voltage service, are built for floor mounting, and access to the inside of the tank is usually secured by placing a manhole at the top.

Live Tanks. Although most oil circuit breakers are of the dead tank construction so that the tank may be grounded, the live tank construction indicated in Fig. 9 has been employed for many years on certain lines of breakers. The general design of the breaker has a form of inverted explosion chamber with main contacts in air. The explosion chamber consists of a steel cylindrical oil tank with insulated linings supported on a porcelain post, set in a base with clamp fittings and mounting bolts. Inside the oil tank is a system of baffle plates held in place and supported from the oil tank top. Separation chambers above the explosion chamber contain a quantity of quartz pebbles through which the gas has to pass in escaping. The oil condensed drains through the perforated disk and exhaust opening in the breaker top into the explosion chamber.

Mufflers are used in many breakers for scavenging the gases which are developed when the breakers are opened. The mufflers allow the gases to escape but prevent the throwing of the oil. These mufflers are usually arranged in the form of a labyrinth.

Tank Tops are not merely covers for oil receptacles; they also carry insulating bushings for the breaker studs and contacts, and often they carry the breaker mechanism and perform other functions. Where the leads through the bushings in the top carry heavy currents at 60 cycles, the possible heating of these tops has to be investigated very carefully. The heating of the tank tops is caused by hysteresis and eddy-current losses. To avoid these losses, breakers for the heavier currents utilize bronze inserts around the bushings or all-bronze tops for currents in excess of 1200 amp at 60 cycles.

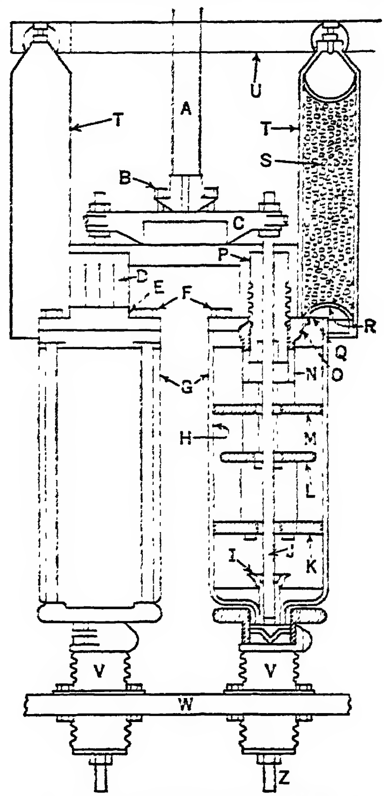

FIG. 9. Typical Live-tank Breaker

BUSHINGS. Bushings are required in the normal design of top-connected oil circuit breakers for insulating, from the metal top, the copper studs that support the stationary contacts and carry the current to these contacts. These terminal bushings range in voltage requirements from 2.5 to 287 kv or higher and in current from about 200 to about 6000 amp. Up to 23 kv for small amounts of power, porcelain bushings can be employed; for higher voltages, oil-filled or condenser bushings are used.

Oil-filled bushings shown in Fig. 10 consist in general of metal tubes at the center and series of short insulating cylinders separated by radial disks to increase creepage distances. These cylinders and disks taper gradually from the flange toward the end. Oil is admitted through the top of the visual gage at the top of the bushing and can be removed through the oil drain at the bottom.

Condenser Bushings used on the high-voltage Westinghouse breakers are usually of the design shown in Fig. 11. The condenser bushing is made by rolling, pressing, and baking onto a conductor alternate layers of Micarta paper and metal foil. The bushing is thus made of concentric cylinders of insulation with a layer of metal foil between them. The area of the foil and the thickness of the Micarta cylinders are controlled to give suita-

ble capacitances and uniform voltage drops from the center to the surface. In the typical condenser bushing illustrated, the part outside of the tank is covered in a weather casing of porcelain, the space between the bushing and the casing being filled with an insulating compound. A portion of the bushing inside the tank under the oil and near the contact is protected by a porcelain arc shield. Bushing-type current transformers are employed with breakers of the high-voltage design; the copper conductor of this bushing forms a primary winding, the secondary winding and the iron constituting the bushing transformer itself. Because of the voltage gradient provided by the condenser bushing, it is possible to make a connection between the last metal foil, the one nearest to ground, and the tank and secure economically a reliable potential device to use in operating synchroscopes and certain relay coils.

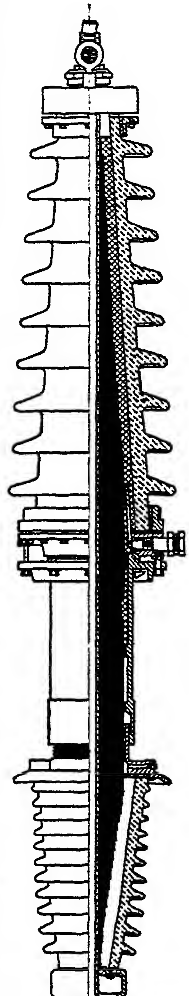

FIG. 11. Condenser Bushing

11. OPERATING MECHANISMS

Various methods are employed for operating oil circuit breakers. The smaller oil breakers are operated manually. For voltages up to 2500 volts, currents up to 1200 amp, and station capacities under 3000 kva, direct control is usual with the breakers mounted directly on the panel or panel framework. For higher voltages, heavier currents, or larger kilovolt-ampere capacity, the breakers are mounted apart from the panel, and connections between the panels and breakers are made by rods, bell cranks, and levers. With smaller sizes of manually operated remote-control circuit breakers, the latches and their release coils, by which automatic operation is secured, are mounted directly on the cover plate of the panel. The handle is in two parts to form a trip-free feature to prevent the breaker's being held in the closed position on overloads.

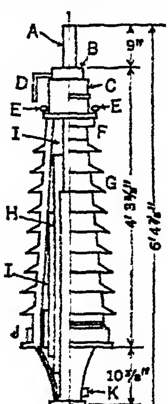

FIG. 10. Oil-filled Bushing. *A*, line terminal; *B*, metal cap; *C*, oil gage; *D*, air breathing tube; *E*, lifting eyebolts; *F*, top casting; *G*, porcelain shell; *H*, insulating barriers; *I*, oil space; *J*, bottom casting; *K*, oil drain; *L*, cable sleeve; *M*, cable.

Fig. 12 shows a single-handle cover plate such as is used with moderate-capacity breakers with two trip coils. In the larger sizes, the automatic latching details are located at the circuit breaker, thus taking the strain of the latched load off the panel and remote-control bell cranks and levers, and also reducing the mass to be accelerated at the time of automatic opening of the breaker. In American practice, mechanical remote control is practically always through a system of operating rods (usually pull), bell cranks, and levers.

Electrical Operation in some form is used when the distance between the switchboard and switching devices makes the application of hand-operated breakers questionable, or when the physical size of the apparatus is too great for convenient manual operation. Solenoid operation is the method usually employed in the majority of American plants; a typical solenoid mechanism is indicated in Fig. 13. This mechanism can be mounted in any desired location with reference to the breaker itself, and the pipes connected from the mechanism to the breaker can be attached to either the down-pull rod end or the up-pull rod end. All the newer solenoid mechanisms include a mechanical trip free feature which furnishes free opening of the breaker without the restraint of the inertia of the core. Owing to the greater simplicity of the d-c solenoid type of mechanism, it is normally employed, the current for this operation being obtained from a storage battery or through a rectifier like the Rectox from an a-c source of power in preference to using a motor mechanism.

Motor Mechanisms of the flyball type are used by various builders in installations where only a-c control circuits are available and, in certain cases, for d-c operation. Fly-

balls are used as they furnish a convenient means of translating rotary to linear motion and they permit the motor to get nearly up to speed before imposing any load on it, thus obviating the necessity of a motor of abnormally high starting torque. The mechanism

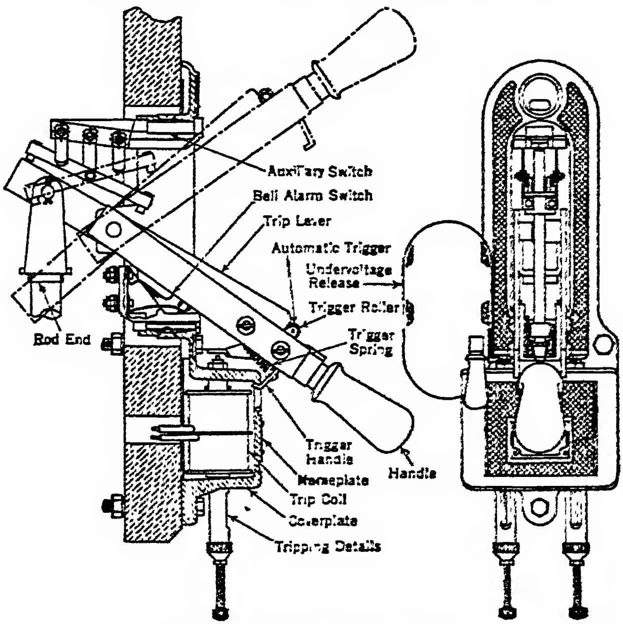

FIG. 12. Single-handle Cover Plate

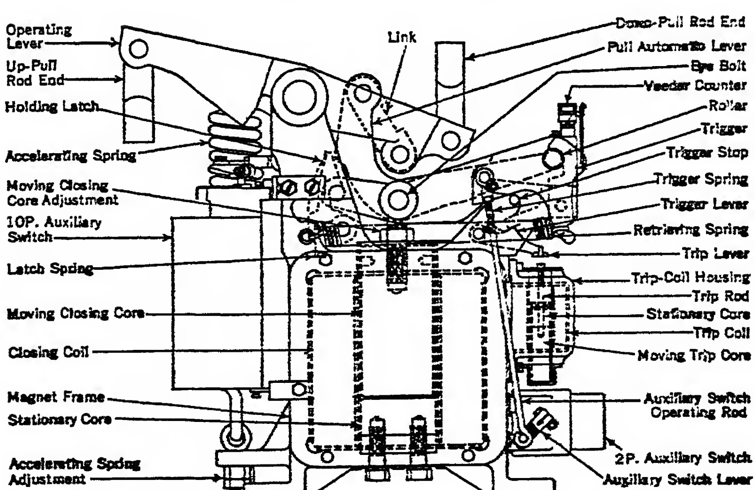

FIG. 13. Solenoid-operated Mechanism

consists of a motor-driven system of flyballs, sleeve shaft, and operating levers, mechanically trip free in action, for closing the breakers; a hardened-steel latch maintaining it in the closed position; a tripping device to disengage the latch automatically when the

tripping coil becomes energized; and an accelerating spring to insure positive fast opening of the breaker contacts upon release of the latch.

Outside Mechanism. The arrangement shown in Fig. 14 has been utilized in the older and smaller breakers as affording a simple and cheap method of operation. With this type of construction the steel lifting rods attached to the outside mechanism pass up through the top of the tank, and any gas formed in the breaker tank during operation passes out through the vent in the top provided for this steel lifting rod. This type of construction gives entire satisfaction for moderate capacity breakers and moderate

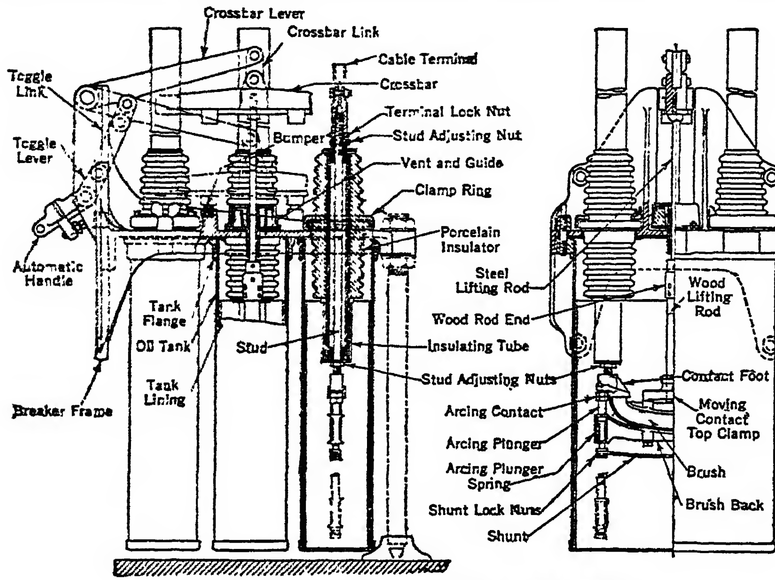

Fig. 14. Typical Oil Breaker with Outside Mechanism

voltages, but it is not so well adapted to breakers of higher rupturing rating and higher voltage as is the inside mechanism.

Inside Mechanism. With the modern design of breakers of moderate and large rupturing capacity the tops provide space for the installation of the breaker mechanism inside the breaker chamber, without appreciably increasing the overall height of the breaker structure. The only outside mechanical connection is then through a rotating shaft extending through a reamed and bushed hole in the side of the breaker top. This design removes the levers entirely from the vicinity of the live contact terminals, thus greatly increasing their electrical clearances to the grounded parts outside the breaker. It also eliminates the necessity of carrying the moving-contact lifting rod through the breaker top, avoiding the possibility of unbalanced forces on the lifting rods, and moreover leaves the outside of the breaker structure with a neat, trim appearance. Fig. 15 shows the arrangement of the inside breaker mechanism of typical design.

CONTROL OF OPERATION. Control energy for electrically operated circuit breakers and similar apparatus and switchgear installations is a very important matter. The amount of energy required for the closing of solenoid-operated breakers ranges from approximately 5 kw for the smaller breakers to 50 kw for the larger ones. The time demand is only 10 to 15 cycles, and usually a storage battery is furnished to supply the energy. In most electrical power plants an operating voltage having a nominal rating of 110 to 125 volts is used, but electrical equipment can be made suitable for 220–250 volts or any other desired voltage.

It is usually found desirable to segregate various control circuits. Where there is a natural grouping of breakers ordinarily a separate control circuit is provided for each group. Each circuit should be protected by its own switch and fused for not less than three times the maximum current needed for closing the largest breaker. This fusing will give protection in case of a short circuit in the control system and yet assure a supply of current under normal operating conditions. Individual circuits, usually at the breaker

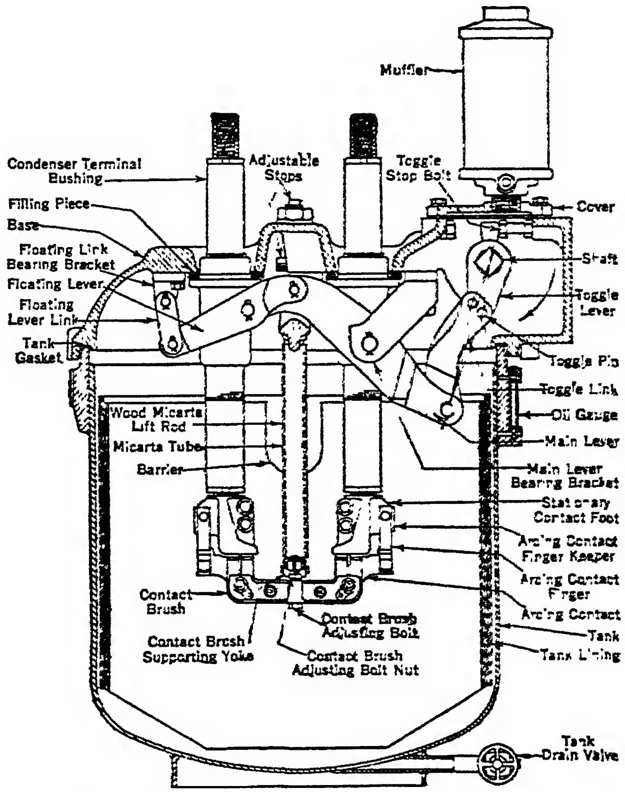

Fig. 15. Typical Oil Breaker with Inside Mechanism

points, should be fused at about half the current rating of the closing coil circuit, owing to the fact that the time of closing is extremely short and the closing current seldom reaches the full-load amount before it is cut off by the signal switch on the oil circuit breaker.

12. RELAYS

Relays are provided for use in connection with breakers to give breakers certain characteristics that cannot readily be taken care of in the breaker design. These relays may provide protection against overload, overcurrent, reverse current underload, overvoltage, undervoltage, reverse power, reverse phase connection, or open circuit on one phase, and can be made instantaneous or inverse time limit with an adjustable minimum tripping point. Various relays can be suitably interlocked so that breakers will function in certain predetermined sequences. Relays have three types of applications: service protection, apparatus protection, and automatic control.

Service Interruption is the most important factor to be guarded against by the protective relay. This may be done either by automatically sectionalizing the electrical system so as to disconnect the disabled section, or by automatically restoring the service after it has been accidentally interrupted.

Apparatus Protection. Another use for protective relays is to protect apparatus either by disconnecting it from service in case of failure or on the occurrence of abnormal conditions, or by functioning to remedy wholly or partially the abnormal condition. In cases where a short circuit or ground occurs in the winding of a machine such as a generator or transformer, it is usually necessary to have the apparatus disconnected.

D-c Relays for overload can be built either with series coils in the form of a solenoid

or with a magnetic circuit to slip over a stud or bus-bar, or they can be operated from a shunt. By the addition of a voltage coil, a d-c reverse power relay can be arranged.

A-c Relays for overcurrent of modern design operate on the induction principle, the contacts being closed by the rotation of a disk. It is necessary to have a certain quantity of current flowing in the relay winding before the disk will begin to rotate. After it has once been started, the speed of rotation is directly proportional to the current flowing in the winding until such a current reaches an excessively high value. This gives the relay an inverse time characteristic, or in other words, the greater the current flowing in the relay winding, the sooner the relay contact will close. The design of the relay and the action of the damping magnet are such that the time of action is definite for any given current value.

Directional Relay. This is usually obtained by means of combination of an overcurrent relay and a wattmeter element. The relay is made as a single-phase device, and the current element is very similar to the standard overcurrent relay and has identical characteristics. The wattmeter element operates on a very small percentage of normal voltage. The contacts of the overcurrent element are connected in series with the contacts of the wattmeter element, and the contacts of the wattmeter will close only when the power flows in one direction, so the relay as a unit operates only when power is flowing in one given direction.

Impedance Relays. On large, complicated transmission systems, the method of sectionalizing by means of overcurrent and directional relays is often difficult and sometimes even impossible to apply. This is due to the necessity of employing such a large number of relays that the timing sequence cannot be kept within safe limits. For such a system a special relay has been developed consisting of an overcurrent element of normal design with special voltage element so constructed that its action in relation to the closing of the relay contact depends on the impedance between the relay and the fault. In other words, the voltage element acts in opposition to the overcurrent element, and when the relay is a considerable distance from the fault, the voltage on the relay is comparatively high, thus taking a long time for the relay to close its contacts. On the other hand, the relays near the fault will have a very low voltage imposed on the voltage element, thus causing the relay to operate in much less time because of less opposition being offered to the action of the overload element by the voltage element. Thus the relay that is nearest the fault operates first without any special attention being given to time settings.

Balanced Relays. Balanced current protection is very often desirable when two or three similar transmission lines are used to connect two stations or two different points in a system. Balanced current protection on such lines means that each line normally carries approximately the same current, and when this condition does not exist, the line carrying the greatest current must be in fault.

Carrier Current Relays can be used to advantage in a few very special cases where long lines at high voltage and large power demands are to be controlled, as the lines from Boulder Dam to Los Angeles. The scheme involves the use of coupling condensers on the high-tension lines so that the power lines themselves can be used for carrying control circuits of 50- to 150-kc frequency, and these radio-frequency currents are utilized for the control of relays of various types at each end of each line. Under certain conditions, an impulse is set up at one end of the line by the action of certain relay devices, and this impulse is communicated to the other end as a 50- to 150-kc signal sent over the main transmission lines. These high-frequency circuits permit the operation of relays of all kinds to give the protection desired.

Pilot Wire Relaying can be carried out where the distances are small and the importance of the relaying sufficiently great to warrant running "pilot wires" between stations where parallel lines between them have to be protected at each end. This normally involves balancing the current that flows into a tie circuit against that which flows out so that if these two currents are the same the relays will not operate. In other words, these function only in the case of a fault on the tie lines between stations; they will not function in the case of a fault external to the section being protected.

High-speed Relays are becoming available to speed up the functioning of a protective system and to energize the tripping circuit of an oil circuit breaker in the minimum time to get full advantage of the high speed of action of some of the latest breakers. Various schemes are used to obtain the high speed on different types of relays.

Ground Protection can be obtained from overcurrent, differential, or balanced relays by operating these from suitable arrangements of transformers so that the current in the ground leg and not in the phase legs will act on the relays. Impedance relays are not usually employed to advantage for ground protection owing to the high impedance often found in the ground circuit.

13. SELECTION OF OIL CIRCUIT BREAKER

The smallest non-automatic oil circuit breakers are essentially knife switches whose jaws and blades are located under oil with an external operating handle. One type is built up to 60 amp and 4500 volts, and one for heavier currents at lower voltages. The smallest automatic oil circuit breakers available for indoor service wall mounting have capacities up to 200 amp 2500 volts. The smallest type suitable for switchboard mounting is made in capacities of 400 amp 5000 volts. The next larger size is built in capacities of 400 and 600 amp at 7500 volts, 800 amp at 2500 volts. These smaller breakers have a single rectangular tank enclosing all the contacts. A larger breaker is built with each pole of the breaker as a separate unit with its own frame and tank. One mechanism is used to operate all poles. Other indoor breakers are available having individual tanks per pole for service up to 23,000 volts. Practically all breakers of 50,000 kva rupturing capacity and above are oil tight and equipped with arc control and extinguishing devices.

Single Circular Tank Three-pole Breakers during the last few years have been made by many manufacturers; they are particularly suitable where relatively high rupturing capacity is to be obtained in a relatively small space. One design of breaker has tanks ranging in diameter from 16 to 32 in., current ratings 600 to 3000 amp, breakers being suitable for 15 or 7 1/2 kv. At 7 1/2 kv, rupturing capacity ranges from 8000 to 50,000 amp, and for 15 kv on the three larger diameter tanks, the capacities range from 6000 to 20,000 amp. The essential feature of all these breakers is the enclosing of the three phases in a single breaker chamber. This single round tank provides the most economical form in space requirements for increasing the body of oil, and the single circular tank represents the most economical form of material used as well as the shape best suited to the bearing of heavy internal pressures. The structural details of these breakers differ slightly, but their general arrangement is approximately the same except for modifications in the contacts and other detail features.

Indoor Oval Tank Breakers are available in ratings of 600, 1200, and 2000 amp, all rated normally at 15,000 volts. The line of oval tank breakers have rupturing capacities of 4000, 6000, and 10,000 amp at their rated voltage. In the complete line of oval tank breakers the mechanisms are arranged so as to have all moving parts inside the breaker. These breakers have mechanically trip-free mechanisms and condenser type bushings, and each breaker unit is vented to a common muffler.

Round Tank Breakers with one tank per pole are available where greater rupturing capacities are desired. These breakers use circular tanks, usually with each pole in a separate masonry compartment or steel cubicle. This type of indoor oil circuit breaker is adapted for the control of circuits up to 6000 amp at 15,000 volts, and 3000 amp at 23,000 volts. The main brushes are of the parallel-path design for most sizes. Although these various round tank breakers are normally utilized as completely assembled three-pole breakers, they are adaptable for segregated phase construction with the breaker unit arranged either vertically or horizontally.

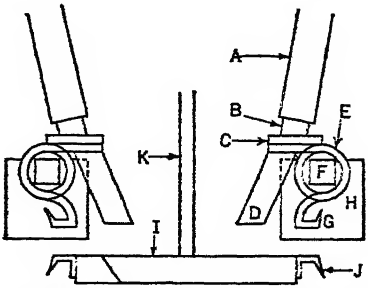

FIG. 16. High-speed A-c Oil Circuit Breaker. *A*, bushing; *B*, contact stud; *C*, contact foot; *D*, laminated brush stationary contact; *E*, series blow-out coils; *F*, magnetic circuit; *G*, stationary arcing tip; *H*, arc chute; *I*, moving contact-aluminum; *J*, moving arcing tip; *K*, insulating lift rod.

High-speed Railway Oil Circuit Breaker of a typical design has most of its interesting features indicated in Fig. 16. The breaker is essentially a single-pole outdoor round tank oil circuit breaker provided with a magnetic blowout for the arc with a contact designed to start quickly and to move rapidly. The main features of this breaker are

indicated on the drawing. The breaker with its actuating relay is designed to operate so that the short-circuit current on a 25-cycle railway system will be limited to not more than two half cycles, for currents of 6000 amp upward.

Outdoor Breakers are available having various current and voltage ratings and various assigned rupturing capacities. These breakers are for use on heavy-duty a-c circuits of large capacity of moderate or high voltages; they can be used for indoor or outdoor service up to 287 kv, the lower voltage ratings being available in capacities of 6000, 1200, and 2000 amp as frame-mounted breakers, Fig. 17, and those of the higher voltages for 600 and

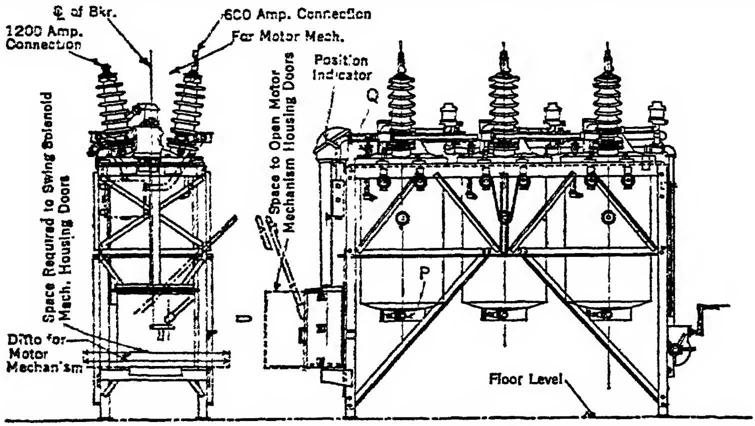

Fig. 17. Frame-mounted Oil Circuit Breaker

1200 amp as floor-mounted breakers, Fig. 18. Rupturing capacities up to 3,500,000 arc kva are available.

The selection of an oil circuit breaker for application to an electrical system or circuit requires a knowledge of the characteristics of the breaker and the characteristics of the system or circuit. Breakers are usually classified according to their rated voltage, rated current, etc., at a definite frequency, interrupting capacity, 5-sec and momentary current-carrying capacity. Systems may be classified according to their normal operating voltage, normal current, normal frequency, and short-circuit characteristics.

RATING. Tables 1 and 2 give the latest available data on this subject (N.E.M.A. tabulation):

Table 1. Schedule of Ratings for Indoor Oil Circuit Breakers as of Oct. 1, 1935

Rated Voltage	Interrupting Capacity, kva	Current Rating, amp	Rated Voltage	Interrupting Capacity, kva	Current Rating, amp
5,000	20,000	400	15,000	1,000,000 (M)	3,000
5,000	50,000 (M)	2,000	15,000	1,500,000 (M)	1,200
7,500	25,000	600	15,000	1,500,000 (M)	2,000
7,500	50,000 (M)	1,200	15,000	1,500,000 (M)	3,000
7,500	100,000 (M)	600	15,000	1,500,000 (M)	4,000
7,500	350,000 (M)	3,000	23,000	500,000 (M)	600
15,000	50,000 (M)	600	23,000	500,000 (M)	1,200
15,000	100,000 (M)	600	23,000	500,000 (M)	2,000
15,000	100,000 (M)	1,200	23,000	1,000,000 (M)	*
15,000	100,000 (M)	2,000	23,000	1,500,000 (M)	†
15,000	150,000 (M)	600	23,000	2,500,000 (M)	†
15,000	150,000 (M)	1,200	34,500	500,000	600
15,000	250,000 (M)	600	34,500	1,000,000 (M)	1,200
15,000	250,000 (M)	1,200	34,500	1,000,000 (M)	2,000
15,000	250,000 (M)	2,000	34,500	1,500,000 (M)	1,200
15,000	500,000 (M)	600	34,500	1,500,000 (M)	2,000
15,000	500,000 (M)	1,200	34,500	1,500,000 (M)	3,000
15,000	500,000 (M)	2,000	34,500	2,500,000 (M)	2,000
15,000	1,000,000 (M)	1,200	34,500	2,500,000 (M)	3,000
15,000	1,000,000 (M)	2,000			

* Use breaker of same rating. † Of 34,500 volts class.

Note: "M" Ratings applicable to indoor oil circuit breakers and either indoor or outdoor metal-clad switchgear. For outdoor oil circuit breakers for 46 kv and above see below.

It should be noted that most of the smaller breakers are hand-operated distant control whereas the larger ones are electrically operated distant control. In every case these are the non-automatic breakers, that are made automatic by the use of proper relays and current transformers.

Oil circuit breakers and other switching equipment are rated in rms volts based on a dielectric test in accordance with the A.I.E.E. Rules that all indoor breakers be tested

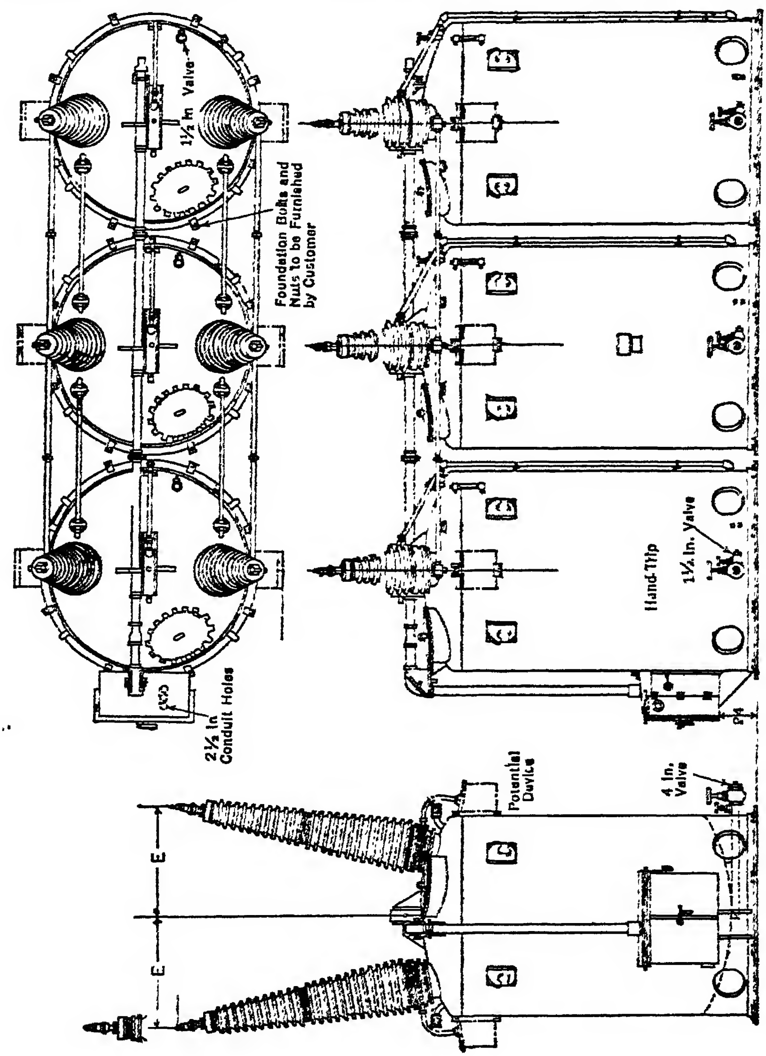

FIG. 18. Floor-mounted Oil Circuit Breaker

at 2 1/4 times rated voltage plus 2000 volts. Outdoor breakers will meet this same dry test and will meet a wet test of 2 times rated voltage plus 1000 volts.

Altitude affects arcing distances in air. For definite voltages these distances increase with the decrease in atmospheric pressure while the cooling effect diminishes. Standard ratings of all oil circuit breakers are assigned to altitudes of 1 km (3300 ft) above sea-level and less; for higher altitudes standard listed breakers must be de-rated according to tables published by the manufacturers.

Table 2. Schedule of Ratings for Outdoor Oil Circuit Breakers as of Oct. 1, 1935

Rated Voltage	Interrupting Capacity, kva	Current Rating, amp	Rated Voltage	Interrupting Capacity, kva	Current Rating, amp
15,000	50,000	600	34,500	1,500,000	3,000
15,000	100,000	600	46,000	150,000	600
15,000	175,000	600	46,000	500,000	600
15,000	500,000	600	46,000	1,000,000	1,200
15,000	500,000	1,200	69,000	250,000	600
15,000	500,000	2,000	69,000	500,000	600
15,000	1,000,000	1,200	69,000	1,000,000	600
15,000	1,000,000	2,000	69,000	1,000,000	1,200
15,000	1,000,000	3,000	69,000	1,500,000	600
15,000	1,500,000	2,000	69,000	1,500,000	1,200
15,000	1,500,000	3,000	69,000	2,500,000	1,200
15,000	1,500,000	4,000	69,000	2,500,000	2,000
23,000	150,000	600	115,000	500,000	600
23,000	500,000	600	115,000	1,000,000	600
23,000	500,000	1,200	115,000	1,500,000	600
23,000	500,000	2,000	115,000	1,500,000	1,200
34,500	150,000	600	138,000	750,000	600
34,500	500,000	600	138,000	1,500,000	600
34,500	500,000	1,200	138,000	1,500,000	1,200
34,500	500,000	2,000	138,000	2,500,000	1,200
34,500	1,000,000	1,200	161,000	1,500,000	1,200
34,500	1,000,000	2,000	161,000	2,500,000	1,200
34,500	1,000,000	3,000	230,000	2,500,000	1,200
34,500	1,500,000	1,200	345,000	3,500,000	1,200
34,500	1,500,000	2,000			

Interrupting Ratings are usually based on the highest rms current at specified voltage which the breaker can interrupt and close against a short circuit, followed immediately by the reopening of the breaker, that is without purposely delayed action; allowed to remain open for 15 sec for the larger "oil-tight" breakers; or 2 sec for the smaller "non-oil-tight" breakers; and then closed against the short circuit and followed immediately by the reopening of the breaker, that is, without purposely delayed action. The breaker should perform its rated duty under these conditions without emitting flame and, at the end of the duty cycle, must be in substantially the same mechanical condition as at the beginning, but the interrupting capacity may be materially reduced.

Speed of Operation has been given a great deal of attention in the past few years, and breakers are now available that will open a 60-cycle circuit in 3 cycles, and breakers have been built to open a 25-cycle railway circuit in 1 cycle on the 25-cycle basis, at 25 to 100 per cent short-circuit current and at nominal voltage.

Impulse Tests have been applied to high-voltage breakers the same as to other high-voltage equipment so that proper coordination has been obtained between the flashovers of transmission-line insulators, lightning arresters, bushings for transformers and circuit breakers, supports for the high-tension wiring, and other parts subject to high-voltage surges.

The effects of short circuits on the breakers may manifest themselves as strains on the tanks, fittings, mechanism, contacts, bushings, etc., caused by electromagnetic stresses, reduction of insulation value, and reduced ability to carry current. Excessive current may burn or weld the contacts, take the temper out of brush contacts or backing springs —in effect, cut down the carrying capacity of the breaker for subsequent service.

SHORT-CIRCUIT CALCULATIONS. Satisfactory calculations of short-circuit characteristics of a system can be made on simple systems rather readily, but on complicated ones the calculations are very involved. For the simpler cases, an approximation sufficiently close for practical purposes can generally be made by neglecting the effect of resistance and capacitance and using the reactance only, along with suitable time decrement curves. These curves show graphically the test results of short-circuiting a-c synchronous machines, and are available in the publications of circuit-breaker manufacturers.

Reactances of generators, transformers, etc., may be estimated where the actual data for a proposed system are unknown, but certain preliminary calculations are to be made. The reactance in generators varies from about 8 per cent for a small high-speed unit to about 30 per cent for large slow-speed water-wheel machines, and that in the transformers varies from about 3 to 15 per cent of their ratings. A fair figure to use in a hydroelectric system with step-up transformers is a combined reactance of generators and transformers of roughly 33 per cent so that the current in a symmetrical short circuit on the high-

tension side of the step-up transformers of the generating station is approximately three times full-load rating. In a relatively long transmission line the reactance may be in the nature of 10 per cent, the reactance of the step-down transformers 7 or 8 per cent, so that a symmetrical short circuit on the low-tension side of the transformers of the substation will probably be about twice the full-load rating, assuming the capacity of the substation to be the equivalent of the generating station.

CONTROLLERS AND REGULATORS

The function of control apparatus when used with industrial motors of various kinds is to enable the latter to take care of various features not directly incorporated in the motor design. The functions of control apparatus are some or all of the following:

To limit the current during the acceleration of the motor.
To limit the torque during acceleration.
To change the direction of rotation of the motor.
To limit the load on the motor.
To disconnect the motor on failure of voltage.
To regulate the speed of rotation.

To start and stop the motor at fixed points on the cycle of operation, or at the limit of travel of the load.

To stop the motor.

To protect the operator from injury.

The simplest of the control apparatus are those intended only for starting the motors; the more complicated devices also provide for speed regulation, reversing the direction of rotation, and other features.

The starting and speed regulating can be accomplished by means of switches, contactors, or similar devices. The switches can be the plain knife switches described in Art. 3 (p. 12–03), or they can be in the form of face plates with contact arms, drum controllers, or contactors.

Contactors are modified forms of air circuit breakers and are used principally in industrial work for motor control and in automatic stations. In general, a contactor like Fig. 1 might be considered as a circuit breaker normally requiring some auxiliary source of

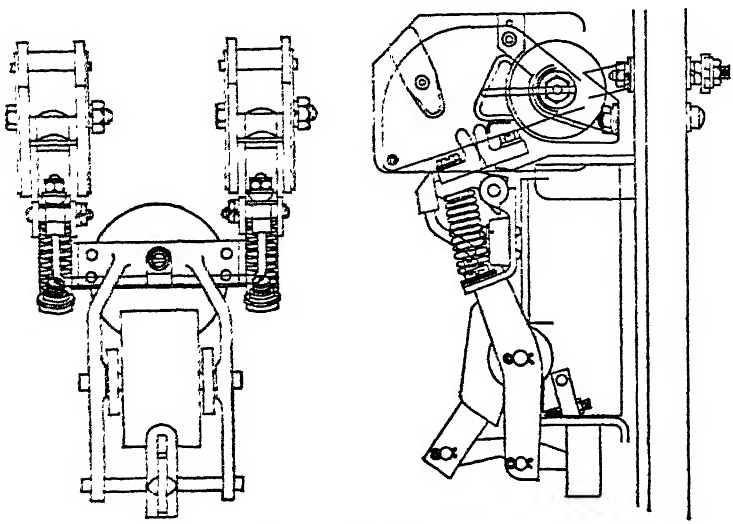

Fig. 1. Typical Contactor

power, like a solenoid, to hold it in the closed position. Latching contactors can be supplied.

Contactors are designed to withstand the severe requirements of general industrial service and are rated on a continuous current-carrying capacity basis. They will carry a 25 per cent overload for 1 hr and will successfully rupture four times their rated current. Low-voltage release is an inherent characteristic of magnetic control when used with any sort of two-wire master switch. The normal design of contactor consists of an insulating base with a contactor mounted on it. The contactor illustrated in Fig. 1 has copper-to-copper contacts which roll into engagement and is provided with the arc-splitter construction of the magnetic blowout. The circuit is closed and opened on the extreme tip of the contacts, and the burning, due to hot spots when closing and rupturing the arc when opening, is in this way localized. As the contactor closes, the area of contact is quickly transferred from the burned tips to the clean surface at the heel. What actually takes place is that the moving contact rolls down along the surface of the stationary contact. The tendency to stick or weld at the instant of closing, which characterizes most forms of copper-to-copper contact, is completely eliminated by the powerful leverage introduced by this rolling movement. Also a slight sliding or wiping action takes place which serves to prevent overheating of the contacts due to an accumulation of dust or oxidized scale. The arc splitter and the magnetic blowout lengthen and cool the arc incident to opening the circuit. The resultant burning is in this way materially reduced, and experience has shown that the useful life of the contact is prolonged. Contactors are available in various current ratings from 50 to 1600 amp and can be made single pole or multipole. Wherever

possible direct current is utilized to operate the contactors but modifications are available utilizing alternating current for this service.

Network Protectors are special types of contactors or air breakers, motor or solenoid-operated, with associated relays designed to connect transformers to an a-c network when the conditions are correct and to disconnect them when conditions are wrong. To withstand high temperatures, high-pressure butt contacts are used, employing silver main contacts as silver maintains a much better contact surface over a long time than copper, silver oxide being a much better conductor than copper oxide.

Network protectors of the air-break type are utilized chiefly in connection with low-voltage three-phase four-wire systems of 115–199 or 120–208 volts. Special types of oil circuit breakers have been developed as network protectors for use on three-phase four-wire 2300–4000 volt systems. These network systems themselves are considered in the section of this handbook dealing with Distribution.

14. MOTOR-STARTING DEVICES

STARTING SWITCH. Motors up to 1 hp, whether d-c or single-phase, can usually be started by closing a switch that connects the motor directly to the source of power. Automatic protection against overload can be provided by fuses or circuit breakers, the latter sometimes being incorporated in the design of the main switch. So-called sentinel breakers and similar types can be furnished with current rating suitable for any motor from $1/20$ up to 1 hp. This device is essentially a small combination switch and circuit breaker in a Bakelite case and is provided with a bimetallic thermal element. A momentary overload will not cause the breaker to trip. If, however, a load heavy enough to damage the motor should continue, the thermal element will cause the breaker to trip before the motor is harmed. The handle automatically moves to the central position to indicate that the breaker is open. After the cause of the overload has been removed, the breaker is reset by moving the handle to the off position and then to the on position. It cannot be held on the on position while the injurious overload condition exists.

FACE-PLATE STARTERS. Fig. 2 shows a typical starter for use with series, shunt,

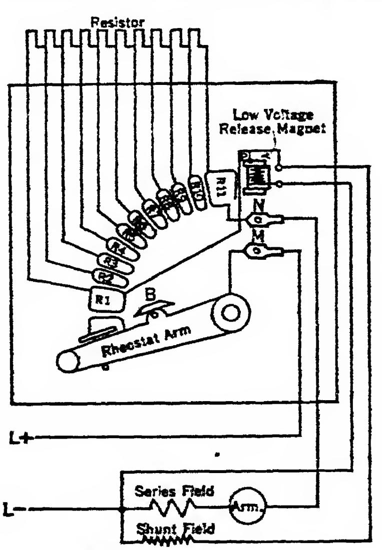

Fig. 2. Face-plate Starter

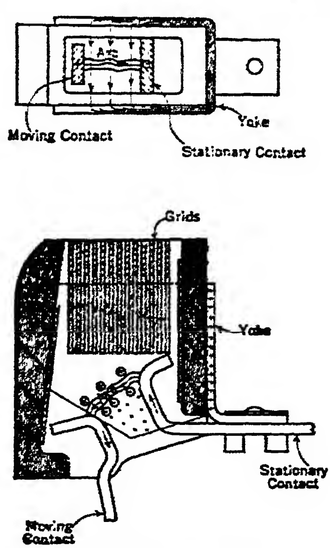

Fig. 3. De-ion Chamber of Contactor

and compound d-c motors in non-reversing service and for single-phase repulsion motors up to 10 hp. This control is applicable to starting duty only. It provides low-voltage protection to the motor. Provision is made by spring return to prevent the arm being left in an intermediate position on the contacts, which in time would endanger the resistors. In case of power failure the arm returns to the off position. The motor is started by moving the rheostat handle slowly to the right. When the arm reaches the full "run" position,

To start and stop the motor at fixed points on the cycle of operation, or at the limit of travel of the load.

To stop the motor.

To protect the operator from injury.

The simplest of the control apparatus are those intended only for starting the motors; the more complicated devices also provide for speed regulation, reversing the direction of rotation, and other features.

The starting and speed regulating can be accomplished by means of switches, contactors, or similar devices. The switches can be the plain knife switches described in Art. 3 (p. 12-03), or they can be in the form of face plates with contact arms, drum controllers, or contactors.

Contactors are modified forms of air circuit breakers and are used principally in industrial work for motor control and in automatic stations. In general, a contactor like Fig. 1 might be considered as a circuit breaker normally requiring some auxiliary source of power, like a solenoid, to hold it in the closed position. Latching contactors can be supplied.

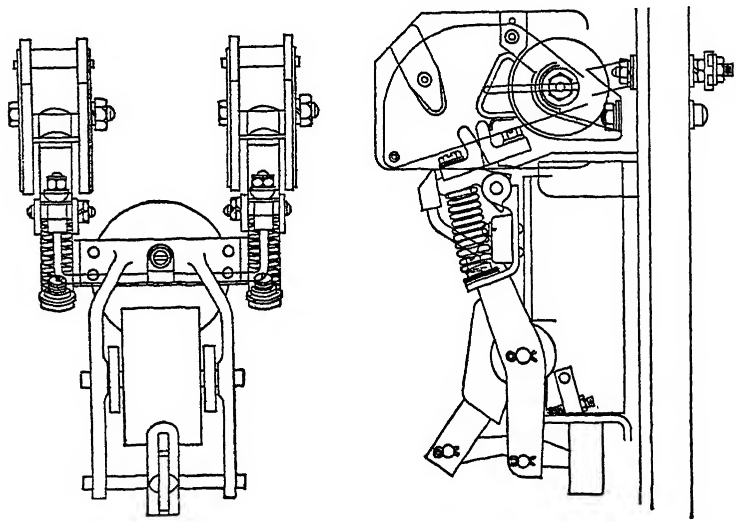

Fig. 1. Typical Contactor

Contactors are designed to withstand the severe requirements of general industrial service and are rated on a continuous current-carrying capacity basis. They will carry a 25 per cent overload for 1 hr and will successfully rupture four times their rated current. Low-voltage release is an inherent characteristic of magnetic control when used with any sort of two-wire master switch. The normal design of contactor consists of an insulating base with a contactor mounted on it. The contactor illustrated in Fig. 1 has copper-to-copper contacts which roll into engagement and is provided with the arc-splitter construction of the magnetic blowout. The circuit is closed and opened on the extreme tip of the contacts, and the burning, due to hot spots when closing and rupturing the arc when opening, is in this way localized. As the contactor closes, the area of contact is quickly transferred from the burned tips to the clean surface at the heel. What actually takes place is that the moving contact rolls down along the surface of the stationary contact. The tendency to stick or weld at the instant of closing, which characterizes most forms of copper-to-copper contact, is completely eliminated by the powerful leverage introduced by this rolling movement. Also a slight sliding or wiping action takes place which serves to prevent overheating of the contacts due to an accumulation of dust or oxidized scale. The arc splitter and the magnetic blowout lengthen and cool the arc incident to opening the circuit. The resultant burning is in this way materially reduced, and experience has shown that the useful life of the contact is prolonged. Contactors are available in various current ratings from 50 to 1600 amp and can be made single pole or multipole. Wherever

possible direct current is utilized to operate the contactors but modifications are available utilizing alternating current for this service.

Network Protectors are special types of contactors or air breakers, motor or solenoid-operated, with associated relays designed to connect transformers to an a-c network when the conditions are correct and to disconnect them when conditions are wrong. To withstand high temperatures, high-pressure butt contacts are used, employing silver main contacts as silver maintains a much better contact surface over a long time than copper, silver oxide being a much better conductor than copper oxide.

Network protectors of the air-break type are utilized chiefly in connection with low-voltage three-phase four-wire systems of 115–199 or 120–208 volts. Special types of oil circuit breakers have been developed as network protectors for use on three-phase four-wire 2300–4000 volt systems. These network systems themselves are considered in the section of this handbook dealing with Distribution.

14. MOTOR-STARTING DEVICES

STARTING SWITCH. Motors up to 1 hp, whether d-c or single-phase, can usually be started by closing a switch that connects the motor directly to the source of power. Automatic protection against overload can be provided by fuses or circuit breakers, the latter sometimes being incorporated in the design of the main switch. So-called sentinel breakers and similar types can be furnished with current rating suitable for any motor from $^1/_{20}$ up to 1 hp. This device is essentially a small combination switch and circuit breaker in a Bakelite case and is provided with a bimetallic thermal element. A momentary overload will not cause the breaker to trip. If, however, a load heavy enough to damage the motor should continue, the thermal element will cause the breaker to trip before the motor is harmed. The handle automatically moves to the central position to indicate that the breaker is open. After the cause of the overload has been removed, the breaker is reset by moving the handle to the off position and then to the on position. It cannot be held on the on position while the injurious overload condition exists.

FACE-PLATE STARTERS. Fig. 2 shows a typical starter for use with series, shunt,

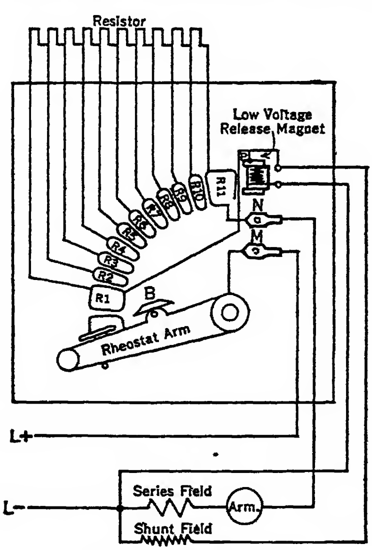

Fig. 2. Face-plate Starter

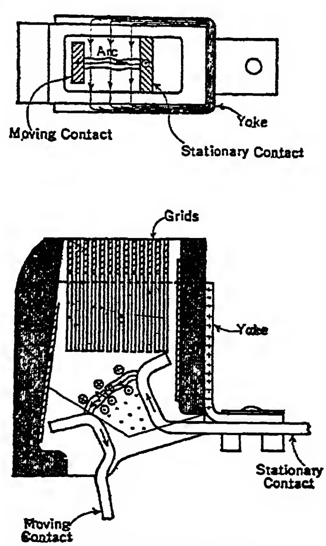

Fig. 3. De-ion Chamber of Contactor

and compound d-c motors in non-reversing service and for single-phase repulsion motors up to 10 hp. This control is applicable to starting duty only. It provides low-voltage protection to the motor. Provision is made by spring return to prevent the arm being left in an intermediate position on the contacts, which in time would endanger the resistors. In case of power failure the arm returns to the off position. The motor is started by moving the rheostat handle slowly to the right. When the arm reaches the full "run" position,

it is held in place by a magnet which has its coil connected across the line. The handle is provided with a spring which prevents it from remaining in any position except off or run. It can remain in the run position only when power is on; in case of power failure the holding magnet releases and the spring returns the arm to the off position.

LINE STARTERS utilizing contactors are used to start compound-wound d-c motors directly across the line in those applications where the high starting torque attained by this method of starting will not injure the driven machine. A thermal overload relay is provided to protect the motor against continuous overload condition.

Line starters with De-ion arc quenchers or similar devices are available for across-the-line starting of squirrel-cage and wound-rotor induction motors ranging in size from $^1/_2$ to 200 hp for voltages up to 600. These devices are particularly suited for starting motors driving machine tools, textile machinery, woodworking machines, pumps, stands, and other machines where remote control with complete protection to the operator, motor, and machine is desired. These are essentially magnetic starters and for the larger capacities De-ion arc quenchers (see Art. 8) like Fig. 3 are furnished.

Where necessary oil-immersed line starters can be provided for such locations as mines, cement mills, chemical plants, and oil refineries. They can also be used in high altitudes where the operation of the standard types would be affected by low barometric pressure. Reversing line starters are available, utilizing two three-pole contactors mounted back to back, one for the forward and one for the reverse direction of rotation. These are mechanically interlocked to prevent closing both at the same time.

MAGNETIC STARTERS. For d-c motors, magnetic starters are available for non-reversing or reversing service, constant or adjustable speed with dynamic braking in the off position, and with thermal overload protection. Magnetic starters are available for use with wound-rotor induction motors. These have a primary contactor and a number of secondary contactors, the latter short-circuiting the various amounts of resistance.

Magnetic starters can be furnished for use with squirrel-cage induction motors where the line or load conditions require reduced-voltage starting and where the advantages of remote control are desired. These starters may be operated either from a push button or from automatic master switches such as float switches or pressure regulators. To start a motor it is merely necessary to press the start push button on an automatic master switch to operate. This closes the circuit through a contact in the timing relay. This relay energizes the starting contactor, or contactors, which close and connect the motor to reduced voltage from the auto-transformer thus limiting the starting current to an allowable value and permitting smooth starting. The time that the motor is connected to the auto-transformer is governed by the setting of the accelerating relay. After a definite time adjustable up to 30 sec, the timing relay opens the circuit of the starting contactor and closes the circuit to the running contactor which connects the motor directly to the line. The motor is therefore accelerated at the most rapid permissible rate, independent of the operator and without damage to the motor or driven machinery. These starters are arranged to provide either low-voltage release or protection depending on conditions. With these larger magnetic starters the auto-transformers are usually provided with 50, 65, and 80 per cent taps so that the starting voltage may be easily adjusted to suit the particular starting conditions.

TIME STARTERS. Time starters are remote-controlled magnetic starters adapted for adjustable-speed d-c motors up to 10 hp, 230 volts. They provide three points of definite time limit acceleration, permitting safe and accurate starting of the motor under full or partial load. A clock escapement mechanism permits changing the accelerating time to suit the application requirement accurately and definitely. The device consists essentially of a three-point accelerating contactor, mechanically connected to an ingenious clock escapement mechanism. Definite time limit acceleration is obtained in starting by delayed action of the accelerating contacts brought about by a clock escapement mechanism.

AUTO-STARTERS. An auto-starter is a reduced-voltage non-reversing auto-transformer type starter for use with squirrel-cage induction motors. This device is furnished with overload protection by an inverse time limit overload relay and low-voltage protection in case of power failure. Low-voltage starters for use up to 50 hp 60 cycle, 30 hp 25 cycle are designed for operation without the immersion of the contacts in oil. Where needed, however, or for the larger starters, oil immersion of the contacts is normally used. Overload protection is provided by a thermal relay for the smaller sizes, this relay depending for its operation on the fact that a bimetal trip arm bends under the influence of the heat from the heater. Heating elements are available in capacities up to 95 amp. When the starter rating requires the heater to carry more than 95 amp, a relay provided with parallel heaters can be furnished. Low-voltage protection is provided by a relay which holds the operating handle in the running position as long as normal voltage is maintained but

releases it and disconnects the motor from the line whenever the voltage fails. A time delay low-voltage device can be furnished providing a time delay adjustable from 1/2 to 2 1/2 sec, so that, if the voltage returns to normal after having failed within the time setting of the attachment, the auto-starter will not drop out and the motor will continue to run.

For larger motors, using auto-transformer starting, a double-throw breaker is provided with special moving and stationary contact arrangements which provides three poles in the run position and five poles in the start position. The additional poles for the start position are utilized to connect in the auto-transformers that are disconnected in the running position as shown in Fig. 4.

With manually operated reduced voltage starters, connections can be made for either

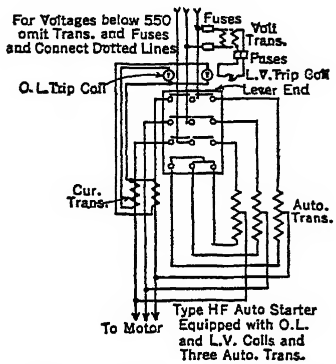

FIG. 4. Auto-starter Connections

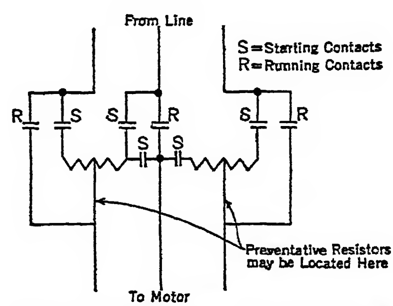

FIG. 5. Auto-starter Connections from Line

the open transition starting or the closed transition starting, these connections being indicated in Fig. 5.

15. DRUM CONTROLLERS

Drum reversing switches for d-c motors are available for use principally with small d-c motors. These are sometimes provided with ballast resistors or starting resistors.

For larger motors reversing drum switches of the cam contactor construction are available, being used particularly for controlling series-, shunt-, or compound-wound motors in general reversing service on cranes, bridges, roll and transfer tables, and in similar applications where starting and speed control are desired by means of resistance in series with the armature. These drum switches are designed for frequent and severe service. The operating principles of the cam-type switch are similar to those of magnetic contactors except that the contacts are closed by cams instead of magnets. A heavy helical spring opens the contacts. The shape of the cam gives a quick break and quick make action to the contacts regardless of how slowly the handle is moved. The contacts are the same as those used on magnetic starters and have the same rolling action when opening or closing. The arcing can take place only at the contact tips, leaving the heel clean and smooth for carrying the current. Individual magnetic blowouts with arc splitters are provided to cool and stretch the arc under the influence of magnetic field and to rupture it quickly. These magnetic blowouts are used on all 550-volt drum switches.

Drum starters, either reversing or non-reversing, can be furnished for small polyphase squirrel-cage induction motors to connect them directly to the line. These devices are used extensively where the air may become charged with explosive gases or highly inflammable particles of dust or lint, as in textile mills, flour mills, and woodworking plants. With these starters the contacts are usually immersed in oil. Similar across-the-line reversing-drum controllers can be furnished where the oil immersion of the contact is not required.

Drum controllers are available for 230-volt motors from 1 to 35 hp for machine tool service and similar duties where it is desired to have complete control of the motor from one operating handle. They are designed for starting and controlling the speed of adjustable-speed shunt-wound motors having speed ranges of 1 1/2 to 1, 2 to 1, 3 to 1, or 4 to 1. They are built for reversing service and can be provided with an arrangement for dynamic braking.

Non-reversing drum controllers can also be used to advantage for the secondary control

of wound rotor induction motors. The controller may be used for either starting or speed-regulating duties depending upon the resistors employed. A separate switch for the primary motor circuit, which includes the advantages of low voltage and overload protection, is required for use with these drum controllers.

16. CONTROL PANELS

D-c protective panels are available for use with manual controllers to provide overload and low-voltage protection. The contactor can be provided with a thermal overload relay operated by heaters selected according to the motor ratings. In addition to overload protection, low-voltage protection is provided by this device. The wiring is so arranged that the protective panel remains inoperative until the drum is again returned to the off position. This insures starting the motor with all resistance in series with the armature. Panels can be provided to furnish protection of this type for any number of motors up to 7. Overload protection is provided by relays with oil dashpots giving inverse time limit action. All overload relays are gravity-reset, making it necessary only to return all master switches and drum controllers to the off position and to press the start button to start again after an overload has tripped open the line contactors.

For the larger sizes of wound rotor motors ranging up to 500 hp 220 volts, 1000 hp 440–6600 volts, control panels are frequently employed, one panel containing the oil circuit breaker for use in the primary circuit and the other panel containing the drum controller for use in the secondary circuit of the motor. The motor is started by closing the primary oil circuit breaker with all the resistance in the secondary circuit. The secondary drum is then gradually rotated to its successive contact positions, each movement of the drum short-circuiting a portion of the resistor and thus allowing the motor to accelerate. The drum is finally moved either to the run position or to some speed position depending upon whether the duty is for starting or for speed regulation. The motor is stopped by returning the drum to the off position, by tripping of the primary breaker or by use of a stop push button in series with the undervoltage trip of the primary breaker. In all cases the drum must be returned to the off position before the motor can be started.

17. CONTROL RHEOSTATS

On a-c or d-c systems, where rotating machines are used, it is possible, in most cases, to vary the voltage, speed, power factor, or other characteristics of the machine by adjusting the field excitation. This can be done either by hand control of the field rheostat or by automatic control of the main field or exciter field by means of a faceplate regulator or by a carbon-pile or vibrating type of voltage regulator.

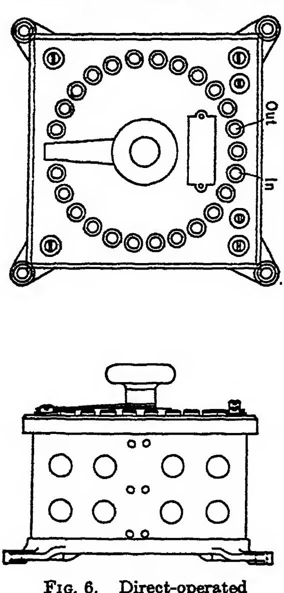

FIG. 6. Direct-operated Field Rheostat

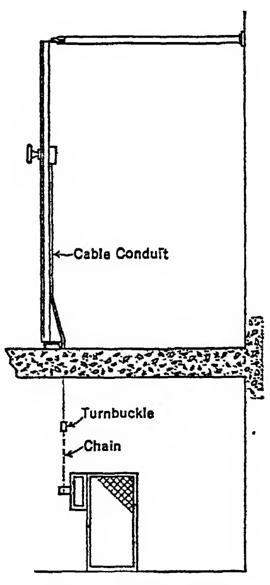
FIELD RHEOSTATS. When adjusting the current in the shunt field or separately excited fields of a-c and d-c generators and motors, it is customary to use field rheostats made up of faceplates and resistors of suitable design. The faceplate comprises a series of contacts arranged in a circle mounted on a slate or marble base and provided with movable contact arms. With small units direct operation of the rheostat by means of a hand wheel and shaft is frequently possible as indicated in Fig. 6. In moderate-capacity plants, sprocket chain and wire rope transmission is customarily employed connecting together the hand wheel of the switchboard and the faceplate near the resistors, as indicated in Fig. 7. In very large stations where electrical operation is applied to the oil circuit breakers, the field rheostat faceplates are usually made motor operated. The faceplate and resistors of field rheostats are usually assembled on an angle- or strap-iron frame protected by grillework. Remote-control rheostats are used to permit mounting the faceplate adjacent to its grid resistors and for reducing the length of cable connections from fields to rheostats and exciters, particularly in large machines. By having these resistors properly located, the heat from them can be readily carried away without discomfort to the operator.

The number of steps for a field rheostat depends on the closeness with which adjustments of field currents are to be made and on the range desired. They usually have 30 to 70 divisions of resistance, but double this number may be obtained in the case of two or more plates by staggering the levers.

To select the proper rheostat it is necessary to know the resistance of the field, the minimum field current required, and the voltage of the circuit. For ordinary conditions, a rheostat resistance equal to the resistance of the generator field is satisfactory. Machines which are regulated by automatic voltage regulators frequently require a rheostat resistance of two to four times that of the generator field. The resistance per step is also tapered so that at the " all resistance in " end of the rheostat the resistance per step is higher than the value at the " resistance out " end. A logical choice of resistances per step would cause each step to make a fixed percentage change in the field current.

The current-carrying capacity of the steps of the rheostat is tapered so that the capacity at the high-capacity end is two to three times that when the resistance is all inserted. For small values of current the resistance element is usually imbedded in a vitreous enamel compound which attaches it to the plate of the rheostat. Only the contacts extend through the enamel, which acts as a mechanical support for the resistance element. For currents above 60 amp, grid or some other high-capacity type of resistor can be furnished connected electrically to a faceplate, the faceplate in turn being operated by a sprocket mechanism.



Rheostat on Floor below Switchboard

Fig. 7. Sprocket-operated Field Rheostat

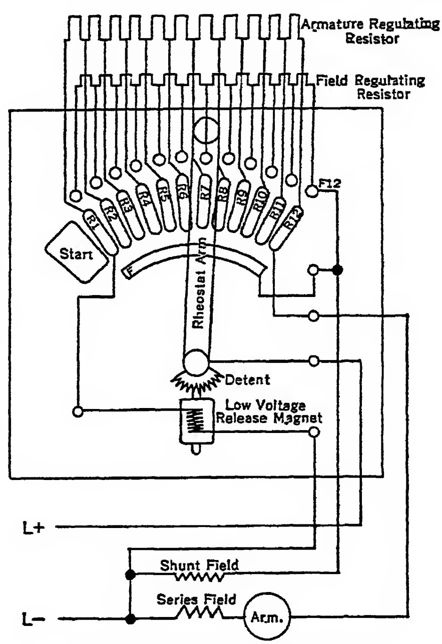


Fig. 8. Starting and Speed-control Rheostats

With those rheostats which contain distinct resistance elements per unit, the terminals of the elements are brought out to the metal contacts usually arranged in a circle on an insulating fireproof plate. The contact of the switch arms for currents up to 25 amp per contact arm consists of an ordinary straight finger contact brush; for currents up to 350 amp solid sliding plungers with evenly faced surfaces held by springs against the contact segments are used in the switch arms. For higher currents the laminated brush has been found more satisfactory.

SPEED-REGULATING RHEOSTATS. Starting and speed-regulating rheostats are available for wound rotor induction motors to be used in the secondary circuits with line starters employed as primary switches. These rheostats are used where it is desirable to operate the motor at less than full speed by having resistance connected into the secondary

wiring. Resistors, capable of carrying the load current continuously, are provided, usually giving about 29 points of speed control.

Speed-regulating rheostats with or without combination starting rheostats can be furnished for regulating the speed of shunt- or compound-wound d-c motors in nonreversing service, where a 50 per cent speed reduction through armature control or field control is desirable. Where the starting and field control are combined in a single device like Fig. 8, the rheostat has two arms, one of which cuts out the armature starting resistors and the other cuts in the field resistors. When the arm reaches the position where all the starting resistors are cut out, the armature contact arm is held in place by a magnet which leaves the field contact arm free to move, regulating the speed of the motor.

The field contactor is so interlocked with the armature contact arm that the field resistance can be cut in for speed regulation only when the armature contact arm is in the run position. It must always be returned with the armature arm to the off position. This prevents the motor from starting without full field strength on it.

MOTOR-OPERATED RHEOSTATS. These are usually provided with limit switches that will be thrown over by the movement of the rheostat arm when it reaches either extremity of its travel. This limit switch shuts power off from the motor when the connections of the motor are such as to tend to move the rheostat arm beyond the limiting point. They allow connections to be so made that the motor can move the arm back, away from the limiting point. When the rheostat is first placed in service the connections should be carefully checked up to see that the limit switches function properly to permit the desired connection to the motor.

18. GENERATOR VOLTAGE REGULATORS

The earliest a-c plants with poorly regulating generators were able to maintain proper voltage only by depending on the switchboard operator continually to adjust the voltage by means of the rheostat. To reduce the amount of adjusting, generators were made with very good inherent regulation, but they were expensive to build and their windings were difficult to brace against the effects of their heavy short-circuit currents, so the trend of generator design returned to generators of high reactance and poor inherent regulation as soon as a satisfactory regulator had been developed for maintaining the a-c voltage at its proper value under conditions of varying load.

To maintain proper voltage on a-c generators, regulators are available that adjust the field current either of the generator itself or of its exciter. In order to maintain practically constant voltage on the a-c and d-c generators, or to have these machines compound automatically to take care of feeder drop, field regulators of various kinds have been designed.

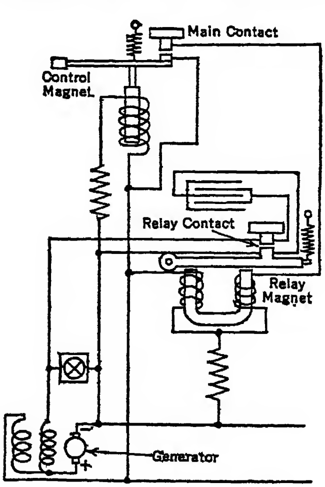

FIG. 9. D-c Controlled D-c Regulator

Two types of voltage regulators have been developed to meet various problems of adequate voltage regulation satisfactorily. One is the well-known vibrating type of voltage regulator, and the other the rheostatic type of voltage regulator. Another development is the carbon-pile regulator.

VIBRATING REGULATORS. These are made in two principal forms, one using a d-c vibrating magnet and the other an a-c vibrating magnet relay as the anti-hunting control device. Either design of vibrating regulator depends on the rapid opening and closing of a circuit that shunts the field rheostats and thus changes the resistance in the field circuit of the generator to be regulated. For d-c service the regulator usually works upon the main generator field and for a-c service upon the field of the exciter. In both cases the rheostat is so adjusted that when in circuit it tends to lower the voltage considerably below normal, and when the rheostat is short-circuited the generator voltage rises. The regulator automatically closes the shunt circuit when the voltage drops to a predetermined value and opens it when the voltage rises above that value.

The regulator with the d-c vibrating magnet for the control of a d-c generator consists essentially of a main control magnet (Fig. 9) whose winding is connected across the gen-

erator terminals, and a differentially wound relay magnet. When the effect of the potential winding increases because of a rise in generator voltage, the contact of the main control magnet is opened and in turn one winding of the relay magnet is de-energized. Thus the relay contact is opened and the short circuit removed from the generator rheostat.

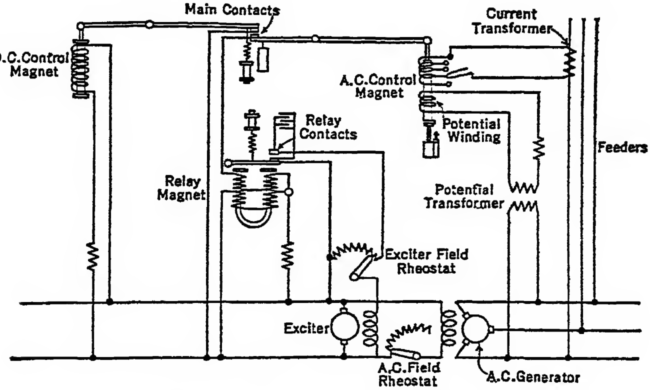

FIG. 10 D-c Controlled A-c Regulator

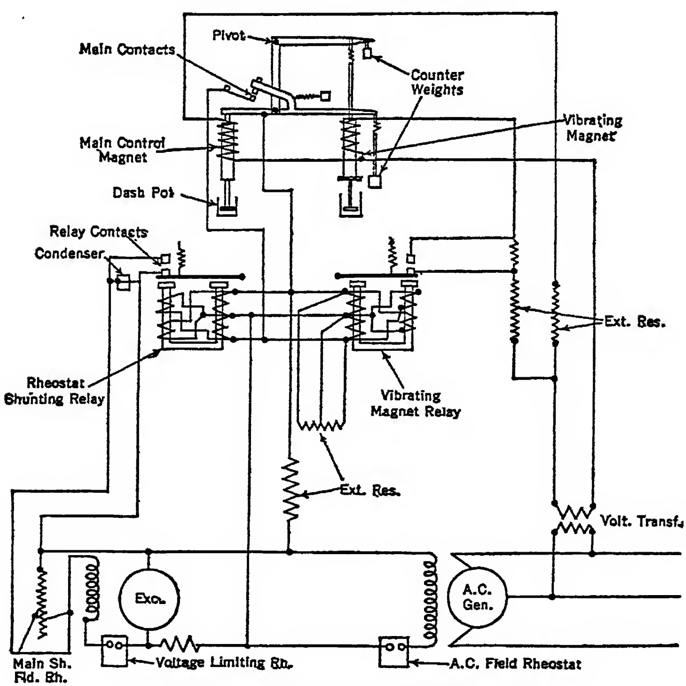

FIG. 11. Regulator with A-c Vibrating Relay Control

When the voltage drops, the main contact is closed and the differentially wound relay magnet acts to short-circuit the field rheostat. The relay contacts are shunted by a condenser to reduce sparking.

The regulator with the d-c vibrating magnet for the control of a-c generators works on the exciter field as shown in Fig. 10. The main contacts with this type of regulator are

acted on by two sets of control magnets, one connected across the exciter bus and tending to move the main contacts farther apart as the exciter voltage rises and the other acted on by a-c potential coils and current coils. When the main contact closes it energizes the relay magnet, thus closing the relay contact, short-circuiting the exciter rheostat, and raising the voltage of exciter and generator.

The use of the exciter voltage as one of the main control elements prevents the generator voltage overshooting, for, as the exciter voltage rises to bring up the generator a-c voltage, the d-c control tends to pull the main contacts apart and so reduce the voltage again. The compensating current winding of the a-c solenoid is provided with a dial switch to give any desired amount of compensation for the line drop in the feeder circuit in which the current transformer for the current coil is located.

The regulator with the a-c vibrating magnet connected like Fig. 11 momentarily short-circuits and reintroduces a portion of the resistance in the exciter circuit, and the average voltage delivered by the exciter will depend on the relative portion of the time that this part of the field resistance is in circuit. The main control magnet has its core attracted upwards and its core stem connected to a floating lever which is pivoted to the bell crank of the vibrating magnet. The two magnets are energized from the same voltage transformer that actuates the main contacts.

CARBON-PILE REGULATORS. A coil, core stem, lever system, carbon disks, and inverted air dashpot constitute a carbon-pile regulator. The coil has a current winding for parallel operation with another regulator, or line drop compensator, and a voltage winding. Pressure on the disks is supplied by a main spring, and is released by the pull of the core on the lever system. By varying the pressure on the carbon piles the resistance is adjustable through rather wide limits, and by automatically controlling the pressure the voltage is automatically controlled. The carbon-pile regulator connected like Fig. 12 is applied exactly as a field rheostat. On any generator the field current increases with the load or voltage according to the saturation curve of the generator. The total field resistance must decrease as the field current increases. If the range of resistance and current required between no load and full load does not exceed certain values, a carbon-pile regulator can be employed to advantage and is usually cheaper and almost as fast in response as the vibrating type.

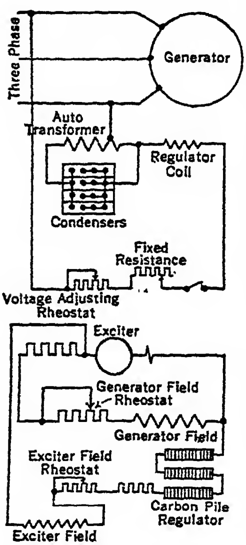

FIG. 12. Carbon Pile Regulator

RHEOSTATIC REGULATOR. The faceplate type regulator differs from the vibrating type in that there is a gradual cutting in or cutting out of field resistance, instead of the short-circuiting of a portion of resistance, for a greater or shorter length of time. The exciter rheostatic type provides a motor-operated rheostat in the exciter field circuit.

ELECTRONIC REGULATORS. Regulators utilizing the new electronic tubes of various designs are available for numerous applications where the energy available to operate the regulating equipment is of such low magnitude that the application of the conventional electromechanical regulators cannot be considered. Most electromagnetic regulators require approximately 100 volt-amperes for operation whereas electronic regulators can be designed to operate from considerably less than 1 microwatt. Owing to this reduction in control energy requirement brought about by the electronic tube the entire art of regulator design has been modified to obtain extremely high sensitivity and a quick response characteristic. The cost of the tubes and their upkeep militate somewhat against the use of the electronic regulator, and the application of this type of regulator can be considered as a special one.

D-c Machine Voltage Regulators of the electronic type have been used in applications where high sensitivity and quick response action are of importance. In most industrial applications of d-c voltage regulators a sensitivity of 1 per cent is entirely satisfactory, and this can be obtained with standard electromechanical voltage regulators at lower cost than the electronic type which can be used to obtain a sensitivity of 0.1 per cent.

A-c Machine Voltage Regulators of the electronic type of various designs have been available for several years and have given very satisfactory results. With electronic regulators a sensitivity of 0.1 per cent has been obtained for testing lamps and in other applications where a very close margin of voltage must be obtained. For ordinary industrial service such a high sensitivity is not needed, and electromechanical regulators are

used; also a simplified electronic type with one control tube and two power tubes has been developed.

QUICK RESPONSE EXCITATION is usually provided by a combination of faceplate and vibrating-type regulators utilized with exciters of proper characteristics. When a sudden demand is made on the excitation circuit a single relay or group of relays will short-circuit a portion of the exciter field resistance and the faceplate regulator will follow it up until the arm of the faceplate regulator is in such a position that the excitor is delivering the voltage required for the new conditions.

To obtain this quick response regulation various devices are utilized by different manufacturers. Among the most successful is a " pilot exciter " to excite the main exciter, often eliminating the main generator field rheostat. This " pilot exciter " is specially designed for very quick response and will momentarily impose on the field of the main exciter a very high voltage, enabling " field forcing " either up or down to be obtained. Another scheme is to split the exciter field into parallel paths with a permanent resistance in series with them. By this means an exciter response is obtained in 3 cycles on a 60-cycle circuit. For example, the normal voltage of the " pilot exciter " may be 250 with a maximum " ceiling voltage of 350," and each of the split fields of the main exciter might normally require only 60–80 volts except for the external resistance. Putting 250–350 volts on these fields momentarily will build up the exciter voltage very rapidly. The control of the regulator of the " pilot exciter " may involve a " torque motor element," " phase sequence network," or other device of similar nature. The use of a rectifier to place a high voltage on the exciter fields momentarily is another means of getting quick action.

APPLICATION OF VOLTAGE REGULATORS depends on several factors, entirely independent of the size and design of the regulator itself. It is not only necessary that the regulator be properly designed, but it is also essential that the exciters, generators, and prime movers possess characteristics that will harmonize with each other and will assist in keeping the voltage at the desired value under rapidly changing load conditions. Regulators are also used to maintain proper frequency, to control loads, to permit automatic synchronizing, etc. By using two current transformers, " cross-current compensation " can be obtained and speed or other characteristics controlled for industrial service.

RANGE. The standard a-c generator voltage regulators are adapted for voltage regulation of a-c generators requiring a nominal excitation range of either 45–135 volts or 60–150 volts, that is, a voltage range of 1 to 3 or 1 to 2 1/2.

With the broad range system of regulation, full automatic voltage regulation can be obtained for all ranges of excitation within the limits of the exciter. The standard regulator can be made broad range by energizing the relays from a separate source of direct current, such as a small motor-generator or a storage battery. The broad range system of regulation is directly applicable to synchronous condensers for maintaining voltage at the receiving end of a transmission line by adjusting the wattless load of the synchronous condenser either lagging or leading as required.

A standard vibrating regulator cannot be used if the minimum field voltage required is near or below the residual of the exciter. This is often the case where synchronous condensers are used for line regulation owing to the wide operating range required and the fact that synchronous condensers are usually designed for low field voltage with zero power factor lagging in order to keep the size, and consequently the cost, of the machine as low as possible. The extended broad range type which has been designed for such applications is a combination of a vibrating regulator and a rheostatic regulator. Within the stable limits of the exciter, the vibrating part of the regulator will function in the ordinary manner. When it is necessary to reduce the voltage across the generator field to a value that is below the residual point of the exciters, the rheostat part of the regulator comes into play and inserts some resistance in the field of the generator, necessitating an increased exciter voltage.

19. INDUCTION VOLTAGE REGULATORS

On a-c circuits containing no generating equipment or other rotating apparatus, voltage regulation is usually obtained by means of induction regulators, changing taps on transformers, or some combination of these two schemes. Where two systems, or two portions of the same system, are tied together for power interchange, voltage regulation at the tie point is usually necessary to regulate the interchange of wattless kva at such a point, and many interesting arrangements have been made for carrying out this voltage regulation.

The first type of regulator was a transformer with many taps and provision for

connecting the feeder to any tap. This could be done by switches of various kinds, and the natural development was to arrange the contacts in the form of a ring on a suitable face-plate and to provide a movable arm for connecting the feeders with any of the taps.

Induction regulators are made for single- or three-phase service and arranged for hand operation and motor operation, for motor operation controlled from a distant point, or for complete automatic operation by means of relays.

SINGLE-PHASE REGULATOR. Fig. 13 is in effect a two-winding transformer with the secondary winding arranged for connection in series and the primary winding arranged for connection directly across the line. With the transformer thus connected, a voltage will be induced in the secondary that will add to or subtract from the feeder voltage, according to the connections used. The current in the primary produces a magnetic field that induces a voltage in the secondary. The portion of this field passing through the secondary winding, and consequently the voltage induced in that winding, depend upon the angular position of the secondary with respect to the direction of the primary field. The induced voltage is a maximum when the axis of the coils coincide, zero when the coils are at right angles to each other, and maximum in the opposite direction when the axis of the coils coincide but with primary coils reversed in position. This induced voltage in the secondary therefore adds to or subtracts from the feeder voltage by a value varying from maximum regulation to zero according to the position of the coils.

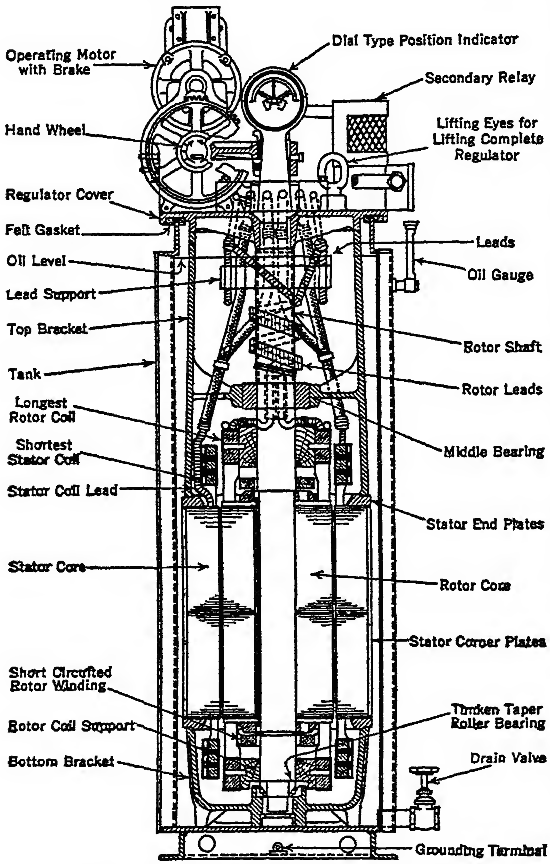

FIG. 13. Single-phase Induction Regulator, Self-cooled

The single-phase regulator adds or subtracts its voltage directly and not vectorially relative to the voltage from the main circuit so that the use of a single-phase regulator does not cause any phase displacement by its use.

POLYPHASE REGULATOR. Fig. 14 resembles somewhat a vertical shaft, phase wound, polyphase motor, immersed in oil in a suitable tank. The regulator primary is wound with a distributed winding of the same number of phases as there are phases in the feeder to be regulated, and each phase of the regulator is connected across a separate phase of the feeder. The secondary winding is made up of the same number of separate windings as the primary, and each of these separate windings is connected in series with one of the feeder wires. The primary sets up a magnetic flux of constant value which induces a constant voltage in each of the secondary windings. The induced voltage of the secondary is combined vectorially with that of the feeder. As the position of the rotor is changed, the phase angle between the feeder voltage and the secondary voltage changes, the feeder voltage is either increased or decreased.

Induction regulators can be arranged either for indoor or outdoor service and can be

self-cooled, air-blast cooled, or water-cooled, depending upon their size and local condition.

CONSTANT-CURRENT REGULATORS are a special type of transformer with movable coils that change a constant potential source of supply into a constant-current feeder. These are used chiefly for series lamp circuits, but they have other purposes.

AUTOMATIC OPERATION. If desired for either single or three-phase regulation, automatic operation can be obtained by the action of a voltage relay either with or without a compensating device. This relay acts in conjunction with the motor on the regulator so that, as the load comes on, or the bus voltage drops, the motor will turn the regulator in such a direction as to increase the voltage. By means of a compensator, which can be set for certain ohmic and certain inductive drops, the voltage at the point of distribution can be maintained constant, independent of the amount or power factor of the load, if the total drop is within the range of the regulator.

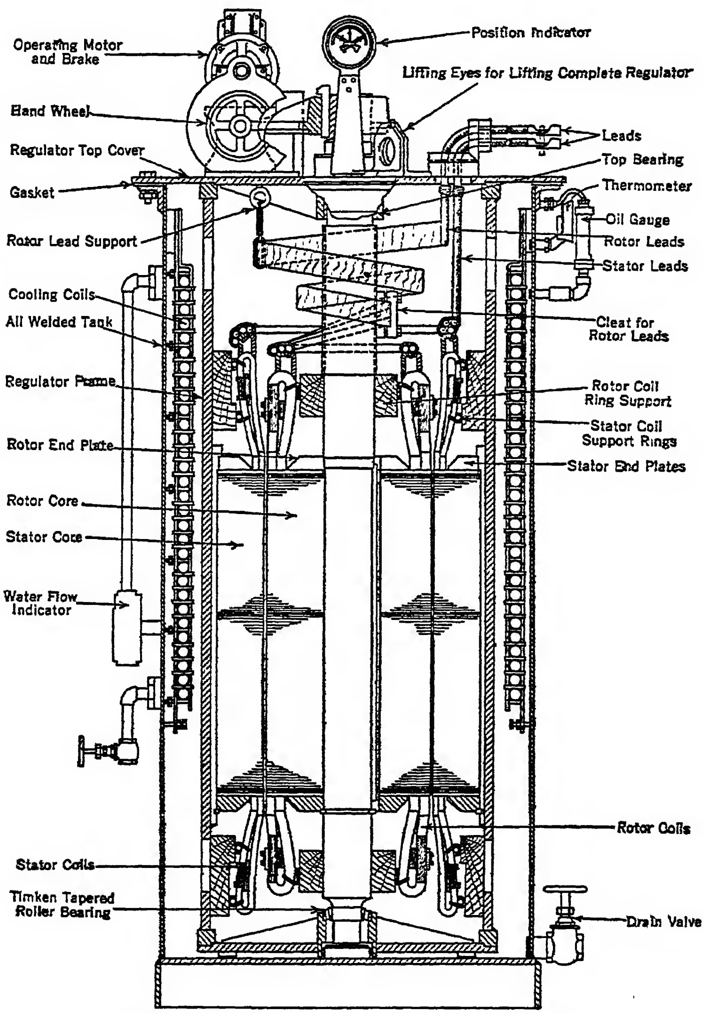

FIG. 14. Polyphase Induction Regulator, Water-cooled

FEEDER VOLTAGE REGULATORS of the electronic type utilize a reactor or impedance in the form of a two-winding transformer. The primary of this transformer is connected in series with the circuit to be controlled while the secondary is connected across the anode and cathode of the tube. The tube varies the effective impedance of the reactor. The action involves the reflection of varying impedance from the tube back into the primary. The tube can be considered as a switch to short-circuit the secondary, the time of remaining closed being varied.

STEP-INDUCTION REGULATOR. For very large capacities, a combination of taps on a step-down transformer or an auto-transformer with an induction regulator is sometimes used and is called a step-induction regulator. By designing the transformer with a voltage between the taps not greater than that of the induction regulator, it is possible to get a smooth voltage variation over the entire range of voltage covered by taps from the highest to the lowest.

Regulating the voltage of high-voltage transmission lines is now possible by means of taps in the step-up or step-down transformers through which the ratio is changed without disconnecting the transformers from service or interrupting the load. Various schemes of tap changing are available, and their details are considered in connection with the part of this handbook dealing with transformers.

PROTECTION

The fundamental problem in all protective schemes is to differentiate accurately between normal and abnormal conditions and to distinguish positively, under abnormal conditions, between faulty apparatus and line and the remainder of the system. Then the faulty apparatus or line must be disconnected from the remainder of the system with the least possible disturbance. In general, the function of the circuit breaker, acted on by a trip-coil or protective relay, is to disconnect the faulty apparatus or line from the remainder of the system before trouble can spread, and this separation should be made with the least possible interruption to service.

20. D-C CIRCUIT PROTECTION

For the automatic protection of d-c circuits, air circuit breakers or fuses are usually employed. For the protection of two-wire generators, single-pole circuit breakers are used on large panels; either fuses or breakers are used on smaller panels. For the protection of three-wire generators, circuit breakers with equalizer contacts are used on the large boards and four-pole circuit breakers on the smaller switchboards, as it is necessary to open up the positive equalizer and negative equalizer circuits as well as the main positive and main negative circuits under most conditions.

GENERATOR PROTECTION. In considering the type of protection for generators the following abnormal conditions should be taken into account: sustained overload, excessive temperature, and internal faults. In the usual attended station it is not present-day practice to provide automatic protection against sustained overloads and excessive temperature but to allow the operator, warned by instrument readings and alarms, to take the necessary steps to correct these conditions. In non-attended stations, relays perform the necessary duties.

FEEDER PROTECTION. For the protection of lighting feeder circuits up to 600-amp capacity, enclosed fuses were formerly used but are rapidly being replaced by small air or De-ion breakers. For feeders of capacities greater than 600 amp, circuit breakers are used.

Single bus railway panels provide overcurrent protection in one side of the circuit only, namely, in the positive side, opposite the series field. This protection is sufficient for synchronous converters having overcurrent protection on the a-c side and for motor-driven generators having overcurrent protection on the motor circuit.

Two-wire lighting and power panels provide automatic overcurrent protection in only one side of the circuit, namely, in the positive side opposite the series field. Three-wire lighting and power panels provide complete automatic protection in positive and negative circuits.

21. A-C CIRCUIT PROTECTION

In modern a-c generating stations, it is not considered good practice to provide overload protection for generators as the windings of such machines are so thoroughly braced that they will withstand momentarily a short circuit with full voltage maintained on the field. The objection to the use of overload protection in the generator circuit is that such devices might cause the machine to be disconnected from the bus-bars and to shut down the plant without any real necessity. The heating of the generator windings has to be watched carefully by means of good temperature indicators.

Generator failures usually occur in the armature circuit. The usual protection for armature faults is the use of differentially connected overcurrent relays or biased current differential relays. Essentially the scheme is to balance the current entering the apparatus against the current coming out. Any leakage of current to another phase or the ground, if of sufficient magnitude, will upset the balance and send the current through relays which, when actuated, trip the circuit breakers and other devices and disconnect the faulty apparatus by tripping the generator main breakers, the generator neutral breaker, and the generator field switch.

FIELD AND EXCITER CIRCUITS. It is standard practice not to supply automatic protection in exciter or field circuits. The sudden opening of the field circuit of an a-c generator caused by the operation of a fuse or breaker in the field or exciter circuit might cause far greater damage, by puncturing the insulation of the a-c generator, than would result from the overloading or even short-circuiting of an exciter.

FEEDER PROTECTION. Automatic overload protection for the feeder circuits of a-c systems may be provided by means of either fuses or circuit breakers depending on the capacity, voltage, and application of the system. Instantaneous trip breakers, within their breaker capacity ratings, are satisfactory for feeders supplying a lighting load or a steady power load. Breakers in circuits subject to high fluctuating overload should be equipped with inverse time limit devices so that breakers will not trip out on load fluctuations of normal character.

TRANSFORMER PROTECTION. Transformers can be protected by straight overcurrent relays, but it has become general practice to provide differential current balance protection by using current transformers in the high-tension and low-tension main transformer windings. It is sometimes difficult to obtain correct ratios for current balance with standard current transformers, but relays with suitable taps are available to take care of this condition.

SYNCHRONOUS CONVERTER PROTECTION. Protection for the a-c side of a synchronous converter is provided on the high-tension side of the step-down transformer by an instantaneous overload oil circuit breaker tripped from current transformers. The breaker is also equipped with low-voltage release and auxiliary switch. A low-voltage trip, instantaneous overload carbon circuit breaker is provided for the d-c side. The speed limit switch furnished with and mounted on the converter opens upon overspeed and causes both a-c and d-c breakers to trip simultaneously. Reverse current relays are also provided on the d-c panel arranged to open the a-c breaker upon reversal of d-c power which in turn opens the d-c breaker.

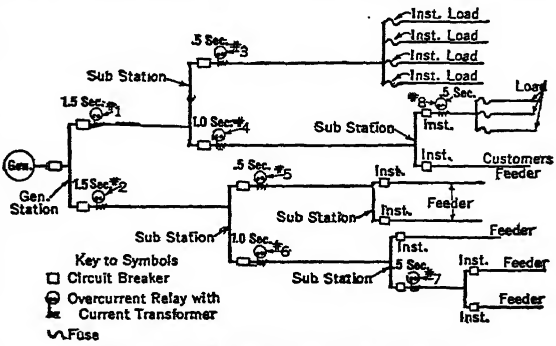

Fig. 1. Typical Radial Transmission System

RADIAL DISTRIBUTION. The simplest system of distribution is where there is a single source of power, with a number of feeders leaving the generator bus-bar, each feeder in turn being subdivided into a number of small feeders. This is termed the radial distribution system shown in Fig. 1. The protection of such a system against short circuit may be secured by overcurrent protective devices. The smaller branches may be disconnected automatically from the remainder of the system by the blowing of a fuse or the operation of instantaneous circuit breakers. The circuit breakers near the generator

should be equipped with definite time relays. A time interval between the successive relays long enough to assure a reasonable margin of safety above that required for a circuit breaker to operate is allowed. Relays at the generator bus are given the higher time settings. The setting of the other relays is decreased as the distance away from the generator increases till the most remote relay has an instantaneous setting.

RING OR LOOP SYSTEM. This system is shown in Fig. 2; it is simply a continuous transmission line running through a series of substations and finally terminating at its starting point. This forms one of the best ways of securing uninterrupted service with a minimum expense for feeders. The number of substations which may be thus tied together depends upon their geographical location and the relay protection desired. With the normal overcurrent and reverse power relays, the number of stations is limited, by reason of the fact that the required time interval necessary between successive relays adds up to an unsafe value. By the use of the impedance relays, this difficulty is largely removed.

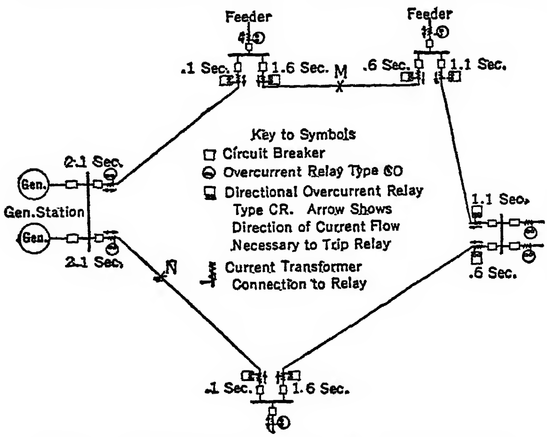

Fig. 2. Diagram of Ring or Loop System of Distribution

On a simple loop system having only one source of power, directional overcurrent relays with definite time limit characteristics may be used for protection against short circuit. The time setting of each successive relay must be increased by an amount sufficient (usually 0.5 sec in practice) to allow time for the circuit breaker in the preceding substation to open. The directional relays applied to each substation are fixed so that they will trip only when excess power is flowing away from the substation bus.

Network Systems both primary and secondary are dealt with in the section of this handbook dealing with Distribution. Suitable relays and switching devices are available for these networks.

Balanced Relays can take care of parallel circuits between a generating station and receiving stations as shown in Fig. 3. Under normal conditions, the current in each of the parallel feeders will be the same; and since the relays have a higher impedance than the current transformers, the current from the latter will circulate through all of them in series without any flowing through the relays.

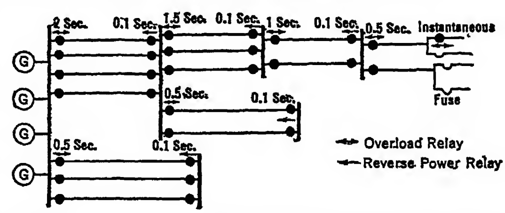

Fig. 3. System whereby Lines Run To and Through Several Sub-stations

Inasmuch as the action of the balanced current relay is practically instantaneous in clearing faulty lines, it makes an ideal application for protection for parallel lines between generating stations. On other parallel feeders, it is very often advisable to use overcurrent relays in connection with balanced current relays, thus securing single line protection in addition to the quick balance protection when both lines are in service.

SYMMETRICAL COMPONENTS. One of the recent developments in connection with a-c circuits is the use of "symmetrical components" (see Sect. 3, Art. 37), permitting the convenient analysis of unbalanced loads and single-phase short circuits in polyphase systems. For a three-phase system the components consist of positive, negative, and zero phase sequence sets of current and voltage vectors which may be combined to give the actual currents and voltages in each phase for any condition of unbalance, thus facilitating proper relay settings. The components themselves may often be of use, and can be measured with the aid of certain "networks." The positive phase sequence components

of current and voltage are a measure of the balanced load and become equal to the actual currents and voltages under balanced conditions. The negative phase sequence components are a measure of phase unbalance, and a relay responding to the negative sequence current may be used for protecting a machine against internal faults on unbalanced operation. The zero phase sequence components are a measure of ground unbalance. The zero sequence component of current is a measure of the ground or " residual " current and is often used to energize relays protecting against ground faults. The zero sequence voltage is likewise a measure of " residual " voltage, which is often used with the " residual " current for directional ground relay operation.

HIGH-SPEED RELAYS. The time delay introduced by the usual relay is advantageous only because of the reduced circuit-breaker duty resulting from the decrement in short-circuit current. The disturbance to the system produced by a short circuit will be considerably reduced if a faulted section or piece of equipment is instantaneously isolated from the remainder of the system; and where stability or inductive interference with neighboring circuits is a factor, high-speed fault clearing is of the greatest importance. As definite time delay may no longer be utilized to select the faulted section, relay systems operating upon other principles are required. High-speed overcurrent, directional overcurrent, balanced current, differential, and distance (impedance or reactance) relays have been developed which when used with high-speed circuit breakers are capable of isolating a faulted section in one-fourth of a second or even less. A set-up of the system on an a-c calculating table enables the proper selection of relays, current transformers, etc., to be selected to obtain the best scheme of relaying.

22. LIGHTNING PROTECTION

All electrical systems are subjected to transient or short-duration overvoltages in some degree. These overvoltages arise from various causes, and their intensity varies over a wide range. Since the major cause of the ultimate failure of electrical apparatus is insulation failure and since any overvoltage hastens this failure, a benefit will always be derived from the use of static protective equipment. The decision in any specific case as to whether or not such equipment shall be used, and as to the type to be selected, is dependent on the relation between the cost of the equipment, initial and maintenance, and the savings by the use of equipment, both in apparatus and service.

The factors which control the application of static protective equipment are so varied and some of them so uncertain quantitatively that there are no exact rules to follow. Each case is an individual problem which must be solved individually by experience on the actual system, or on similar systems, similarly located, taking into account not only the prevalence of trouble but also the specific conditions such as value of apparatus, expense of repairs, expense of service maintenance, and results of failure of service.

GROUND WIRES. A very effective protection for an overhead, high-voltage transmission line can usually be obtained by the use of an overhead ground wire. This is a grounded wire which is run above and parallel to the main wires of an overhead line. This acts as a partial screen and is one of the oest means for protecting such a line from lightning disturbances. The protection is not perfect, however, since the wire forms only a partial screen.

INSULATION COORDINATION has been adopted a great deal in recent years to get the proper breakdown values for the insulation of the transmission line, the circuit breakers, transformers, and other important pieces of apparatus in a step-up or step-down transforming station. Suitable insulation levels against breakdown under impulse voltages should be established. The insulation strength of the transformers is made the highest, followed by the transformer bushings to insure the arcing over of the bushings before any internal breakdown of transformer occurs. The insulation strength of oil circuit breakers is made a little lower than that of the transformers, and the oil circuit breaker bushings will arc over before puncture or circuit-breaker failure. The insulation of the transmission line is made a little weaker than that of the oil breakers so that in case of a lightning stroke near the station there will be an arc-over of the line insulators before there is trouble elsewhere.

LIGHTNING ARRESTERS. At the step-up and step-down transforming stations where there are valuable banks of transformers to be protected, or where there is an extended distribution system to protect, it has been found well worth while to install lightning arresters to provide a shunt path to ground in case of overvoltages arising from any causes.

Arresters are of two main classes, those with resistance characteristics and those with valve or counter electromotive force characteristics. The resistance characteristic class

includes the various multigap types, the horn gap and resistance type, circuit-breaker type, and the magnetic blowout. In these, the current flowing after the gap is broken down is proportional to the applied voltage. The valve or counter electromotive force class includes the electrolytic, auto-valve and oxide film types. The latest developments of arresters are the " thyrite " resistance type and " porous block " valve designs.

The simplest resistance type of arrester comprises a spark gap so set that excess voltage will cause the gap to arc over, allowing the charge due to the voltage to pass to ground. There is combined with the gap some means of suppressing the power arc which follows and which tends to continue after the abnormal voltage has ceased. An ideal lightning arrester should take no current at the ordinary operating potential, but at any potential much higher than ordinary there should pass enough current to limit the abnormal potential to some safe value. When the abnormal potential ceases, the arrester should stop taking current from the line. The closer an arrester approaches this ideal the better the arrester.

Horn Arresters like Fig. 4 have been employed on high-voltage circuits to give a certain amount of protection at a relatively low price. One or more horn gaps are connected in series with a resistance to ground. When a surge has caused the horn gap to arc over, the resistance limits the power current that tends to follow. The magnetic effect of this limited current with the tendency of air heated by the arc to rise is usually sufficient to cause the arc to rise up the horns and blow itself out. The resistor in the ground circuit can be made in the form of resistance rods or in the form of a jet or column of water. The latter form of resistance is usually made of earthenware tubes containing a mixture of water and glycerin, and the resistance is selected to allow about 1 amp to flow at the time of a discharge.

Gap Arresters. For lower voltages, various designs have been employed that utilized the " non-arcing metal " discovered by A. J. Wurts. This metal, a type of brass, when arranged in the form of knurled cylinders with a small space separating them, would discharge the excess voltage without allowing the power current to follow, provided the amount of power available was small and certain other conditions were met.

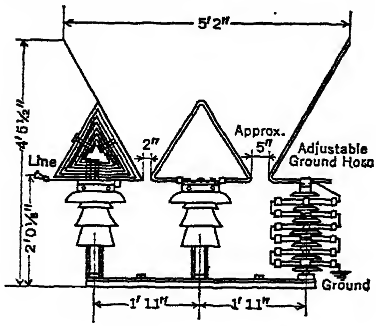

Fig. 4. Horn Type Arrester

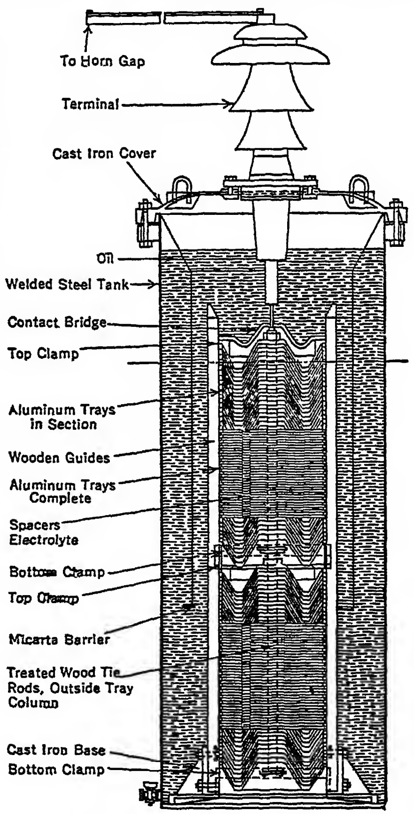

Fig. 5. Electrolytic Arrester

Electrolytic Arresters. These were the first " valve-type arresters " that were suitable for high voltages and large power systems. This type of arrester consisted of nested conical or cup-shaped aluminum trays like Fig. 5 filled with a liquid electrolyte and immersed in oil in a steel tank. The liquid electrolyte formed an insulating film on the trays, and this permitted only a very small current to flow at normal voltage. The film

broke down at high voltage, discharging the line, but the film sealed up quickly on the cessation of the abnormal voltage and shut off the power current. A horn gap was usually provided in series with this set of trays or aluminum cells. Periodic charging was needed to maintain the films in good condition. Although they were relatively expensive, they were used to a very large extent until the introduction of the "oxide film" and "autovalve" designs that gave about the same protective value at a lower cost, and without attendance.

Oxide Film Arresters, Fig. 6, depend for their functioning on the fact that certain dry chemical compounds, such as lead oxide, can be readily changed from a very good conductor (litharge) by the application of a slight degree of heat, such as would be caused by the passage of a lightning discharge, to a practical insulator (lead peroxide). The litharge was assembled in porcelain containers between metal covers with a film of insulating lacquer, and enough of these assemblies were placed in series to withstand the normal voltage. An overvoltage would puncture the lacquer film, and the power current that tended to follow the discharge would heat up a small part of the litharge (lead oxide), changing it to peroxide whose insulating properties sealed off the follow current. For the more moderate voltages on distribution circuits the lead oxide was made up into pellets the size of sugar pills, and these were assembled in a tube with metal caps making essentially a number of small pellets in series and parallel to form the arrester. This oxide film arrester was the standard of the General Electric Co. until it brought out its latest design.

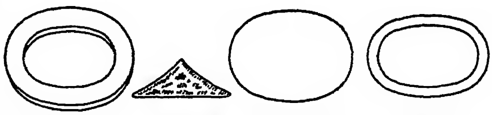

Fig. 6. Oxide-film Arrester Parts

Thyrite Arresters, brought out early in 1930, depend on the non-linear relation between voltage and current in the material, so that at heavy surge current the resistance of the arrester is low enough to limit high surge voltages to an appreciable degree. The Thyrite material is not really a valve-type arrester, so it is necessary to use a series gap which is housed in each 11.5-kv container. Because a single gap is unable to break an arc of the magnitude often met, a series of small gaps is used. At line voltage the resistance is high enough to limit the power current to values that can be interrupted at the zero of the cycle by the multiple gap. No discharge occurs up to a very definite breakdown voltage. After breakdown, the voltage across the gap is very low. The arrester utilizes blocks $^3/_4$ in. thick, 6 in. in diameter for each 1000 volts, employing 11 in series for 11.5 kv. A number of the 11.5-kv containers are assembled in series for higher voltages.

Autovalve Arresters were first brought out in 1922 by the Westinghouse Co. in the "mica disc" form, Fig. 7, utilizing the property of a glow discharge that occurs at a definite voltage of about 350 volts between disks that are very close together and are normally separated by a thin mica washer so proportioned that the discharge occurs at the inner edge of the disk. Later designs eliminated the mica washers. The composition of the disk is such as to furnish enough resistance to limit the power current that might tend to follow to such a low value that the discharge would not change from a "glow discharge" to an "arc discharge." For line arresters and general distribution circuits a series of these disks was used in a porcelain tube with an air gap in series with them. For station service to provide greater discharge capacity, four sets of disks in parallel were used, located in porcelain insulators, provision being made for connecting the groups in series.

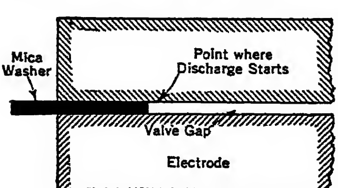

Fig. 7. Mica-spaced Autovalve Arrester Parts

Porous Block Arresters are the latest developments in the line of valve-type arresters (see Fig. 8). The autovalve element consists of one or more porous blocks in series, fabricated from a mixture of ceramic material and conducting particles into a uniform structure. The blocks contain a large number of pores through which the lightning discharge passes. A block 1 in. thick is rated at 3000 volts rms value, and the blocks are made of 4 $^1/_2$ or 2-in. diameter depending on the class of service for which they are intended. An enclosed multiple gap is used in series with the block. The principle of operation depends on the fact that the voltage necessary to maintain a discharge can be raised to a high value by confining the discharge to narrow passages within insulating walls, and in this arrester the discharge takes place through myriads of pores. The pore

equipment as compact as possible. These instruments are only 4 in. wide and 4 1/4 in. high and permit a very compact arrangement on a switchboard. These instruments have been made as small as is practicable while still retaining a long, easily read scale. All conventional indications may be supplied in this form of instrument such as voltage, current, watts, and frequency.

Instrument Transformers are used for two reasons: first, to protect station operators from contact with high-voltage circuits; and second, to permit the use of instruments with a reasonable amount of insulation and a reasonable current-carrying capacity (see also Section 5). The function of instrument transformers is to deliver to the instrument a current or voltage which shall be always proportional to the primary current or voltage and which shall not exceed a safe potential above ground. Generally the secondary of a voltage transformer is designed for about 115 volts and the secondary of the current

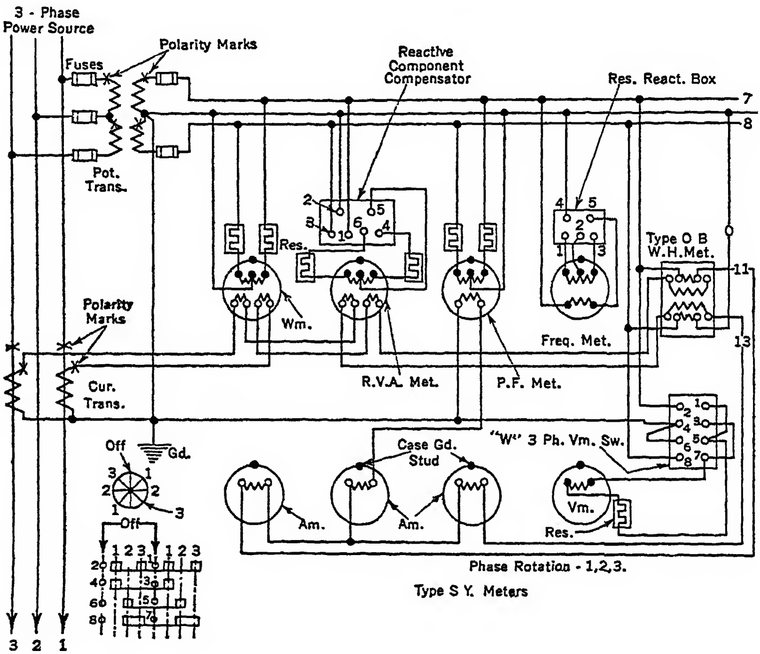

Fig. 1. Metering Equipment on Three-phase, Three-wire Circuit

transformer for 5 amp. Fig. 1 shows typical connections from instrument transformers to instruments of various kinds on a three-phase three-wire circuit.

Grounding. All instrument transformers should be grounded on the secondary side as an extra precaution against danger from the high voltage in case the insulation should be punctured by lightning or other abnormal stresses. In polyphase groups, any point of the secondary may be grounded, but it is preferable to use a neutral point or a common wire between two transformers.

25. MISCELLANEOUS METERS

BUSHING POTENTIAL DEVICES provide means of obtaining low voltages suitable for instrument use without the expense or hazard of the high-voltage potential transformer. The component parts of the device are mounted in a sheet-steel protective housing and are provided to connect to a tap near the grounded end on a special bushing of an oil breaker. The equipment within the housing consists of an enclosed spark gap, a low-voltage potential transformer, and a reactor and a condenser. The limitations on the burden of these devices depend on the primary voltage and are 66 kv 7 volt-amperes, 110 kv 15 volt-amperes, 132 kv 20 volt-amperes, 154 kv 27 volt-amperes, 187 kv 50 volt-

amperes, 220 kv 60 volt-amperes. These burdens are based on 60-cycle service and must be reduced proportionately for other frequencies. These condenser taps can also be used on porcelain or oil-filled bushings having condenser characteristics. Also a separate device may be provided having condensers in series to ground, lower ones being tapped for potential. The capacity of these devices are up to 120 volt-amperes at 287 kv 60 cycles.

Ground Detectors are not usually mounted on switchboards but are employed to indicate grounds on circuits that are normally ungrounded. On ungrounded two-wire d-c systems a voltmeter with a central zero may be employed connected between ground and the neutral point of a resistance across the d-c circuit. For low-voltage circuits lamps can be used as in Fig. 2. For a-c circuits of 2300 volts and above electrostatic ground detectors can be employed. These may be made as single-phase instruments or as three phase, connected to the circuits through condensers as shown in Fig. 3. Neon lamps can often be used as ground detectors connected directly to the lines or to condensers or to a string of suspension insulators as shown in Fig. 4. Ground detectors of the tube type coupled with suitable resistors can be used.

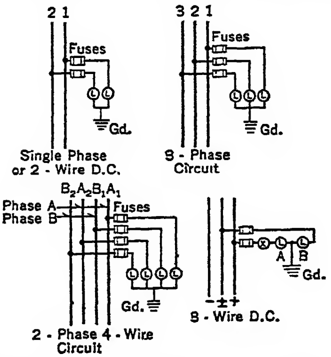

FIG. 2. Diagrams of Ground Detector Equipments - Using Lamps Only. For 125–250 volts use three 110-volt lamps; for 250–500-volts use three 220-volt lamps

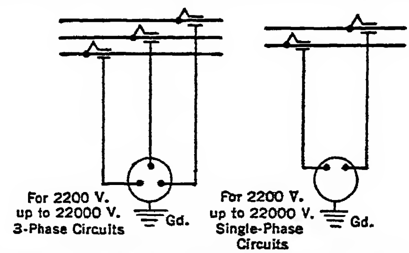

FIG. 3. Diagrams of Electrostatic Ground Detectors

26. PANELS AND DESKS

Type of current, voltage, and similar factors determine the class of switching device which should be used, and this, in turn, determines the class of switchboard to be installed. The desired operating conditions for an installation are factors in the selection of either mechanically or electrically controlled apparatus. The allowable space may determine the type of equipment.

The switching arrangement should not offer an unnecessary risk to the men who have to operate the switching apparatus, particularly under conditions arising from electrical failures of lines and apparatus. Simplicity should be the guiding spirit in the layout of the switching equipment. Satisfactory operating results cannot be obtained from poorly arranged layouts. Coincident with simplicity there should be a reasonable degree of flexibility which has for its object the providing of such a degree of continuity of service as may be commensurate with the class of load.

Direct-control Boards are those like Fig. 5 where all the apparatus is mounted, either directly or partly, upon the panels and the remainder on the panel-supporting framework. This switchboard for 2400 volt, three-phase service controls two a-c generators, with vibrating regulator voltage control, exciters, two power feeders, rectifier circuits for arc lights, and a-c synchronous motor-generator for supplying direct current.

Manual Remote-control Boards are those on which only the lighter pieces of apparatus are mounted. The main circuit breakers and their associated apparatus are supported on suitable framework at a reasonable distance from the panel board. The oil circuit breakers

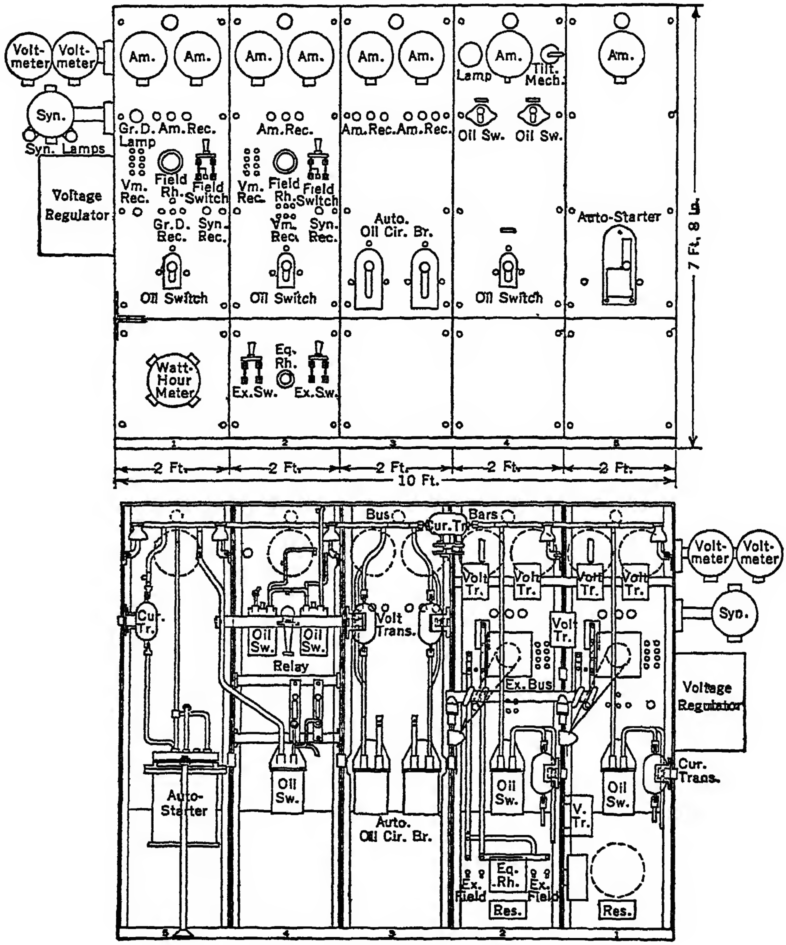

FIG. 5. Direct-control Switchboard

or other switching devices are operated by suitable operating rods and links attached to the handles on the front of the panels, like Fig. 6.

Electrical Remote-control Boards are those which use electrically operated circuit breakers and other electrically operated switching devices located apart from the panels and operated either by means of manual control switches or automatically through suitable relay equipments.

LIMITS. The direct-control switchboard is usually limited to a station capacity not exceeding 3000 kva, a maximum circuit capacity a-c 1200 amp, and a maximum voltage of 2500, although in special cases these limits may be exceeded. The manual remote-

control switchboards are usually limited to approximately 25,000 kva, the limitations really arising from the distance between the location of the switchboard panels and its correlated oil switching devices and from the physical effort required to operate switching devices through systems of bell cranks and connecting-rods. For systems of more than 25,000 kva capacity the short-circuit conditions usually require breakers of such a size that manual closing is apt to prove difficult. The electrical remote-control switchboards have practically no limitations and are used to control any amount of power up to the maximum concentration encountered in large power systems.

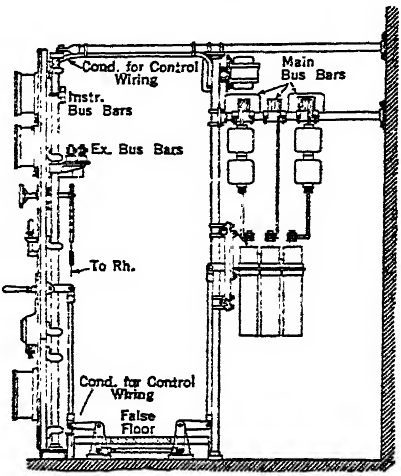

FIG. 6. Manual Remote-control Switchboard

ELECTRICALLY OPERATED SWITCHBOARDS. These boards usually take one of three general forms. Namely, the panel board, the combination control desk and elevated instrument board, or the combination pedestal and board. Various standard arrangements for electrically controlled equipment are shown in Fig. 7. *a* illustrates a typical vertical panel board with the instruments, control switches, relays, and similar devices mounted on the face of the panel. *b* shows the arrangement of a control desk with the control switches placed on the desk and the instruments mounted on the wall in front of the operator. *c* shows the control desk where there are only a comparatively few meters, these being set flush in the face of the desk. *d* shows the modification of the desk arrangement with the meters on a small slab or bracket extending up from the horizontal slab of the desk. *e* shows the control desk arrangement with vertical panels forming the back of the desk and the vertical panels containing indicating meters. *f* is a further modification of the control desk arrangement with vertical panels containing the indicating meters and a complete switchboard at the rear to contain the recording meters, relays, and similar devices. With this arrangement, a self-supporting control desk is provided. *g* shows the so-called gallery type of desk with the meters located on a framework supported from the horizontal slab of the desk at such a height that the operator standing at the control desk can look above the edge of the desk and below the meter panel to observe, from the switchboard gallery, the machine which he is controlling. *h* is a modification of the gallery type of control desk. *i* is a modified arrangement of control desk using a separate instrument frame supported on ornamental pillars, these pillars as a rule being arranged to form the support of a gallery railing. *j* shows the combination utilizing a gallery-type control desk for the generators and a vertical panel switchboard for the feeders. *k* shows a combination control desk and panel board, the generator breakers being controlled from the desk, the generator instruments being on the vertical panel, and all the

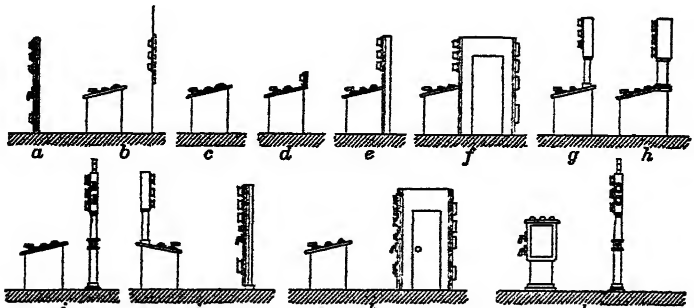

FIG. 7. Forms of Control Switchboards for Electrically Operated Switchgear

feeders being controlled by the vertical panels. The recording meters, graphic meters, and relays are placed on an auxiliary board back to back with the feeder board. *L* shows an arrangement of control pedestals and instrument posts. Where it is desired to have a very compact arrangement the control desk has many advantages.

PANEL GROUPING. Switchboard panels are normally grouped into a continuous board to facilitate more ready control by the station attendant and to also facilitate short connections between the wiring and bus-bars between the various panels.

For a long while, black finished slate was considered the standard material for most switchboards, and it still is used where knife switches, carbon breakers, or similar live equipment is employed. Where live parts can be mounted away from or back of the panel, the present tendency is to use steel wherever it can be employed to advantage. Where slate or marble panels are used, the standard switchboard frames are made up of angle iron, Fig. 8, or gas pipe construction, Fig. 9. For the smaller panels, the frame consists of vertical sections of gas pipes resting in floor flanges and supporting the necessary panel brackets to which the panel is bolted. Pipe frame is also used for many of the larger panels.

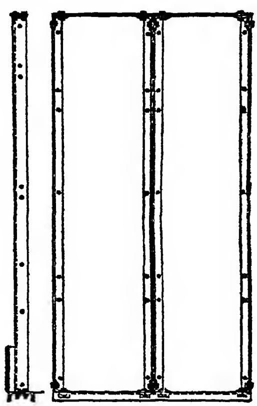

FIG. 8. Angle Frame

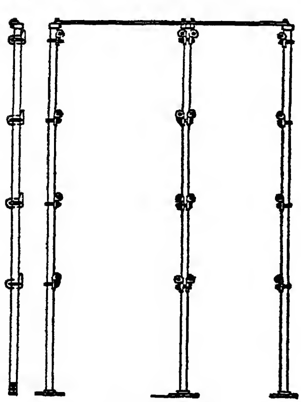

FIG. 9. Pipe Frame

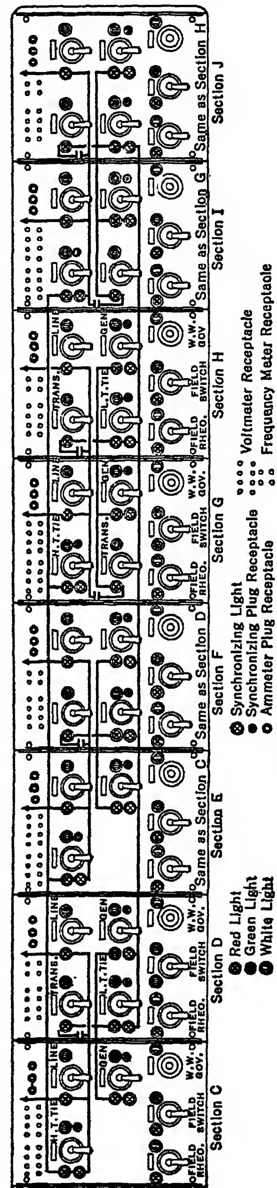

FIG. 10. Miniature Bus on Control Desk

One of the recent developments is to utilize steel panels up to 90 in. high made of stretcher level steel 1/8 in. thick with the sides bent 3 to 6 in. at right angles to the face and then 1 in. parallel to the face so that the plan view of the panel resembles a very narrow letter C. The material used is the same steel as is employed in metal furniture and presents a very fine appearance. Sufficient stiffness is obtained by the shape of the steel so that no auxiliary framing of any kind is required.

Adjacent panels are bolted together through the web of the steelwork in the same manner as angle iron framework on switchboards. The final bend in the steel panel is a 1-in. projection parallel to the face of the switchboard, and this projection is utilized for the purpose of attaching suitable steel brackets spanning the panels and used for the support of wiring and other details.

The same type of construction has been extended to cover the field of control desks, housing back of board breakers, miniature boards, etc. The advantages are fine appearance, permanence, safety, light weight, more complete factory assembly, and low cost.

Miniature Control Switchboards have been designed to meet the growing need for smaller and more compact centralized control boards on which the various control switches and instruments are concentrated in full view and under the control of one operator. A complete set of miniature switchboard devices has been developed to provide a much smaller switchboard capable of doing everything that is ordinarily performed with the conventional but larger switchboard. The miniature switchboard is particularly well adapted to control electric generating stations and their associated transmission systems and for operating distribution and switching substations. Owing to a substantial saving in space, better supervision because of smaller size, and lower installation cost, the miniature switchboard is finding increased favor. Remote control over extended distances up to approximately 6000 ft is economically possible, by using telephone cable with interposing relays and auxiliary transformers for the instruments, these transformers being about the size of bell-ringing transformers. The simplest form of miniature switchboard makes use of the modern stretcher-leveled steel panels, but more elaborate arrangements such as desks may be used.

Miniature Bus is extremely desirable for the proper and efficient operation of electrically operated panel boards or control desks of any size. It furnishes the operator a bird's-eye view, as it were, of the station wiring, since the miniature bus is a skeleton or single-wire diagram of all main circuits of the station with devices for indicating the relative location of all circuit breakers, disconnecting switches, power transformers, and feeder circuits. Miniature bus, Fig. 10, showing the top of a linear control desk is usually made of polished copper strap run along the top of the desk or, in a vertical board, on the face of the panel. Frequently, when a station used for power transmission supplies various voltages, different colors are adopted for the low-voltage and high-voltage miniature buses so as to distinguish them more readily.

27. D-C SWITCHBOARDS

D-c switchboards cover a wide field and include in their range every application of direct current. The larger boards are used for d-c railway systems and the lighting or power systems of large industrial plants, hotels, central stations, etc. The smaller generator and feeder panels like Fig. 11 are intended primarily for light and power systems of small industrial plants, small hotels, and central stations of small capacity; the battery charging panels are designed for controlling the charging of storage batteries used in lighting service and hence on electric vehicles.

Battery Charging in garages, small plants, etc., usually employs a switchboard consisting of a generator, or an incoming line, section; meter equipment; and one or more charging sections where the direct current is to be used for battery charging.

Small D-c Panels. The next larger size d-c panels utilize slabs 48 in. high and pipe framework, and these switchboards are particularly adapted to welding service and to the control of one to three generators in small industrial plants or central stations operating d-c two-wire systems of 250 volts or less. The capacity of a single generator panel is limited to 600 amp, and that of a complete switchboard composed of these panels to 1500 amp, with the number of panels limited to 6. For greater capacities, 90-in. switchboard panels are recommended.

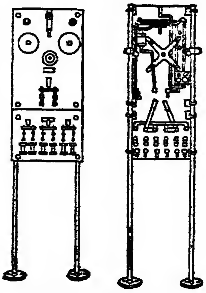

Fig. 11. Small D-c Switchboard

Mining Switchboards suitable for substation service in mining installations controlling motor-generator sets are usually arranged with very simple connections.

Large D-c Panels. For the control of d-c generators, the d-c end of synchronous converters and d-c feeders for 250 volts, two-and three-wire light and power service, and 600-volt railway service, panels with a total height of 90 in. have been standardized by various switchboard builders. These 90-in. panels are usually provided with two or three sections with the carbon breakers mounted on the top sections. Electrical operation is fairly common for high-voltage a-c boards using oil circuit breakers; it is not used so frequently for direct current or low-voltage alternating current with carbon breakers, but there are some cases where it is also used to advantage for that class of service. Probably the place where electrical operation is used most frequently for d-c service is for the control of exciters and field circuits in a generating station where electrical control is employed for a main a-c circuit and the exciter and field switchboards are electrically controlled from the generator switchboard. Newer tendency is to mount heavy low-voltage live apparatus, such as large air circuit breakers, away from the control board.

28. A-C SWITCHBOARDS

A-c switchboards may be divided into the following three classes depending on the mounting and method of operation of the apparatus: direct control, distant mechanical control, and electrically operated switchboards.

For moderate-capacity low-voltage a-c service, switchboards are particularly designed for the control of from one to three generators in small industrial plants and central stations operating a-c systems below 500 volts. The capacity of the single generator panel is limited to 600 amp, and that of a complete switchboard, composed of these panels, to 1800 amp with the number of panels limited to 6. For greater capacities 90-in. panel switchboards are preferable.

Remote-control A-c. Hand-operated remote-control a-c switchboards are applicable where the simplicity of connections or accessibility desired cannot be obtained with panel-mounted apparatus, where the station's capacity or voltage is so high as to make it desirable to mount switching equipment apart from panels, and where the station arrangement permits the use of manually operated remote-controlled oil circuit breakers. Electrically operated remote-controlled switchboards are applicable where the equipment must be remote controlled but where manually operated switchboard apparatus is not suitable. With remote-control switchboards, either manually or electrically operated, the most interesting features of design center in the arrangement of the breakers, bus-bars, and connections in the structure, and these are considered in the chapter on Station Structures and Layout. Similarly, metal-clad switchboards are described in Art. 35.

29. BUS-BARS

In order to provide facilities for utilizing the current developed in an electrical generating station to the best advantage, it is customary to have one or more sets of circuits into which the various generators deliver all their current and from which the various feeders draw all their current. These common circuits were originally known as " omnibus " bars, which term was later shortened to " bus "-bars.

D-C BUS-BARS. With shunt-wound d-c machines, it is necessary to have a positive bus and a negative bus; if two machines are run in series on a three-wire system, a neutral bus is also needed. For compound wound d-c generators on a two-wire system, an equalizer bus is required. For railway service, with ground return, the feeder connects only to one bus, usually the positive, the other bus, the negative, being grounded, and the equalizer bus merely running between the machines. The equalizer bus is normally made half the capacity of a main d-c bus, but the cable connections from the generator equalizer should be of full capacity.

EXCITER BUS, on panel switchboards for a-c service, ordinarily extends across the exciter panels and the a-c generator panels, and if it is used exclusively for the exciting current the capacity need not exceed the total current required for the generator fields. Fig. 12 shows the usual arrangement of panels and bus-bar systems for moderate-voltage a-c switchboards with the bus-bars on the rear. In the third arrangement shown the station load consists of two parts, lighting and power. A tie switch is provided to permit parallel operation of the two halves of the station when desirable. The feeder panels are placed at the extreme ends of the board to permit addition to feeders without disturbing the rest of the board, lighting feeders being taken out at one end and power feeders at the other. The switchboard and exciters are located in the center of the station with the a-c generators symmetrically arranged on either side. The last arrangement shown consists of double-throw feeder circuits and single-throw generator circuits. This system may be desirable

because of the difficulty of parallel operation where one set of generators differs in characteristics from the other, because of different voltages on the two bus-bars, or because one is alternating and the other direct current. Dotted lines in the main bus-bars indicate an arrangement for double-throw generator circuits; in the exciter bus-bars they indicate that arrangement is made for parallel operation of all exciters, and in the instrument and synchronoscope bus-bars they indicate that arrangement is made for using either set of instruments for the station as desired.

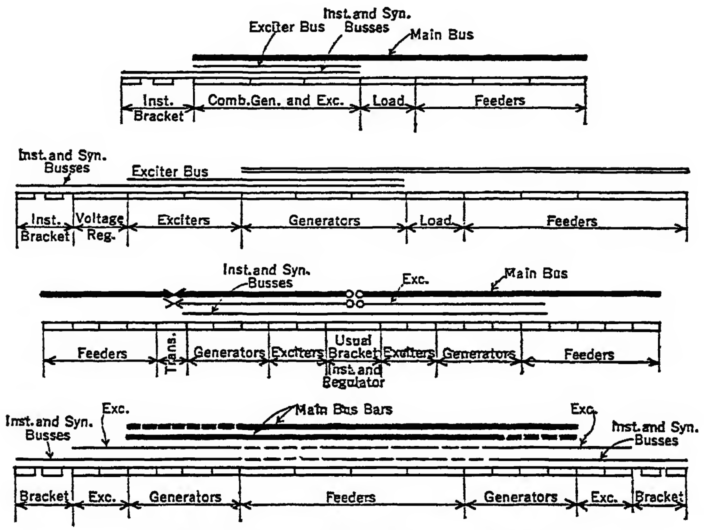

FIG. 12. Arrangement of Panels and Bus-bars

A-C BUS-BARS. For single-phase a-c systems there are two buses, for two-phase systems usually four buses, and for three-phase usually three buses.

Where there is only a single set of bus-bars, either in d-c or in a-c stations, the connections are said to be arranged on the single-bus system; when the connections can be made to either of two sets of bus-bars, the system is spoken of as double-bus, and if the connections can be made to both sets of bus-bars, instead of only to either set, the system is spoken of as the selector system.

CAPACITY OF BUS-BAR. The amount of bus copper required for a switchboard

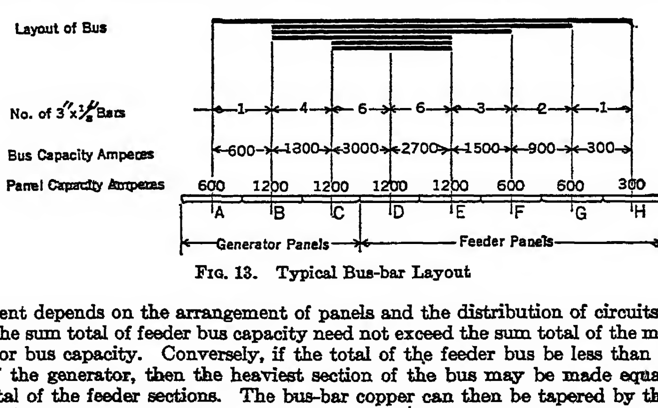

FIG. 13. Typical Bus-bar Layout

equipment depends on the arrangement of panels and the distribution of circuits. Obviously, the sum total of feeder bus capacity need not exceed the sum total of the maximum generator bus capacity. Conversely, if the total of the feeder bus be less than the sum total of the generator, then the heaviest section of the bus may be made equal to the sum total of the feeder sections. The bus-bar copper can then be tapered by the use of laminated bus-bars as indicated in Fig. 13. This construction reduces the amount of bus-bar conductor to a minimum and permits making extensions easily.

High-voltage conductors, with their corresponding relatively small currents, frequently use tubing for bus-bars and connections as this has many advantages over rods, wire, or straps, these advantages being principally increased stiffness for the same amount of

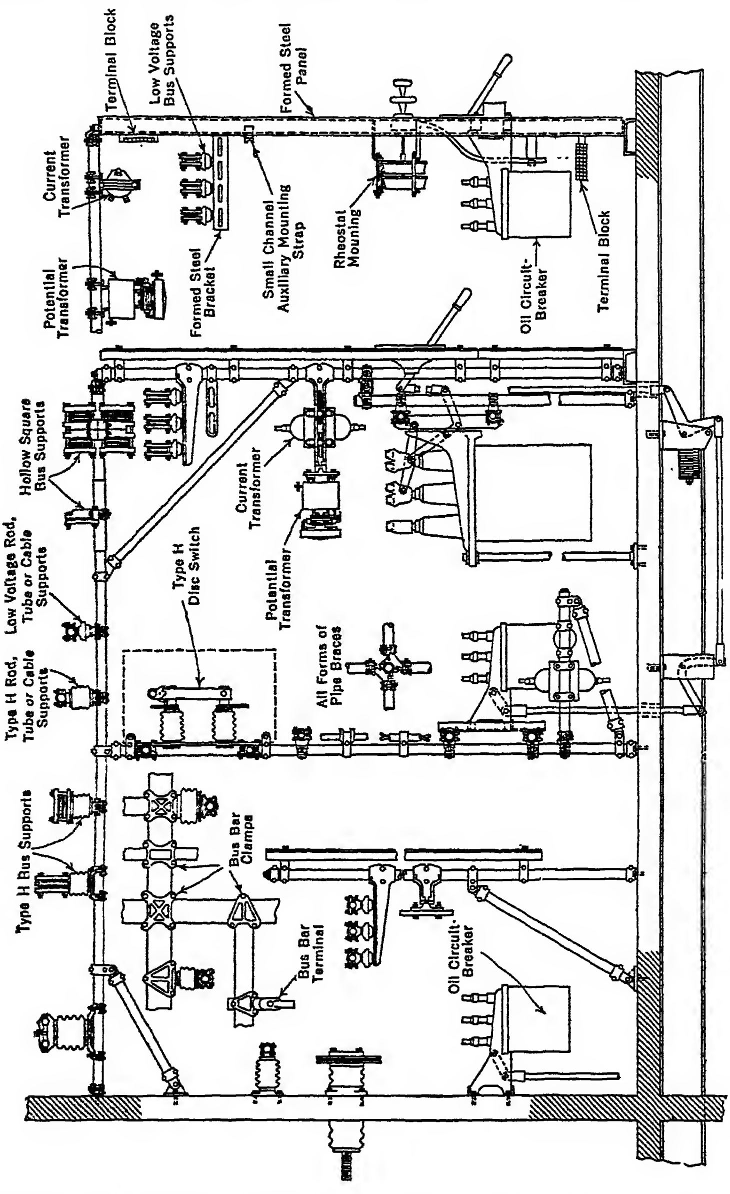

Fig. 14. Switchboard Details and their Application

material, large and effective radiating surface, and the facility of making connections by flattening the tubing at the point desired and bolting the tubing together at such points. In other cases pipes are threaded and standard screwed fittings are used. Tubing of approximately 1-in. outside diameter is not apt to be troubled by brush discharge or

corona effect that is sometimes noted with small wires or straps having sharp edges when used on extremely high-voltage circuits. In many cases standard iron tubing is employed. Corona effects on high-tension conductors may be reduced by using the following minimum sizes of conductors: 35 kv No. 6, 50 kv No. 4, 73 kv No. 1, 115 kv 4/0.

CURRENT DENSITY. The amperes allowable per strap in the main connections and bus-bars will vary according to the conditions of installation and service. For a-c switchboards, for capacities requiring but one copper strap, a 2 by $^1/_4$ in. strap will carry 550 amp and a 3 by $^1/_4$ in. strap will carry 850 amp, with a 30-deg cent rise, at frequencies not greater than 60 cycles. For bus capacities above 2500 amp 60 cycles, or 4000 amp 25 cycles, the arrangement and capacity of panels in order to obtain the most suitable bus-bar layout must be carefully studied. In general, for bus capacities greater than those mentioned, the maximum temperature rise of the copper will exceed 30 deg cent owing to unequal distribution of current in the buses. As a rule, a suitable number of 3 by $^1/_8$ in. or 4 by $^1/_4$ in. straps is used for bus-bar capacities up to 4000 amp, 6 by $^1/_8$ in. straps for bus-bar capacities above 4000 up to 8000 amp, and 10 by $^1/_4$ in. straps for bus-bar capacities above 8000 amp direct current. Above 4000 amp alternating current, copper or aluminum channels are used effectively and economically. The real limits arise from the oxidizing points of the material used for contacts. Provision is made to use vaseline or non-oxidizable films between contact surfaces, silver plating, welding, or brazing. An important consideration is the pressure at the joints.

BUS-BAR STRESSES. In the larger generating stations, on account of the tremendous values of short-circuit currents resulting from the size and number of generators represented in present-day station practice, close attention must be given to the adequacy of the bus-bar supports. Various curves and formulas have been deduced for the purpose of calculating the mechanical strain on bus-bar supports at the instant of short circuit. Careful consideration must be given to obtain adequate mechanical strength and thermal capacity for the current transformers and all apparatus in the circuit under short-circuit conditions.

Supports of bus-bars, connections, etc., are often made as in Fig. 14, which shows a number of applications of brackets and fittings of various kinds for pipe and angle structures, using clamps with cemented type of supports with insulators of various kinds, bus-bar clamp terminals, methods of mounting oil circuit breakers, current and potential transformers, fuses, and similar details. For low-voltage supports cutouts of slate, marble, asbestos, etc., can be used.

MAIN CONNECTIONS. Connections between switches, circuit breakers, current transformers, and bus-bars, where heavy currents are to be carried, frequently use copper straps, and the same material is supplied for the bus-bars. The exact amount of current to be carried for a given rise depends somewhat on local conditions, ventilation, etc., and whether the bus is being used for d-c, 25-cycle, or 60-cycle service, and the temperature rise is not the same for different parts of the bar. A typical test of the average conditions for 60-cycle service at 25-deg cent rise, indicated that one bar 3 by $^1/_8$ in. would carry 650 amp; two bars, 1150 amp; three, 1500; four, 1800; five, 2000; six, 2160, showing that, owing to skin effect, lack of ventilation, etc., permissible current density falls off rather rapidly as the number of bars increase.

ELECTRICAL OPERATION. When electrical operation is employed, no main connections on the back of the switchboard panels are required, but usually a very considerable amount of small wiring has to be done for interconnecting the control switches, indicating lamps, instruments, relays, etc., and various methods of running this fine wiring have been developed. The method used depends largely on the number of wires involved and the amount of space available at the rear of the panel.

30. CABLES

For the connections between generators, transformers, feeder circuits, and the switching gear, it is occasionally possible to use bare copper conductors, although in most cases, particularly for the connection between the generators, the low-tension side of step-up transformers, and their switchgear, insulated wire or cables are better adapted to the actual arrangement of the station. Under certain conditions of very heavy currents where bus and connections are relatively long, aluminum can frequently be used to advantage in place of copper.

The carrying capacity of insulated cables and wires is determined by the maximum temperature at which it is safe to operate them with insulation of various kinds (see Section 14, Arts. 58 and 60). The permissible maximum temperature with rubber insulation is lower than with varnished cloth, and that in turn is lower than with certain other types

of insulation. On account of the unequal distribution of alternating current in large conductors, the large stranded cables will have a higher temperature rise with alternating than with direct current. For this reason, it is recommended that single-conductor stranded cables, unless built with a hemp core, be limited to 1,000,000 cir mils for all a-c circuits. When a cable of 1,000,000 cir mils is used on 60 cycles, the carrying capacity is approximately 10 per cent less than that assigned to d-c service.

Single-conductor a-c cables should not be placed in an iron conduit owing to the hysteresis loss. Three conductor cables carrying separate phases of a three-phase circuit can usually be placed in such a conduit without any difficulty arising. If the currents are small, such as those from current and potential transformers, the hysteresis loss in iron conduit is inappreciable.

For three-phase generator leads where the current is small enough to permit the use of standard three-conductor cables, these are to be preferred to three single-conductor cables. It is not practical to make three-conductor cables larger than 750,000 cir mils; therefore single-conductor cables in parallel are recommended for larger capacities.

Multiple-conductor cables are used with electrically operated switchboards, as the instruments and control switches are usually located some distance from meter transformers, circuit breakers, rheostats, and other accessories, and it is necessary to use connecting leads of varying lengths. Each individual conductor is insulated for 600-volt service and is covered with braid having an identifying color. The insulated conductors are assembled and covered with a layer of tape and an outer braided covering or lead sheath. The outer covering of the cable selected depends upon the nature of the installation.

STATION STRUCTURES AND LAYOUT

In the earliest plants the switchgear was scattered around the station or possibly assembled on the walls, so that no floor space was allotted to it that could be used for other purposes. The next step involved placing the apparatus on a panel switchboard near the wall where little room was taken up by it. As stations grew, more space had to be devoted to the switchgear, until in the modern high-voltage, large-capacity plants one portion of the building, or in some cases a separate building, is assigned to the switchgear and is designed especially for its proper housing.

Direct-control switchgear has the switching apparatus mounted directly on the panels and has no structure of the type considered in this article.

Distant-control switchgear is often used in stations that distribute at the generator voltage where, owing to the size of the breakers, the voltage employed, the capacity of the system, or for other reasons, it is not advisable to mount the switchgear directly on the switchboard panels. For this service the breakers and other apparatus are mounted in structures.

The following apparatus must usually be considered in choosing a satisfactory arrangement for distant control: circuit breakers; bus-bars and connections; rheostats; instrument transformers; fuses for potential transformer primaries and for main wiring, when employed; and disconnecting switches.

31. OPEN CONSTRUCTION

Structure arrangements adopted may be of open, semi-enclosed, or entirely enclosed structures. For small stations of 3000 kva or thereabouts the open arrangement is usually employed as masonry structures would hardly be warranted.

Wall Mounting is used when a simple, cheap equipment with wall-mounting breakers is furnished by the switchboard builder, with only the connections to the circuit breakers and bus-bars and bus-bar supports and terminals, wall braces and brackets necessary to adapt the circuit breaker to wall mounting supplied.

Frame Mounting. Each bus and circuit-breaker structure section with frame-mounting breakers consists of 1 1/4-in. pipe framework, together with necessary mounting brackets and supports for the equipment consisting of oil circuit breakers, disconnecting switches, instrument transformers, bus-bars, and connections. In place of pipe, welded structural steel shapes can be used. Fig. 1 shows a typical arrangement of a small oil circuit breaker arranged for distant mechanical control and mounted on a pipe frame structure with disconnecting switches and bus-bars, the structure being located immediately back of the switchboard panel. Disconnecting switches are used between the bus and oil circuit

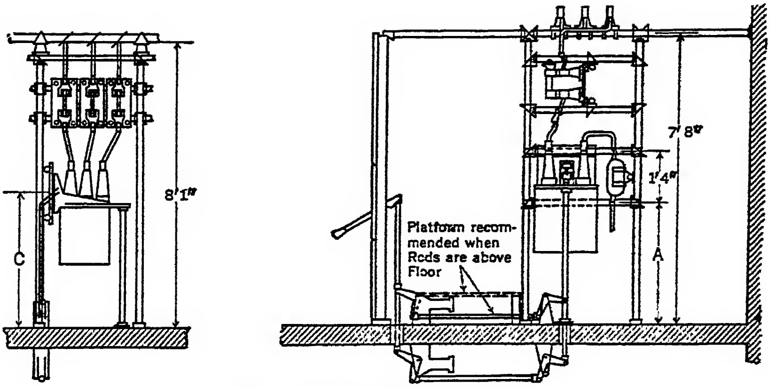

Fig. 1. Typical Open Bus Structure

breaker, and other sets can be used for disconnecting the oil circuit breaker from the outgoing feeder circuit. The breaker illustrated has all three poles in the same tank and hung from a common frame. This design is suitable for various types of breakers of moderate rupturing capacity.

32. SEMI-ENCLOSED CONSTRUCTION

A semi-enclosed structure is employed if the circuit breakers are of the type having one supporting frame for all poles, and it is considered advisable because of frequent heavy overloads and short circuits to enclose them in cells. Fig. 2 shows a typical masonry construction utilizing a moderate-capacity three-pole oil circuit breaker with each pole in a separate tank, and all three poles on the same framework. The breaker is placed in a masonry compartment that can be completely closed in, so that there will be no likelihood that trouble which starts in one breaker compartment may spread to adjacent ones.

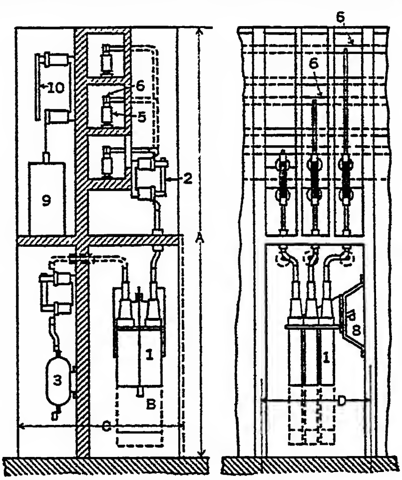

Fig. 2. Typical Semi-enclosed Bus Structure

33. ENCLOSED CONSTRUCTION

In large-capacity a-c plants of 13,200 volts or less, with generators connected directly to the bus, the amount of current that can be concentrated on a short circuit is very great and every precaution has to be taken to prevent trouble spreading if it ever starts. For this reason, it has become customary to employ masonry or metal compartments and cellular construction for the oil circuit breakers and bus-bars in stations of this character. The main idea of the masonry cellular scheme is to provide an insulating fireproof barrier between leads of opposite polarity in heavy-capacity plants. Usually the vertical walls of the circuit-breaker and bus-bar structures are built of brick or concrete, and the horizontal shelves between the bus-bars are ordinarily made of concrete, soapstone, slate, or marble. In some instances, the bus-bar structures have been made of asbestos lumber, transite, or similar material.

Masonry Structures for bus-bar work are made semi-enclosed or entirely enclosed. In the former case, the wall of the structure which separates the horizontal bus-bars, and the vertical connections, are made practically continuous. The back of the bus-bar shelves is built into this wall, and pilasters, properly spaced, support them in the front. A modi-

fication of this scheme uses a continuous wall instead of pilasters as a support of the front of the shelves. The bus-bar, connections, etc., are almost completely enclosed except for openings provided with doors at the bus contacts, etc. Fig. 3 shows a typical arrangement of oil circuit breakers located in a concrete compartment with the bus bars placed above the breakers. With this type of construction each pole of the breaker is in a separate masonry cell. The operating mechanism for the breaker is located on the metal covering above the cells containing the breaker poles. A rectangular opening is left in the back wall of the structure, and the breaker leads, in the form of bare copper strap, are taken through this opening. The back breaker stud connects through a disconnecting switch to the outgoing circuit; the front studs connect through a second disconnecting switch and a series transformer to the bus-bars located in masonry compartments above the breaker. With this type of construction, doors are provided for the front of the breaker structure, closing in the breaker itself, and the use of doors is optional for the rear of the structure.

Limitations. Masonry structures are satisfactory for voltages up to approximately 15 kv. For higher voltages open construction is usually preferable. The masonry con-

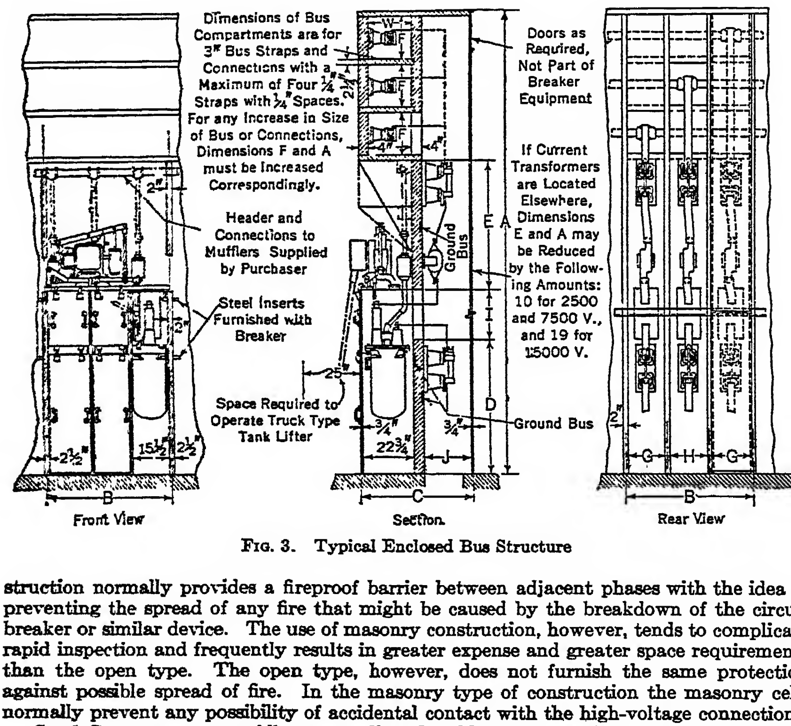

Fig. 3. Typical Enclosed Bus Structure

struction normally provides a fireproof barrier between adjacent phases with the idea of preventing the spread of any fire that might be caused by the breakdown of the circuit breaker or similar device. The use of masonry construction, however, tends to complicate rapid inspection and frequently results in greater expense and greater space requirements than the open type. The open type, however, does not furnish the same protection against possible spread of fire. In the masonry type of construction the masonry cells normally prevent any possibility of accidental contact with the high-voltage connections.

Steel Structures are rapidly superseding the older forms as the complete switchgear can then be a factory-built device and any trouble after erection is usually a phase-to-ground fault instead of a phase-to-phase short circuit. This metal-clad construction is considered in Art. 35.

34. SEGREGATED PHASE

Most of the older installations utilizing structure-mounted breakers had the three poles of each three-phase circuit breaker located side by side with the three bus-bars side by side vertically or horizontally in the same structure. A later modification utilized in some of the more important installations, with a large number of feeders fed from the generator bus, adopted a segregated phase layout. All the breaker poles in the *A* phase are placed together in a single corridor with the *A* bus above them. Similarly the *B* poles and *B* bus are together and the *C* poles and *C* bus together. The three corridors containing

the three independent collections of breaker poles and buses when placed on the same level gave a horizontal segregated phase arrangement such as employed in the Hellgate

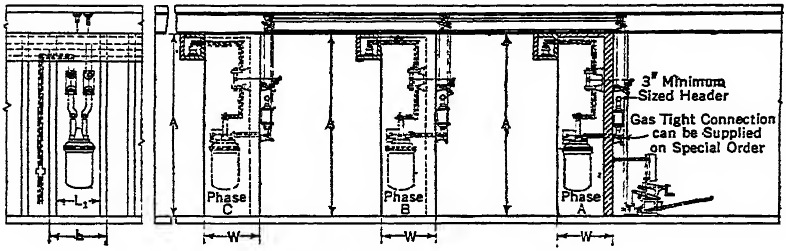

FIG. 4. Typical Horizontal Segregated Phase Structure

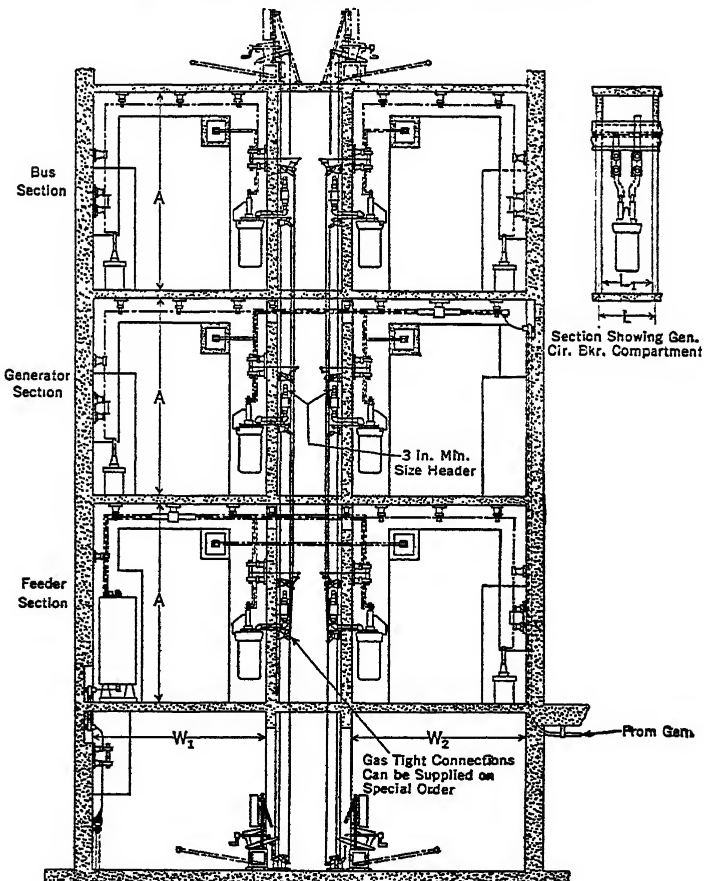

FIG. 5. Typical Vertical Segregated Phase Structure

Station in New York; if they are placed vertically one above the other on separate floors, the scheme is known as the vertical phase segregation.

Horizontal Segregated Phase arrangement is shown in Fig. 4 with the *A* phase at the right, the *B* phase in the middle, the *C* phase on the left, each phase being in its own

separate room or corridor on the same floor. A single mechanism run horizontally overhead operates the three poles of the same breaker simultaneously. All six disconnecting switches associated with the breaker are mechanically operated by a suitable mechanism, and interlocks are provided between the operating mechanism and the breakers and the disconnecting switches to prevent improper manipulation of the disconnects.

Vertical Phase Segregation is shown in Fig. 5 with the *A* phase on the top floor illustrating a bus section, *B* phase on the middle showing a generator section, and the *C* phase at the bottom showing a feeder section. On the top or bottom floor are placed the mechanisms for operating the oil circuit breakers and disconnecting switches, these mechanisms being suitably interlocked. On each of the other floors are placed the oil circuit breakers and buses. The advantage claimed for the segregated phase layout is the practical impossibility of obtaining a phase-to-phase short circuit on the buses, unless simultaneous grounds occur on different phases.

35. METAL-CLAD SWITCHGEAR

Metal-clad switchgear includes indoor cubicles, outdoor switchhouses, truck-type roll-in switchgear, and vertical lift switchgear. Steel panels and desk sections have been considered in previous articles; cubicles and switchhouses will be considered in Art. 36; and truck-type roll-in and verticle-lift switchgear in this article. With the truck-type roll-in switchgear each oil circuit breaker is permanently mounted on its own truck and is rolled into the housing where it makes horizontal connection, through suitable primary devices, to the bus-bars and leads. With the verticle-lift construction the breakers do not always have individual trucks but are placed one at a time on a transport truck, moved into the housing, and lifted vertically into engagement, through suitable primary devices, to the bus-bars and leads. The breaker is locked in position in a suitable support, so that the transport truck may be removed from the housing and used with other breakers. The latest design provides a raising and lowering mechanism in each housing, and the handling carriage is a " dolly " transfer truck.

Metal-clad switchgear with the factory-built and completely assembled features is suitable for installation in any station and for any breaker rupturing capacity, and may be adapted to either indoor or outdoor service. Designs are completed and have been constructed for indoor service up to 22 kv and outdoor service up to 33 kv, but equipments can readily be supplied for higher voltages.

The more general use of metal-clad switch gear is up to 22-kv indoor, 33-kv outdoor, up to 2,500,000-kva rupturing capacity of breakers, but this type of construction is applicable up to higher voltages outdoors. The main advantages of metal-clad switchgear arise from the isolation of the equipment, the possibility of safety interlocks, the interchangeability of spare breaker units, etc.

Complete Switchboards for generating stations, substations, industrial plants, and other locations can be supplied with the safety enclosed design of the vertical lift or removable truck type. Panels are available for the control of feeder circuits, generators, and motors. For generators and motors of large capacity the exciter and field controls are located on a stationary panel at the side of the generator or motor control housing. For moderate-size machines, where the field current does not exceed a few hundred amperes, it is possible to mount the field ammeter and switch on the truck.

TRUCK PANELS. The typical truck-type panel, as the term is generally applied, consists of two elements, the truck or movable element and the housing or stationary element. The former carries the oil circuit breaker, instrument transformers, breaker-operating mechanism, instruments and meters, and movable disconnecting devices. The housing carries the bus-bars, stationary disconnecting devices, cables, and the tracks for removable element.

Housings are extremely rugged structures which will not be distorted during shipment or when inserting or withdrawing the circuit breakers on their own trucks or by means of the transport truck or while interrupting maximum short circuits. The sheet steel used in their construction is not less than $^1/_8$ in. thick. Access to bus-bar supports, primary contacts, cable terminals, and the like is provided by removable plates; and hinged doors are provided on the vertical-lift type opposite the voltage transformer fuses, and similar devices. For the higher voltages using oil-immersed potential transformers, the fuses are attached to the hinged covers of the potential transformer compartments in such a way that they are immersed in oil and connected in circuit when the cover is in the closed position. With cover open, fuses are disconnected from circuit and may be safely handled. Plugs are also used, preferably on large units.

Exhaust pipes are supplied for conducting gases away from the muffler connection of

the oil circuit breaker, and a leak-proof coupling device joins the exhaust pipe and the muffler when the breaker is in the operating position. Terminals for small wiring are provided so that it will be necessary only for the user to connect incoming secondary or control wiring to the terminal points in the housing. A heavy copper ground connection is bolted to the circuit-breaker frame and is carried to the ground bus in the stationary housing through a copper plate, on the circuit breaker of the vertical-lift type or the truck of the roll-in type, and a finger type contact mounted on the side of the housing. Flexible copper shunts provide a positive ground connection to the circuit breaker or truck unit. Additions can be made to metal-clad switchgear installations in a very simple manner by additional housings and extending the bus through these housings.

Manually Operated Truck-type Switchboard is arranged to carry the instruments and relays as well as the operating handles of the circuit breakers. This truck-type switchboard takes the place of the open-type vertical switchboard where the breakers are directly on the rear of the panel or in a structure a short distance back of the board. The truck-type board eliminates the customer's work of assembling a pipe structure with breaker, disconnecting switches, and barriers (if used), and the installation of conduits, cables, and operating rods.

Electrically Operated Truck-type Board is similar to the manually operated board and

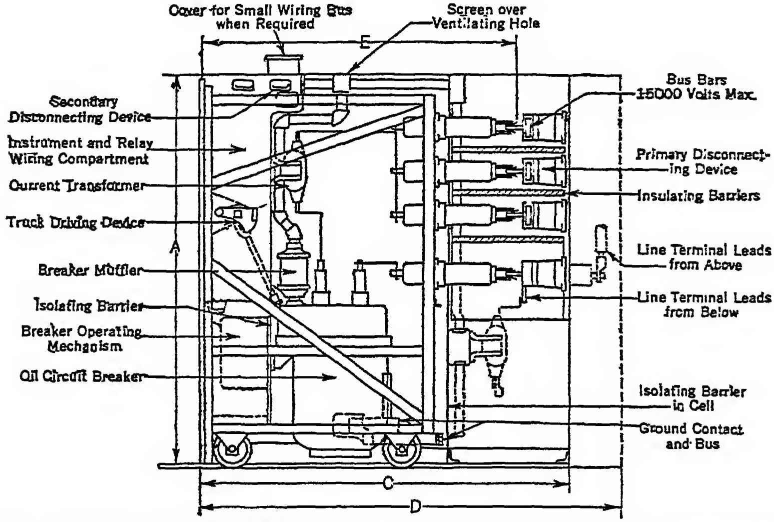

FIG. 6. Outline Drawing of Truck-type Switchgear with Solenoid Operated Oil Circuit Breaker

takes the place of the usual separate structure and panel board. The general arrangement of such an equipment is shown in Fig. 6.

Electrically operated breakers and relays located on a truck and a separate control board for instruments and control switches is an arrangement where the breakers, bus-bars, disconnecting switches, current and potential transformers are all located on a factory-built steel structure instead of being placed in a masonry or pipe frame structure.

Where trucks are controlled from separate panel boards, their housings include two rows of contact shoes, one for the operating position and the other for the disconnected position of the truck. This feature is provided so that the operation of electrically closing and tripping the circuit breaker may be tried out, while the truck is in the disconnected position, and isolated from the bus-bars, in the same manner as though the breaker were mounted in a masonry structure and isolated by means of disconnecting switches.

Disconnecting Devices. The primary disconnecting devices between housing and truck take the place of a six-pole gang-operated disconnecting switch mechanically interlocked with the oil circuit breaker for a three-phase equipment. The stationary disconnecting devices are usually front connected, the buses being mounted directly in front of the insulator. Adapter plates are used to keep the jaws of the disconnecting devices for different bus capacities in the same location relative to the moving element. This insures complete contact between the movable and stationary members of the devices.

Fig. 7 shows a typical primary disconnecting device. The blade member of the disconnecting device is located in a horizontal plane at a fixed height above the rail in the housing. The finger member is located at a corresponding height on the truck. The fingers are on the truck so that they will be dead when accessible for inspection. The fingers are mounted in pairs and are securely bolted to an insulator block in a thoroughly flexible manner. The fingers connect to the block by means of flexible shunts, and flat steel springs are used for holding them in position as well as for furnishing high contact pressure. The two fingers

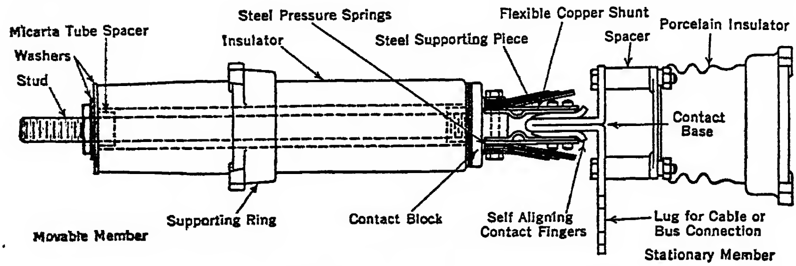

FIG. 7. Primary Disconnecting Contacts for Trucks

forming a pair are assembled so as to have a slight initial pressure, one against the other, and when the blade is in service between the fingers extremely high contact pressure results.

In metal-clad equipment the control and secondary circuits must also be broken, and these pass through secondary disconnecting devices so arranged that proper contact between movable and stationary parts is made not only in the operating position of the oil circuit breaker but also in the disconnected position to permit checking breaker operation and testing of secondary circuits while the equipment is not connected to the bus but is still in the housing.

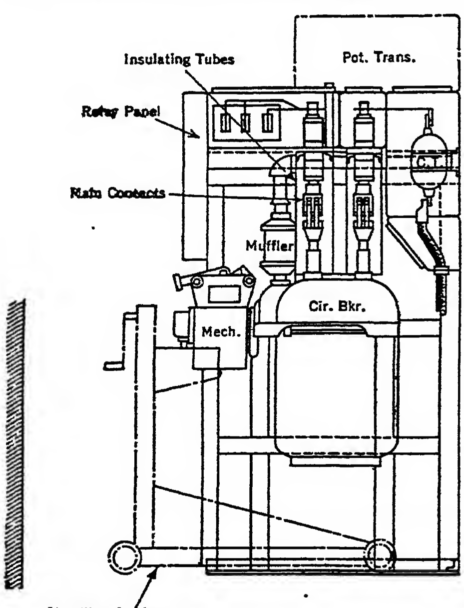

FIG. 8. Indoor Lift-up Switchgear

The secondary disconnecting devices employed in some trucks utilize finger contacts, and contact shoes mounted on insulated blocks threaded over a rectangular steel rod. Contact pressure between fingers and shoes is maintained by means of heavy helical steel springs under the fingers. The insulating pieces have barriers so that short circuits between the fingers or between shoes are impossible.

VERTICAL-LIFT SWITCHGEAR. In addition to the well-known truck-type equipment with horizontal draw-out features, another form of metal-enclosed switchgear has been developed as the vertical-lift type with completely metal-clad buses and connections. This switchgear, Fig. 8, really takes the place of the separately mounted oil circuit breakers, disconnecting switches, bus-bars and connections, current and potential transformers, formerly supplied with an electrically operated switchboard.

The use of single-pole units each with its own operating solenoid is very suitable for three-phase four-wire grounded neutral systems where the individual phase circuits may be opened or closed independently. These individual pole units can, however, be electrically connected together and operated from the same control switch and relays to func-

tion as a three-pole breaker, with the three poles adjacent and the three buses in the same metal bus holder. If preferred, they may be kept entirely independent to obtain the benefit of the segregated phase arrangement where all the poles connecting to the A phase are arranged in one row, those to the B phase in a second row, those to the C phase in the third row. These three rows may be parallel or consecutive, as best fits in with the general arrangement desired at the point of installation. With indoor installations the parallel rows may be arranged for horizontal or vertical phase segregation.

Transport Truck. When a breaker is to be installed in its housing it is brought to the housing on the transport truck, built of structural-steel members. arc welded together. The breaker is lifted from the truck to its operating position in the housing by means of screws and bevel gears, hand operated for the smaller units, motor operated for the larger ones. The wheels on the transport truck are either of the castor or swivel type to permit moving the transport truck in any direction after the breaker has been withdrawn from the housing.

Disconnecting Devices. The breaker studs are provided with rugged primary disconnecting devices, Fig. 9, of the blade and finger types, self-aligning, carefully located by means of jigs and gages to insure interchangeability. The secondary disconnecting devices of the multicontact train coupler type have their stationary members secured to the removable breaker element. The movable members are fastened by flexible cable connectors to the terminal block compartments in the housing so that the breaker may be lowered to the disconnect position and tested without disturbing the control connections.

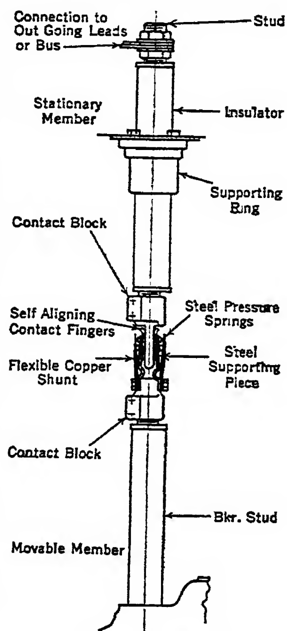

FIG. 9. Primary Disconnecting Contact for Lift-up Switchgear

Buses are thoroughly insulated by tape or tubing and supported throughout by Micarta or similar supports permitting a closer grouping of live parts and smaller clearances to metal casings, and practically eliminating maintenance. Connections to the primary disconnecting devices, including the joints, are also insulated. All buses and connections are enclosed in metal compartments. The compartments may be filled with insulating compounds such as oil, petrolatum, or asphaltum, or may be left unfilled. Most frequently, insulated bus located in air is used.

OUTDOOR METAL-CLAD. A modified form of metal-clad switchgear for outdoor construction has been furnished to certain customers who desired segregated phase layout with draw-out breakers of relatively high rupturing capacities. With this modified arrangement, Fig. 10, each pole of the breaker is on a separate truck similar to the normal truck-type design, but the buses and main connections are enclosed in non-magnetic metal containers and are immersed in an insulating fluid. The breakers in question are single-pole round tank units, having a rated interrupting capacity of 42,900 amp at 15,000 volts, 23,000 amp at 25,000 volts, or an arc rupturing kilovolt-ampere rating of 1,000,000.

OUTDOOR VERTICAL-LIFT. This equipment is a modification of the corresponding indoor equipments with the individual poles arranged to be carried on a transfer truck and then elevated into such a position that one stud connects to the bus and the other to the supply or feeder circuit. At the same time the breaker-operating mechanism and the mufflers for the exhaust gases from the tanks are suitably coupled, and the connections to the control, instrument, and relay wiring are completed. Suitable interlocks are provided, and means are furnished for testing out the secondary circuits. The compartments containing the high-tension bus-bars and connections are usually arranged so that they may be filled with oil or insulating compounds, and proper provision is made for the current and potential transformers.

COMPARATIVE COSTS. First cost of the metal-clad switchgear covers a complete, factory-assembled equipment and is naturally somewhat greater than the cost of switching equipment which is shipped unassembled. It includes the necessary assembly labor. However, the purchaser is saved the cost of building cells with inserts and getting it properly connected and adjusted for successful operation.

Labor cost of assembling, inspecting, and testing equipment in the factory will be

less than the cost of equivalent work done in the field because the factory men have better facilities and are thoroughly experienced in doing such work, particularly with their own apparatus.

Installed cost should always be analyzed by the purchaser when considering the pur-

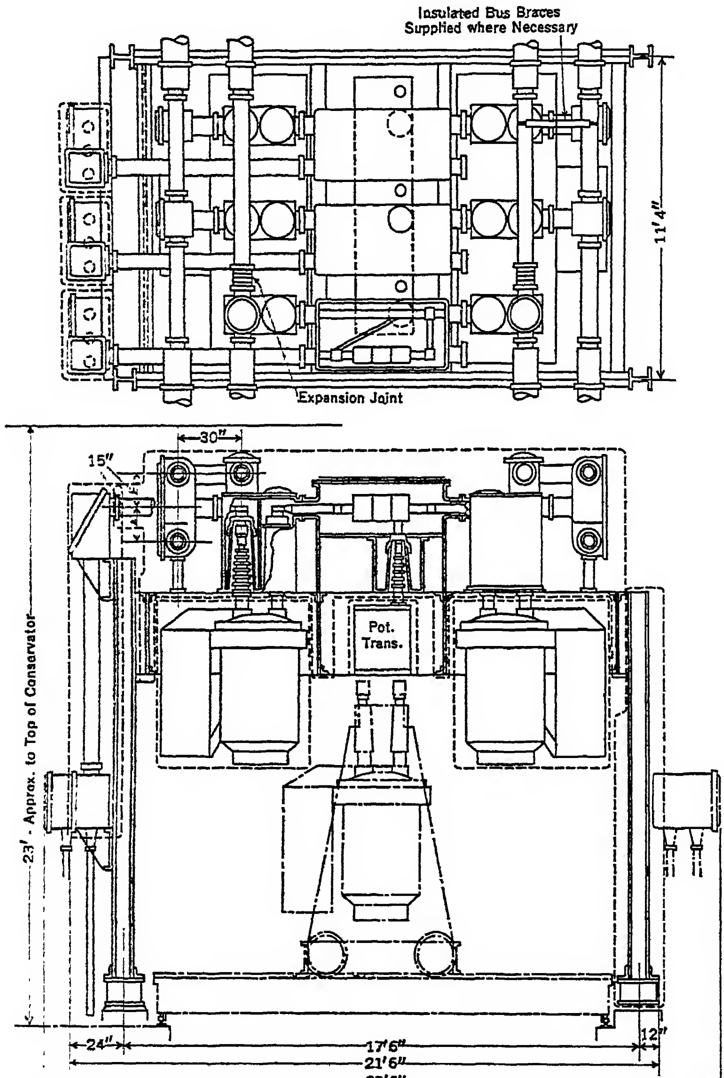

Fig. 10. Outdoor Lift-up Unit.
Dotted lines indicate division points for shipment. Each bay is assembled and shipped filled with oil

chase of switching equipment, and, unless he can design and build structures and install equipment in them for less than the manufacturer, the purchaser can well afford to buy completely assembled equipment.

36. STATION LAYOUT

While the breaker and bus structures in certain plants can be considered independently of the rest of the equipment in the station, it is usual in large plants to give careful consideration to the effect of the switchgear arrangement on the entire design of the station.

Certain features of the arrangement work out best for a location at the end of the building, others for a location at the side of the building or in the separate switchhouse.

The circuit-breaker and bus-bar arrangement in the larger plants often affects to a large extent the general design of the station. In stations that do not contain any prime movers the designer usually has a free hand in determining the best location of switching equipment relative to the feeders, transformers, and rotating machinery which are controlled.

Trend of American design during recent years has been to locate transformers and high-tension switchgear out-of-doors, but there are a few cases where, owing to local conditions, indoor equipment is utilized. It may be advantageous to consider a few typical drawings, some showing indoor equipment and others outdoor arrangements.

SYNCHRONOUS CONVERTER STATION. Fig. 11 shows the sectional view of a synchronous converter substation containing 1000-kw six-phase converters with air-blast

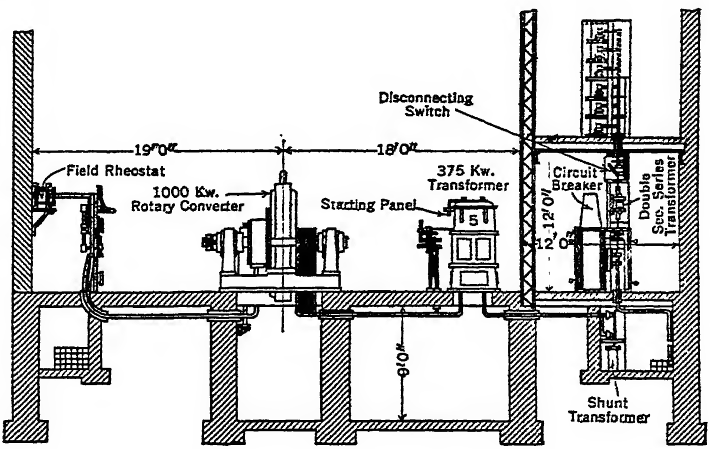

FIG. 11. Synchronous Converter Sub-station

transformers fed from 13,200-volt underground circuits. The incoming leads from the cable ducts pass through an oil breaker and disconnecting switches to the bus-bars located on a gallery, and from the bus-bars back through other disconnecting switches and breakers to the high-tension terminals located at the bottom of the air-blast transformers. The low-tension leads from the transformer go to the starting panel and then to the a-c end of the rotary converter. The d-c end of the converter is connected by suitable cables to the d-c switchboard and placed near the left-hand wall. With such an arrangement the wiring of the station is kept very straight and simple and the space is utilized to the best advantage.

Portable Substations for interurban electric railways have often been made of the semi-outdoor construction type utilizing an outdoor self-cooled three-phase transformer with the converter and low-tension switchgear inside the cabin of the car.

Rectifier Stations have been supplied to certain railways, in which rectifiers have been installed to convert from alternating to direct current for railway service.

HYDROSTATIONS. Fig. 12 shows a sectional view through the Holter plant of the Montana Power Co. installed a number of years ago but still typical of an indoor installation of switchgear. The plant contains four 16,000-hp vertical-shaft waterwheels with 12,000-kva 6600-volt generators and four three-phase transformers stepping up to 110 kv.

STEAM POWER PLANTS. These plants usually have arrangements of transformers and high-tension switching equipment that do not differ very much from the corresponding arrangements in hydroelectric plants except that usually a number of galleries are avail-

able along one side of the generating station and these galleries frequently can be utilized to advantage for the transformers and switching.

On the top floor of the electrical galleries near the center of the building is located the control room with the control desk, instrument panels, feeder switchboard, and similar equipment.

STATION AUXILIARIES. A very important problem in steam station design is the arranging of the switching for the station auxiliaries such as the condenser pumps, boiler supply pumps, draft fans, and coal-handling apparatus. This equipment is often the last decided upon; adequate space is rarely available, and provision for suitable structures is difficult to make. Metal-clad switchgear with the complete factory-built containing structure is frequently the best answer to this problem.

Indoor Cubicles, Fig. 13, are designed to give the advantage of complete factory-

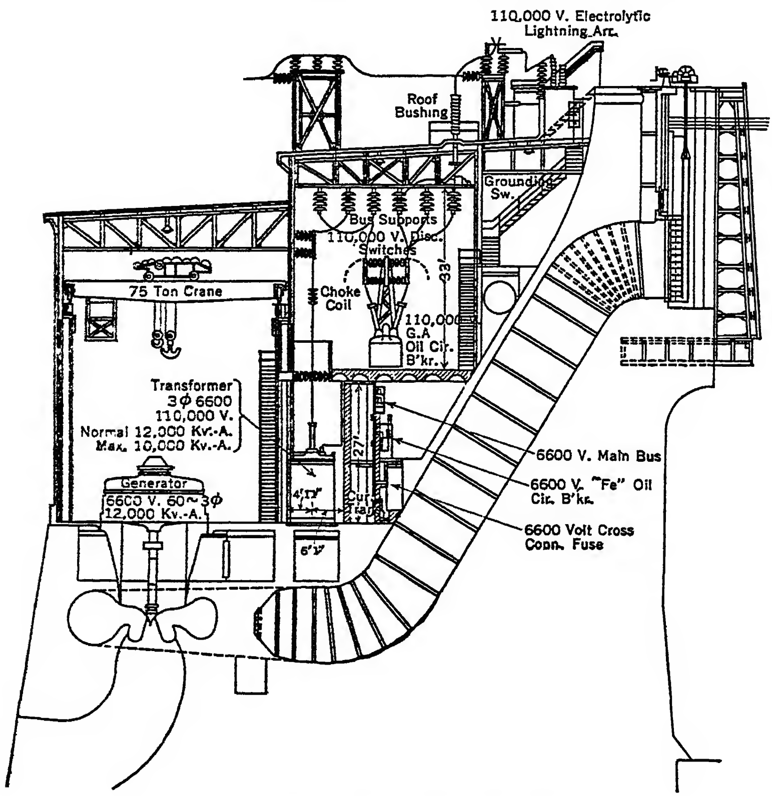

FIG. 12. Sectional View of Water Power Plant

assembled, steel-enclosed, safety-pipe switching equipment at a minimum expense. These units are for either manually, a-c motor-, or d-c-solenoid-operated oil circuit breakers and may be equipped with automatic reclosing equipment, if electrically operated, which will reclose the circuit breaker a definite number of times on a predetermined schedule.

These cubicles are for the control and protection of feeder circuits against overload and short circuits.

They are finished products which have been completely assembled, tested, and inspected before shipment, and they are ready for operation as soon as the incoming and outgoing lines are connected, bus assembled, joints inspected and taped, and the breaker tanks filled with oil.

The cubicles are constructed of structural-steel members and $^1/_8$-in. thick open-hearth

steel sheets securely welded together to form a rigid structure unit that will not warp from changing temperatures or handling.

The lower section of the better-grade cubicles is divided into two compartments, one for housing the oil circuit breaker and instrument transformers and the other for housing the breaker-operating mechanism and control wiring. Between these two compartments is a vertical steel barrier which completely separates the high-tension equipment from the breaker mechanism and secondary control wiring, thus assuring perfect safety to attendants or maintenance men.

Cubicles up to and including 42-in. widths have single hinged doors; those of greater width have double doors hinged at each side. The framework for supporting the oil circuit breaker consists of steel angles and shapes securely welded to the sides of the cubicle and to the foundation angles. The circuit breakers are located at one side of the cubicles to allow room for incoming cables from below.

Separate superstructures constructed of formed sheet steel are bolted to the upper section of the cubicles and are of the same width and depth as the cubicles to which they

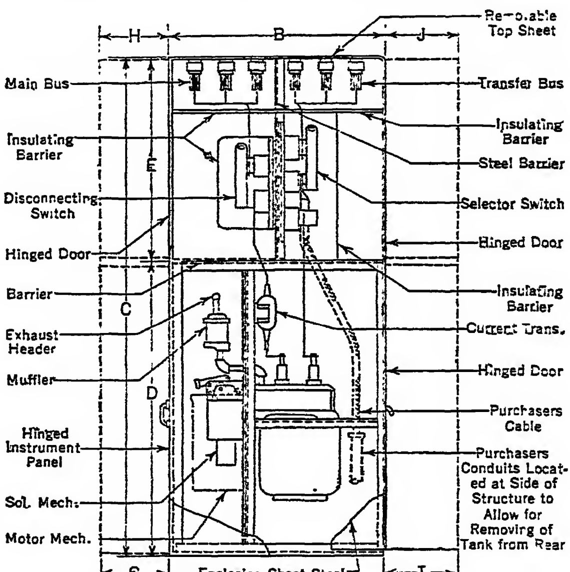

FIG. 13. Indoor Cubicles for Double or Main and Transfer Buses—7500 volts

are attached except in equipments where double-throw or selector-type disconnecting switches are used. In these latter cases it is necessary for the superstructure slightly to overhang the lower section in the rear only.

In the superstructures are mounted the disconnecting switches, bus supports, and bus copper. Hinged doors permit ready access to and convenient operation of the disconnecting switches, and removable sheet-steel covers are provided for access to the bus, busbars, and connections. Insulating barriers are used where necessary between the buses and disconnecting switches, and sheet-steel barriers are provided between the main and transfer buses or double buses where such arrangements are supplied.

The superstructures are suitable for enclosing one bus and either one or two sets of disconnecting switches, or main and transfer buses and two sets of disconnecting switches. Double bus arrangements can also be provided for.

OUTDOOR STATIONS. Fig. 14 shows a typical layout of outdoor transformer and switchyard. This drawing has in most places two sets of dimensions, one giving the dimensions for a 154-kv and the other for a 110-kv installation. The steelwork for the tower construction has been shown in merely typical form, and the dimensions and spacings are more than ample. The drawing gives a fairly clear idea of one manner in which the transformers and switching equipment could be arranged to advantage for outdoor service.

At the time when this drawing was prepared, estimates were made as to the approximate

cost of indoor and outdoor layouts, comparing the space required in the building for housing indoor transformers and switchgear with the cost of the steelwork erected and the extra cost of making the apparatus suitable for outdoor service. Both for 110 kv and 154 kv the calculations indicated that the outdoor equipment would cost approximately 13 per cent less than the building and indoor equipment.

When considering the question of outdoor stations three different types of equipment present themselves, namely: outdoor switchhouses and metering equipment; outdoor substation with air break switches; outdoor substations with oil circuit breakers.

Outdoor metering equipment had been designed for those feeder installations where

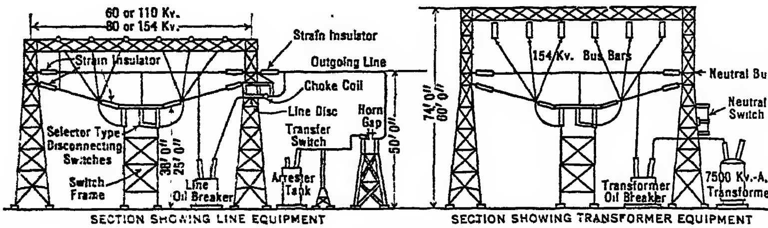

FIG. 14. Transformer and Switchyard—154 kv

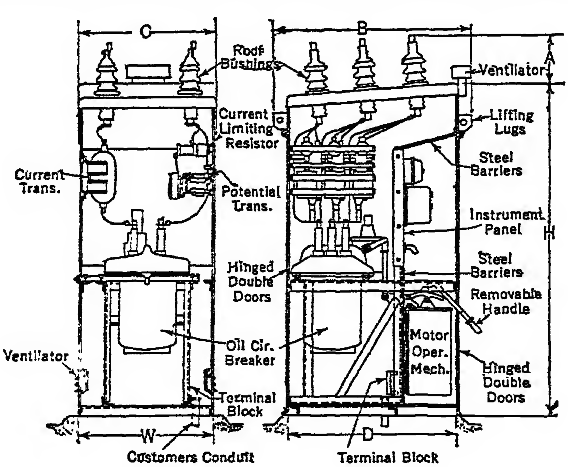
metering is the only requirement or where an air break disconnecting switch is being used. The equipment is usually pole mounted and consists of an accessible housing for the high-tension connections and instrument transformers to be located near the top of the pole, together with a meter cabinet placed at a convenient height above the ground for meter readings. The salient features of outdoor substation structures are to take advantage of the available space and to locate the apparatus in such a way as to facilitate its inspection and adjustment without danger to the operator.

OUTDOOR SWITCHHOUSES usually include both circuit-breaker and watthour-



Rear View - Side View

FIG. 15. Outdoor Switchhouse

meter equipment properly housed and protected for mounting in exposed locations. They are used for the control of outdoor distributing substations which supply power to small towns, farming communities, manufacturing plants, and numerous similar installations where the connected load is not large enough to warrant the expense for substation buildings with indoor apparatus. Fig. 15 is a typical switchhouse designed to stand on its own base and is of sufficient height to prevent accidental contact with the incoming and outcoming leads. Access to the apparatus is gained through large hinged doors at both front and rear of the house.

Outdoor Cubicles are essentially steel houses suitably designed to contain the oil circuit breakers, disconnecting switches, instrument transformers, bus-bars, connections, and wiring and may be considered as a combination of switching equipment, bus structure, and containing building. Incoming and outgoing connections can be made by underground cable or by overhead leads to weatherproof bushings in the same manner as for the individual outdoor switchhouses—as they are the logical development of the same idea to take care of many circuits in place of one.

Outdoor Substations with air break switches are provided for use as small-capacity transforming stations operated from high-voltage transmission and distribution circuits where the use of oil circuit breakers is hardly warranted by the value of the apparatus installed and the importance of the circuit being controlled. For this class of service, air break switches, usually with arcing horns, have been provided. The capacity of a station of this type is limited by the safe rupturing capacity of the fuses, and for ordinary installations a capacity of 7500 kva should not be exceeded.

Outdoor Stations with Oil Circuit Breakers are furnished for larger capacities and higher voltages and more important circuits. The arrangement of any outdoor station has to be determined from local conditions, and circuits to be controlled.

37. AUTOMATIC OPERATION

There has recently been a great development in unattended stations, which are either automatic or operated by supervisory control from the dispatcher's headquarters.

The field of application for automatic substations and hydroelectric generating stations is rapidly broadening. In general, it may be said that any substation which would require the presence of an operator, if manually operated, can be made automatic. If there are not more than two or three machines, saving in operation will usually result.

EQUIPMENT. Automatic substation equipment has been designed to duplicate in every way the manual operation of substation apparatus, without the attention of an operator. Starting and shutting down of the station are functions of the load demand. In addition, many protective devices uncommon to the average substation give absolute protection, which is free from the human element.

Automatic Equipment for Railway Service has usually been designed for full automatic operation; that is, the starting impulse is received automatically, when the trolley voltage drops below a predetermined value. The station also stops automatically when the load demand falls below a predetermined minimum, for a continuous period of time, that can be adjusted from 3 to 30 minutes.

Protective Equipment is exceptionally complete. Every effort has been expended to make the substation equipment simple and compact without the sacrifice of any protective or automatic feature. Each device of an automatic station has a number marked directly on the switchboard and on the wiring diagram. The American companies furnishing automatic substation equipment have agreed on a system of numbering so that the same devices, or similar devices performing certain functions, are assigned definite numbers, and an operating engineer familiar with the connections and equipment of one manufacturer can readily understand the corresponding equipment of another manufacturer.

Synchronous Condensers are used for power-factor correction and for voltage maintenance in terminal substations supplied from power transmission circuits. Automatic equipment is available for starting such condensers, connecting them to the power system and adjusting their field circuits to obtain the maximum corrective benefit from the use of the synchronous condenser. When conditions are such that the condenser is no longer needed it will be automatically disconnected from the circuits.

TYPES OF STATIONS. For railway service, automatic substations have been built for a-c self-starting synchronous converters up to 3000 kw 600 volts direct current. Equipment also can be readily supplied for motor-started converters and for 1200- or 1500-volt d-c service with one 1200- or 1500-volt machine or two 600- or 750-volt machines in series. Automatic equipment has lately been furnished for use on 3000-volt railway service and for mercury-arc rectifier stations.

Mine Service. Automatic equipment has been standardized for motor-generator sets up to 300 kw, 25 or 60 cycle, 2300-volt alternating current, 275- or 550-volt direct current. This capacity is usually the maximum required, but larger capacities can be readily taken care of by substituting larger circuit breakers and contactors. Automatic synchronous converter substation equipment of like capacities can also be supplied.

Three-wire automatic stations have been provided for d-c systems, usually supplied by motor-generator sets or booster converters to allow for proper variation in the d-c voltage by means of suitable voltage regulators.

Hydroelectric Stations can be furnished with automatic switching equipment for the control of waterwheels and generators. These stations may be arranged to start in any of the following manners:

1. By means of push-button control from a distant station.
2. When the frequency of the line is reduced.
3. When the water head exceeds a certain height.
4. When the load on other generators exceeds their rating.
5. Through supervisory control equipment operated by the dispatcher, located at some distant point.

Automatic control equipment can be applied to almost any hydroelectric generating station regardless of size, type, or head of water. Either induction generators or synchronous generators may be used, the latter being preferable on most systems. With synchronous machines, either the self-synchronizing method or the automatic synchronizing method of starting is used. The self-synchronizing method is employed if the relative size of the generator is small compared to the adjacent sections of the power system. When the waterwheel is within 10 per cent of normal speed, the generator, provided with a damper winding, can be thrown on the system and started, and the field circuit will be closed when the machine is up to speed. It pulls into step like any self-starting synchronous motor under similar conditions.

If the generator is large compared to the adjacent parts of the system, or if it does not have a damper winding, an automatic synchronizing equipment is provided, which regulates the waterwheel speed and closes the breaker at the first favorable point of synchronism.

Protection is given by suitable relays against troubles in bearings, governor, exciter, etc., or overspeed, overvoltage, and similar conditions.

Shutting down operation in an automatically controlled hydroelectric station is controlled by protective devices, operating on either the lockout relay or a master relay; or the station is shut down by hand by opening a knife switch. The only immediate action resulting is the de-energization of the governor solenoid. This causes the gates to close, thus shifting the load from this unit to other parallel units of the system. The generator is still connected to the line with normal excitation delivering load in proportion to the diminishing gate opening. As the gates reach a point slightly below the no-load running position, the shunt trip coil, on the oil circuit breaker, opens the breaker. As the gates reach the zero gate opening position, brakes, if used, are applied to stop the machine.

A-c Substations. Where automatic operation is desired in a-c substations without attendants, the main feature desirable is that all transformer and feeder circuits should be normally closed ready for the delivery of power. In case of a feeder overload, the feeder breaker should trip out after a short time interval and should try several times to have service restored on that feeder. For this service periodic reclosing relays are used. These are made in various forms and are arranged to energize one or more circuits several times in succession with regular time intervals between each energization. Also multi-unit transformers are sometimes used to switch in and out automatically on load demand.

38. LOAD DISPATCHER SYSTEMS

In any large power system with several generating stations, many substations, and possible interconnections with other systems, it is customary to center the responsibility and authority for the best operation of the system in the hands of the system operator or load dispatcher. It is necessary for him to know, at all times, what stations are connected to the line, what machines are in operation, what load is being carried, what power resources are available, and what is apt to be the power demand at any hour of the day and any day of the year.

Supervisory Control Equipment has been created to meet a demand for equipment which will automatically give the load dispatcher visual indication of the conditions of his power equipment and at the same time provide him with a means of controlling his power apparatus. The automatic station equipment protects itself during starting, running, and stopping conditions. There are certain emergency conditions, however, over which the automatic station equipment has no control. This might be illustrated by the case of a fire in a certain section of the city where the electrical circuits are supplied from automatic stations so that it would be necessary for the dispatcher to open feeder circuits supplying this district.

For supervisory control equipment the audible, code visual, and synchronous visual types of equipment are available. The latest developments along these lines are the "Visicode supervisory control" and "Polaricode" for high-speed operation. Each system has its own field of application.

Audible Type using a dispatcher's cabinet is usually employed for those applications where low cost and extreme simplicity are the prime requisites. It is suited to the distant control of small hydraulic generating stations, small switching and distributing stations and small interurban railway stations.

Visicode Supervisory Control is the latest development combining simplicity of design with minimum line wire cost, as all the controlling and answer-back signals are handled over two wires. Entire equipment is normally at rest, and any number of apparatus units can be controlled and supervised, with a very compact equipment. Up to 20 points the dispatcher equipment can be mounted on a single panel 16 by 90 in., and the substation equipment placed on a similar panel. From 21 to 90 points take two panels at dispatcher's office; two at substation for 21–30; three for 31–60; and four for 61–90. Greater numbers can be handled if desired by using more panel space.

Synchronous Relay Visual type supervisory control is an all relay system embodying the principle of step-by-step synchronous selectors. The equipment consists of relay cases mounted on steel panels, the relays forming the only moving parts. One of these panels is located in the dispatcher's office and the other in the station to be controlled. The control keys and signalling lamps in the dispatcher's office may be mounted in any convenient arrangement to fit into the general plan.

At the substation there are a number of interposing relays which serve to relay the signals from the relay panel to the power equipment. These are usually mounted on the supervisory switchboard. All apparatus is normally at rest.

Selective Remote Metering may be accomplished over the same wires used for the supervisory control equipment by merely assigning a position for that feature and by pulling out the stop key associated with that position so that drive circuits will be stopped, thus connecting the remote metering transmitters with the supervisory lines at the substation and, at the same time, connecting the meter of the proper type to the lines at the dispatching station and giving the dispatcher an indication of the current or voltage to be metered.

STEAM ELECTRIC POWER STATIONS

F. S. Bennett

1. PLANNING STEAM-ELECTRIC STATIONS

The factors affecting the planning are: location, capacity, size of units, and steam pressure and temperature.

Data on power station equipment will be found in Kent's Handbook for Mechanical Engineers; on structural details, in Merriman's Handbook for Civil Engineers; and on buildings in Kidder-Parker's Architects' and Builders' Handbook.

LOCATION. This factor divides as follows:

1. Real estate values.
2. Location of market.
3. Water supply (quantity and temperature).
4. Cost of intake and outlets for water.
5. Prevailing direction of winds (should be away from residential sections).
6. Railroad and water transportation facilities.
7. Local restrictions on transmission lines.
8. Area of real estate available for coal storage and ash disposal.

CAPACITY. The capacity is determined by:

1. Water supply.
2. Market, present and future.
3. Interconnections to existing systems.

SIZE OF UNITS. The steam and electric units should be carefully studied for the following:

1. Present requirements.
2. Future growth.
3. Type of service (industrial or utility).
4. Expected load curve of station.
5. Spare capacity.

The industrial power plant requires careful study, as small units generally prevent expansion to larger units because of building limitations. One solution is to build in units with little or no building to hamper the next unit which may be larger or smaller.

Central stations are now so interconnected electrically that each one is a potential source of emergency service for the others. The size of units, therefore, does not need to be determined by the spare capacity or the load curve, which may be adjusted by making certain stations for base load. The other factors are more important.

STEAM PRESSURE AND TEMPERATURE. This factor is entirely one of fuel economy. The selection is affected by:

1. Cost of fuel.
2. Load curve (total output and daily output).
3. Reliable apparatus available.
4. Water supply.

A curve, Fig. 1, gives an idea of the gain to be made from increasing the steam pressure. The factor of reliable apparatus affects this curve, as higher initial temperature and higher reheats should be used to get the most out of the higher pressures. Fig. 2 gives data on actual performances of stations using turbines and regenerative feedwater heating. The binary cycle of mercury is just coming into service and may radically affect the choice of steam pressure and temperature.

The present limit of commercial use is 1450 lb gage and 900 deg fahr total temperature.

The industrial plant which has a steam demand for manufacturing purposes can generally employ economically the highest steam pressure. There are, however, some detrimental factors for high pressures and temperatures in industrial plants. A steam pressure of 1450 lb, 900 deg fahr temperature does not lend itself readily to rapid changes

in load and it requires longer to start after shutdown. It requires scale-free pure water. The industrial plant usually has all these handicaps. A pressure of 400 to 600 lb and

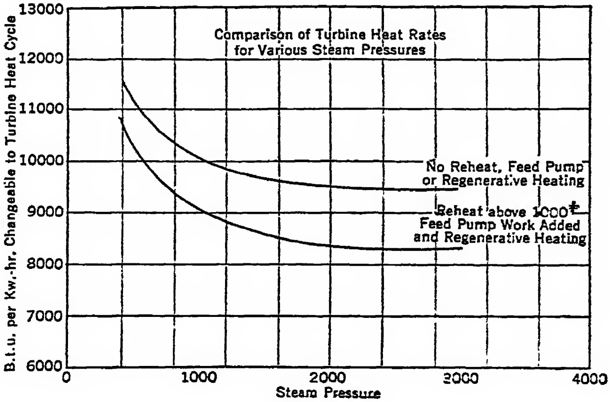

Fig. 1

temperature not above 750 deg fahr have proved successful. Future development may extend this range.

Fig. 2 is based on actual station performances except for 2500-lb steam. This tabulation indicates that the greatest loss is still in the heat not available in a steam turbine

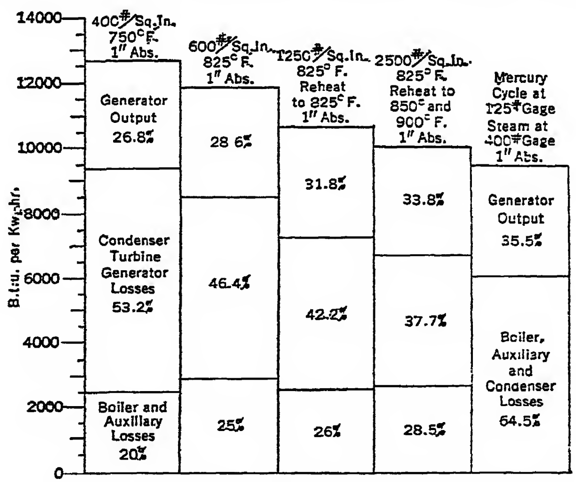

Fig. 2

cycle. These figures are useful in making a preliminary study of economy, but may be slightly altered by efficiencies of individual equipment. They must be modified for losses, such as boiler banking and partial loads of generating machinery.

2. HEAT BALANCE

The distribution of heat in a power station is very necessary to fix the requirements for apparatus.

The distribution of the heat delivered to the turbine has become a very complicated affair owing to regenerative feedwater heating, deaeration of feedwater, and evaporation of boiler make-up water.

FEEDWATER HEATERS. Fig. 3 gives a basis for selecting the number of feedwater heaters and their location in the steam pressure range of the machine. It should be noted that practical difficulties in building a high-pressure machine to extract steam at high initial pressures may be encountered. A simple calculation will show the greater

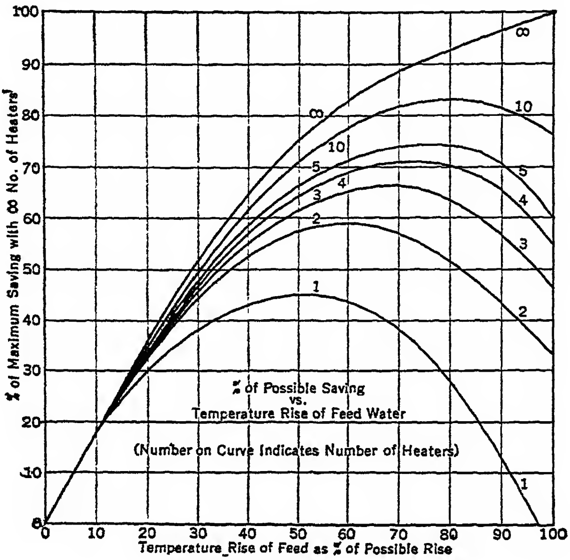

Fig. 3

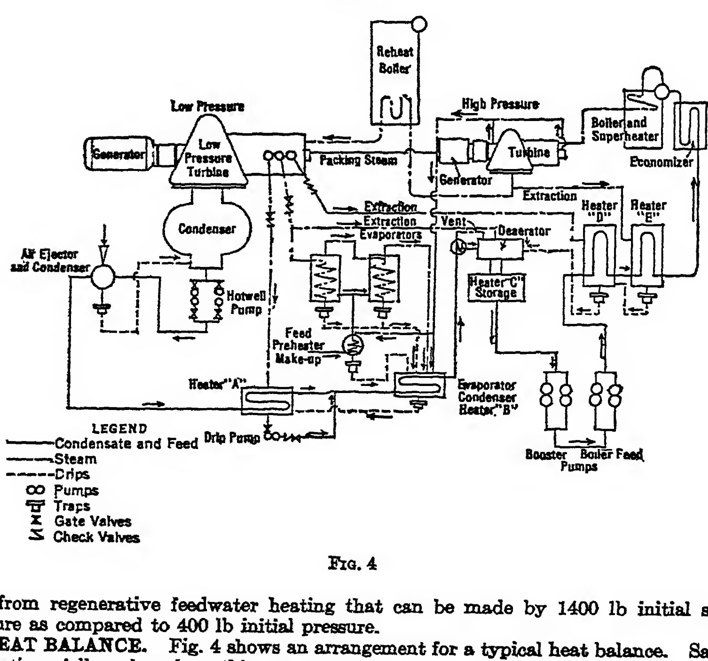

Fig. 4

gain from regenerative feedwater heating that can be made by 1400 lb initial steam pressure as compared to 400 lb initial pressure.

HEAT BALANCE. Fig. 4 shows an arrangement for a typical heat balance. Sample calculations follow, based on this arrangement.

Calculations Turbine Heat Cycle: 80,000-kw unit
Conditions: 1422 lb gage, 825 deg fahr total temperature, 1 in. mercury absolute boiling point.

Kw output	48,985	81,330
Throttle pressure, lb gage	1,422	1,422
Throttle superheat, deg fahr	235	235
Btu per lb at throttle	1,387	1,387
Throttle flow, lb per hr	362,000	652,000
Throttle w.r.	7,390	8,016
Btu per kwhr charged to cycle	9,010	9,000
Condenser flow, lb per hr	271,700	460,920
Condenser w.r.	5,543	5,669
Btu per lb in exhaust l.p.t.	1,024.0	1,011.4
H.p.t. exhaust pressure, lb abs	231	405
Btu per lb in exhaust of h.p.t.	1,239.6	1,277.8
Flow through reheater, lb per hr	328,180	582,900
L.p.t. inlet pressure, lb abs	215.0	377.5

Pounds per hour steam extracted	26,120	60,500
Temperature leaving heater / Final feedwater temperature	375.2	425.8

To make these calculations the following are required: an up-to-date steam table, Mollier diagram with expansion lines of the turbine, pressure flow curves for the extraction points, exhaust loss of the machine, efficiency of the generator, and packing leakage. The machine designer must furnish all these data but the steam table. (See Kent's Handbook for Mechanical Engineers.)

The heat distribution from the fuel to the turbine is generally very simple so far as station design is concerned. The cost and load factor fix the heat recovery beyond the boiler. For pressures up to 600 lb, the boiler takes out 75 to 80 per cent of the heat and an air preheater gets an additional 10 per cent. The preheater limit is to keep the exit flue gases above the dew point which varies from 250 to 300 deg fahr. Exit gases below these values form corrosive acids which rapidly destroy the heat-recovery equipment.

Pressures above 600 lb require economizers to keep the preheated air temperature to a safe value.

3. SELECTION AND TYPE OF APPARATUS

The selection of suitable apparatus is largely a matter of experience. The following general rules should be applied:

1. Make a diagram showing services and connections of other apparatus.
2. Write a specification defining services and capacities.
3. Determine the most suitable manufacturers by records of past performance in other plants, or by other suitable methods.
4. Interview the manufacturers' representatives, requesting data on a definite set of requirements.

DIAGRAM. The preparation of a diagram allows the engineer to complete the picture of the requirements and relations of the various pieces of apparatus and paves the way to make a more complete specification.

SPECIFICATIONS. It is generally undesirable to try to make a specification cover the manufacturing details. The writer usually knows less than the manufacturer and quite often radically increases the cost without any gain in utility or reliability.

The specifications, however, should define the services required of the equipment, the capacities (normal and maximum), the auxiliaries to be furnished, the foundations, erection, and other work to be performed by the contractor.

The types of suitable apparatus are governed by so many factors that only a general discussion of the principal apparatus can be given with a few definite rules.

BOILER TYPES. Steam boilers for 250 lb pressure and above are of two general types: bent-tube multiple-drum and header single-drum. Modern developments have made both suitable for the highest commercial pressure services. The choice is largely a matter of personal opinion.

TYPE OF FUEL. The method of burning fuel pulverized or on a stoker is subject to much discussion. However, several facts are available. Low melting ash coal and high-volatile coals can be burned pulverized at better efficiencies and with higher capacities. Higher overall efficiencies for wider ranges of capacities can be maintained. Pulverized coal requires a larger furnace volume per unit of coal burned than stokers. High-ash-content coals can be handled better with the present development in pulverized-coal burning.

BOILERS. The furnaces are of two general types: a solid refractory wall or a water-cooled wall. The solid refractory wall is definitely limited in capacity. This capacity is rated in Btu released by the fuel per cubic foot of furnace volume. A maximum value for a solid wall is 35,000 Btu and an average 20,000. The completely water-cooled furnace has a maximum value of 60,000 Btu and an average value of 30,000. There are various combinations of solid and water-cooled walls with corresponding rates of heat release.

The water-cooled wall is generally divided into one having bare tubes and one having protected tubes. The bare-tube wall is more satisfactory for base load boilers and dry-ash removal. The wall with tubes protected with refractory or metal blocks maintains better combustion conditions with light and fluctuating loads and is more satisfactory for liquid-ash removal. The metal blocks firmly fastened to the tubes have been the most satisfactory for developing the maximum capacities.

The retention of ash and its disposal present a problem with pulverized fuel. The high furnace temperature obtainable with the covered water-cooled wall furnishes a partial solution. The ashes are melted and collected in the furnace bottom. This molten pool acts as a trap for catching additional ash. This slag bottom furnace catches from 30 to 50 per cent of the ash. The dry bottom furnace catches only from 5 to 25 per cent.

The disposal is most successfully accomplished by a water jet system. The liquid ash is run out on a spout and hit by a jet of water which breaks it up into fine particles. These drop into a metal trough and are carried along by jets to a sump. A pump handling a mixture of this fine ash and water delivers it to a waste space. This system can be applied to a dry bottom furnace or a stoker installation.

BOILER ROOM AUXILIARIES. The auxiliaries of the boiler room are important and need careful study. The supply of pure feedwater for steam pressures above 250 lb is very essential. The make-up supply should be evaporated and the main supply deaerated.

Evaporators are well standardized. The essential features required are easy cleaning and suitable provision for expansion.

The deaerator is usually of the direct contact heating type—either pressure, vacuum, or combination. The capacity should always be adequate to cover the maximum, and not the average, requirements.

The boiler feed pumps are almost universally of the centrifugal type except for capacities of 50 gal per min or less. The essential features are good thrust bearings, heavy castings, and large shafts. The most rugged driving unit is an induction motor. Generally the spare unit is a steam turbine drive.

INSTRUMENTS. The modern station requires indications of apparatus performance. The instrument has taken the place of the experienced guess of the operator. The following list is about the minimum required to operate one modern boiler.

1. Meter to indicate and record steam pressure, steam temperature, steam flow (integrate), and air flow.
2. Meter to indicate and record feedwater pressure, temperature, and flow (integrate).
3. Meter to indicate and record gas temperatures (usually four pens).
4. Meter to indicate and record water level in boiler drum.
5. Meter to indicate air and gas pressures (usually six to eight separate indicators).
6. Meter to indicate and record temperature of coal and air mixture and mill differential pressure (pulverized fuel only).
7. Meter to record boiler gas and air temperatures, including preheater and economizer.
8. Indicating gages for special requirement of boiler, such as spare pump, head tank pressure, etc.

The turbine room also requires instruments for measuring the following quantities:

1. Inlet steam pressure.
2. Vacuum.
3. Barometric pressure.
4. Generator air temperature.
5. Turbine stage pressure.
6. Turbine speed.
7. Generator output.

These instruments are the minimum; generally several special ones are required for the particular installation. In addition, a signal outfit is required.

TURBINE-GENERATOR. The selection of a turbine-generator requires a determination of its capacity, average possible vacuum, steam temperature and pressure, and speed. It is useless to buy a machine for high vacuum and be able to obtain it for only 10 per cent of the year. A water temperature curve over as long a time as possible should be used to fix the best working vacuum. American practice has largely been single-shaft machines for 25 and 60 cycles at 1500 and 1800 revolutions for capacities above 10,000 kw. European practice has tended to multiple-shaft, 3000-rpm speed, for 50 cycles. The developments for high steam pressures, 1200 and higher, have been to higher speeds and multiple-shaft machines. The purchaser is interested only as he may obtain better prices, efficiency, or reliability. The statistical records of both American and European plants indicate much greater reliability for slower-speed single-shaft machines, but slightly better efficiency for the multiple-shaft high-speed machines. The capacity chosen requires data on probable future plant developments. The tendency in the past has been for too small a capacity, especially in industrial plants.

CONDENSERS. The features that must be decided are tube length, size of tubes, material, single or double water pass, and divided water boxes.

The tube length is often a factor of available space. Generally speaking, it is desirable to keep the tube length short, say 12 to 14 ft for 5000- to 10,000-kw machines, 16 to 18 ft for 15,000- to 25,000-kw machines, and 20 to 30 ft for larger machines. One-inch tubes are desirable where the water is dirty, and $^3/_4$- or $^5/_8$-in. are used only where the water is clean. The merits of single or double water pass arrangements are dependent upon the amount of water available and the pumping head exclusive of the condenser.

The condenser auxiliaries have become very nearly standard—steam jet air-removal apparatus with surface coolers and constant-speed motor-driven centrifugal circulating pumps. The large units have at least two pumps, one of which may be used with cold water, in this way saving power input. The condensed steam is handled by constant-speed motor-driven centrifugal pumps.

4. PIPING AND VALVES

The increase in pressure and temperature of steam power plants has made it necessary to study very carefully the expansion stresses and flange construction. The general arrangement tends toward unit systems, particularly in large plants. This is due to

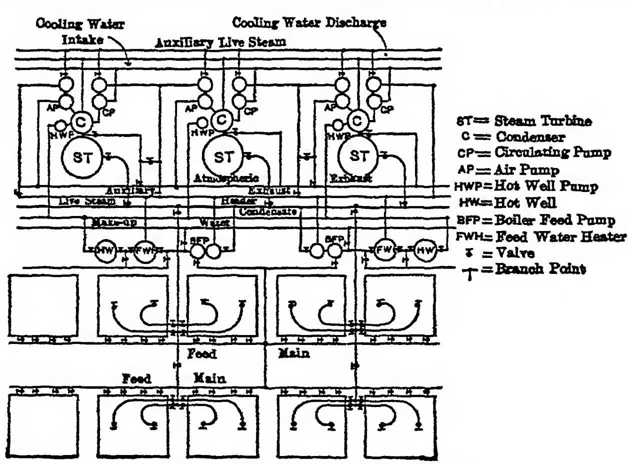

FIG. 5. Parallel Method of Connection

increased pressure and temperature which make it difficult to handle the large headers required.

PIPING ARRANGEMENTS. The parallel system of piping is shown in Fig. 5. This system has many merits and should be used where the capacities and pressure do not require headers beyond the limits of safety.

The unit system (Fig. 6) is used for larger systems and particularly for high pressures, such as 400 to 1200 lb. The majority of operators like to interconnect these units to

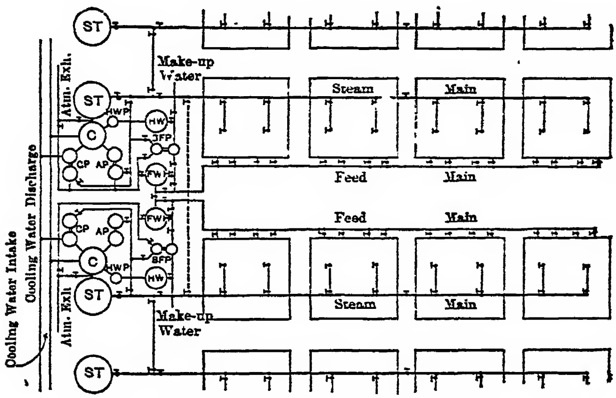

Fig. 6. Unit Method of Connection

obtain more flexibility. This interconnection does not provide for header capacity to carry the capacity of both units connected.

EXPANSION PROVISIONS. The theory underlying the standard forms of pipe bends is well covered by the A.S.M.E. paper by W. H. Shipman, 1930. See Kent's Mechanical Engineers' Handbook, Section 5, vol. 2 of this series.

FLANGES AND WELDED JOINTS. The question of the type of flange joint that should be used has been the subject of much discussion, and many patents and inven-

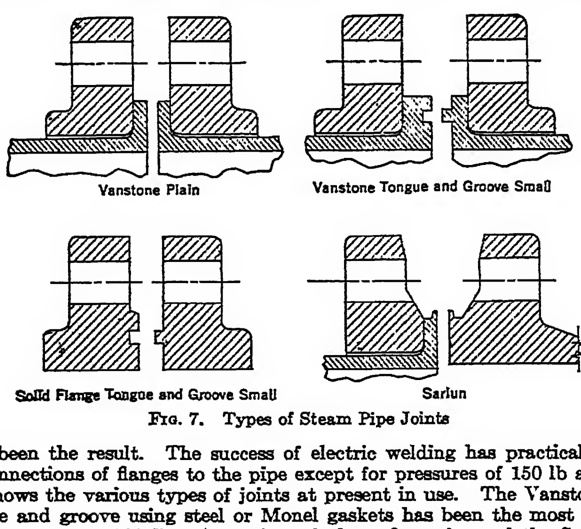

Fig. 7. Types of Steam Pipe Joints

tions have been the result. The success of electric welding has practically eliminated threaded connections of flanges to the pipe except for pressures of 150 lb and less.

Fig. 7 shows the various types of joints at present in use. The Vanstone type with small tongue and groove using steel or Monel gaskets has been the most successful for pressures from 300 to 1200 lb. A number of plants have favored the Sarlun type for 900- and 1200-lb pressures.

The electric arc welded joint has been developed so that the joint at the weld is the equal of the pipe. Fittings and valves have been developed so that a complete job can

be done. This type of joint will supersede all the others for the higher pressures. Fig. 8 shows typical forms of welded joints, valves, and forged fittings. These simplify the piping system and save the cost of expensive bends.

PIPE SIZES. The pipe size is fixed by the allowable drop in pressure. Steam pipes usually have **vapor velocities** from 7000 to 11,000 ft per min. Lower velocities generally represent too large an investment. The usual velocity for a water pipe is from 5 to 8 ft per sec. Condenser hot-well suction pipe may be run at 4 ft per sec to obtain suitable pump suctions and syphon effects. Gas and air pipes are usually run near the lower limit for steam, 5000 to 7000 ft per min.

VALVES. Steel valves, either cast or forged, are required above 600 deg fahr temperature. Globe valves should be used wherever the medium will be throttled. Gate valves should be used for stop valves because their pressure loss is low. The material of the seats and disks of a valve is very important. The requirements are: very hard non-

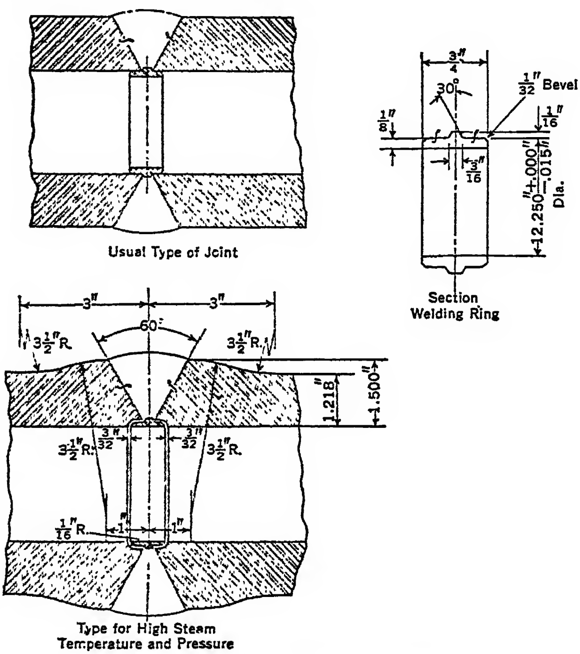

Fig. 8. Types of Welded Pipe Joints

abrasive surfaces free from warping and cracks. These seats and disks should be renewable and capable of refitting.

Motor operation allows valves to be installed in otherwise inaccessible places. The motor operation is a valuable feature for relatively quick operation and shutting off of the lines in case of accident.

A safe rule is to by-pass all valves 6 in. and larger for all pressures above 100 lb. Stop valves should be placed on all pipe lines where they leave the header. Drains are very important on steam lines. They should take care of both the live and dead conditions of the pipe lines.

PIPE INSULATION. Steam and hot water lines require insulation from the heat-loss standpoint; cold water lines from condensation. The general type of insulation is 85 per cent magnesia for temperatures up to 500 deg fahr and special high-temperature type for higher values. There are many other types, such as air cell, hair felt, rock wool, and aluminum foil. These all have a place, but require special study to justify their application. The thickness of insulation should be the subject of a cost study. Quite often the facts are not available for this study, and insulation is arbitrarily selected. The following table can serve as a guide.

Temperatures 500 to 800 Deg Fahr

Pipe Size	Thickness Higher Temperature Type	Thickness 85 Per Cent Magnesia	Thickness Cement
18 to 10 in. inc.	1 1/2 in.	2 in.	1/2 in.
9 to 6 in. inc.	1 1/2 in.	1 3/4 in.	1/2 in.
5 to 4 in. inc.	1 in.	2 in.	1/2 in.
3 in. and smaller	2 in.	....	1/2 in.
Temperatures 500 to 300 Deg Fahr			
18 to 10 in. inc.	....	2 1/2 in.	1/2 in.
9 to 6 in. inc.	....	2 in.	1/2 in.
5 to 4 in. inc.	....	1 1/2 in.	....
3 in. and smaller	....	1 1/2 in.	....

The covering of the insulation depends upon the location. Indoors, where no water or high-moisture air is present, canvas can be used, sewed on where appearance must be considered and pasted on where appearance is not important. Wet places should have two layers of roofing felt wired on and painted with asphalt between layers.

5. ARRANGEMENT OF APPARATUS

The arrangement of power station apparatus is largely dependent upon the kind of service, water conditions, soil conditions, and individual ideas. A few typical considerations will be given.

1. Natural light, as far as possible, should be provided for.
2. Ventilation should leave no dead pockets.
3. Apparatus should be accessible for repairs.
4. Piping should be laid out before the major apparatus is fixed in location.
5. Picture drawings should be made to allow the plant to be visualized.
6. Future expansion of the plant should be provided for by drawing studies of the largest and smallest units.
7. It is desirable to group all the feed pumps and service water pumps so that a common operator can control them.

GENERATING ROOM. There are two general schemes for arranging a turbine electric generating room: units parallel to the boiler axis, and units perpendicular to the boiler axis. The parallel units fit best where there is a multiplicity of boilers. The perpendicular units are best arranged for a single boiler or unit scheme. The parallel units save on building and crane spans. These are a factor with large, long turbine units.

The well-designed generator room sets the generating units on an island foundation and leaves the basement well lighted and accessible to crane service.

The modern turbine and condenser are usually connected solidly on the exhaust, and expansion is provided for by supporting the condenser on springs, so as to give very little uplift on the turbine.

The switching equipment and transformers have all gone from the generating room and are arranged outdoors, with only cable connections and disconnecting switches at the machine. A convenient and general arrangement is to have these switches and the current and potential transformers under the generator foundation.

The general practice is to water-cool the ventilating air for the generator by means of finned tube surface coolers. The ventilating air is circulated in a closed duct system through these coolers and the generator by means of fans on the rotor of the generator or separate motor-driven fans. This system excludes dirt and limits the fire hazard.

The use of steam temperatures from 500 to 1000 deg fahr has created a considerable fire hazard from the lubricating oil. Storage tanks, filtering systems, circulating pipes, and everything containing oil should be kept as far as possible from the steam lines. Flanges should be welded on, and as few joints as possible made. If flanges are used, they should have not less than four bolts, and in general it is desirable to construct them to the 400-lb steam standard.

BOILER ROOM. The modern boiler room should be well lighted, well ventilated, and free from dust and smoke. These features are obtained by making the fuel-handling equipment dust-tight and the operating floor at the lowest level with no intervening floors, access to the upper part being by galleries and stairs. Good ventilation can be obtained where there are no floors and usually natural light. The general tendency is to

make boilers large and expect continuous service with few interruptions for repairs. The making of boiler rooms clean and cool has removed the reason for walling off the generator room. The present tendency is to make the boiler and turbine room one. This saves space and cost and tends to reduce the number of operators required. Another step that has followed the combination of the turbine and boiler room is partial elimination of the building structure. A notable example is the General Electric Co. Outdoor Station at Schenectady, N. Y.

AUXILIARY EQUIPMENT. The auxiliary equipment, such as boiler feed pumps, house service pumps, and feedwater treating, should be concentrated as much as possible, leaving the piping simple and compact. This concentration helps to keep the number of operators small, as the control of these can well be combined with the condensing equipment by locating them adjacent. The general practice is to make the normal units motor-driven and have a few spare steam units for emergency and starting.

6. COST OF POWER STATIONS

The cost of a power station is variable because of the differences in land values, cost of condensing water supply, ideas of designers for arrangement of apparatus, and building construction.

Fig. 9 is based on an average of the cost, per kilowatt of installed capacity, of 60 large stations; it fairly represents the cost at the time (1925 to 1929). The cost per kilowatt, of smaller-capacity plant is shown in Fig. 10.

The majority of central stations today (1936) are below 400 lb and 750 deg fahr temperature. These stations have heat rates per kilowatt-hour from 20,000 to 14,000 Btu.

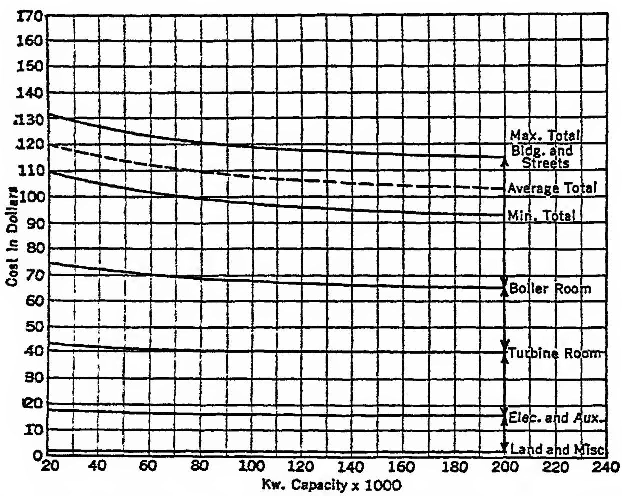

FIG. 9. Typical Costs of Steam Power Stations from 20,000 to 200,000 kw Capacity

These can be improved to 12,000 Btu by adding new boilers for 1200 lb, 900 deg fahr temperature, and new turbines to reduce this pressure to the existing station pressure. The continuity of service can be safeguarded by the existing boilers without spare high-pressure equipment. The cost of such a change is $90 to $100 per kw of the additional capacity. These costs are estimated, as very few stations have been changed in this manner up to 1936.

The most economical change that can be made is to superimpose the mercury cycle. This cycle generates mercury vapor from the fuel; the vapor passes through a turbine and generates electric power; the exhaust from the mercury vapor turbine heats water as it condenses and makes steam, which is superheated in the mercury boiler and then discharged into the station header. This cycle will give a station heat rate of 9000 Btu per kwhr and is estimated to cost $90 to $100 per kw of additional capacity. There are three commercial installations, and the success of these would undoubtedly mean the general use of this cycle instead of the 1200-lb superimposed capacity.

The industrial plant presents a large field for increase in economy by superimposing higher pressure or the mercury cycle. Fig. 11 has been prepared on the 1200-lb cycle to show the effect of initial pressure on the cost of additional capacity. The curve is based on 300,000 lb of steam per hour, 250 lb exhaust discharge pressure, and 750 deg total temperature. It is evident that 1200 lb is somewhere near the economical. There is no experience beyond this pressure, so that the exact performance can only be estimated.

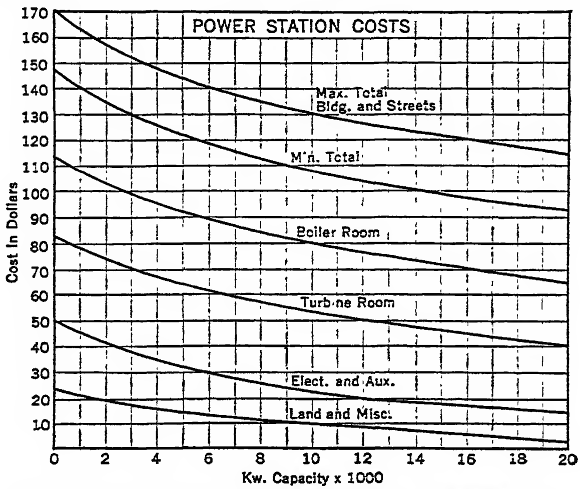

FIG. 10. Typical Costs of Steam Power Stations up to 20,000 kw Capacity

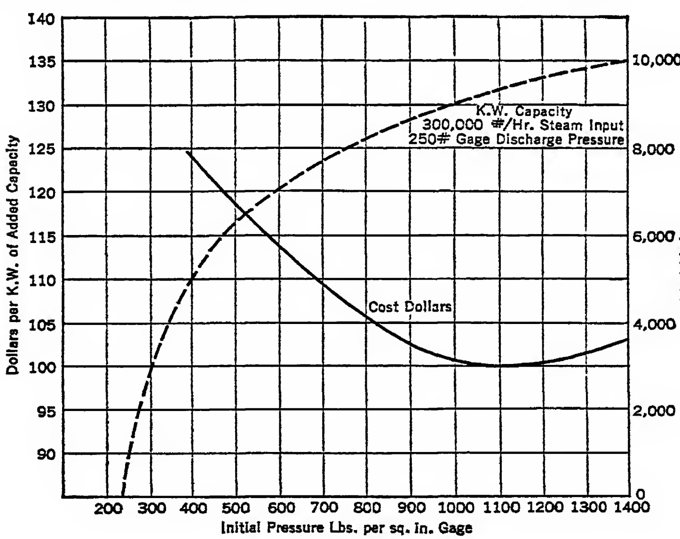

FIG. 11

The operating costs of a plant are variable and tend to decrease as the plant capacity increases. These costs are usually divided into operating labor, maintenance and supplies, fixed costs, and fuel. These costs are usually expressed as mills per kilowatthour. The cost, therefore, is a function of the total kilowatthours produced per year. This is expressed as load factor or the ratio of actual kilowatthours to maximum possible kilowatthours that can be generated per year. The total cost ranges from eight (8) to ten (10)

mills for small plants and from five (5) to seven (7) mills for large plants. These costs are divided—three (0.3) to five (0.5) tenths mills for labor; two (0.2) to four (0.4) tenths mills for supplies and repairs; two and one-half (2.5) to three and one-half (3.5) mills for fuel, and three (3) to five (5) mills for capital charges. These costs may be larger if fuel is above $5 per net ton or the load factor is below 35 per cent.

HYDROELECTRIC POWER STATIONS

By R. A. Hopkins and A. G. Cherry

8. SELECTION OF SITE

In the selection of a water-power site, approximate methods are used for preliminary studies, but in the final consideration of an important power site there is no substitute for an exhaustive study of its potentialities.

AVAILABLE POWER AND ENERGY. Analysis of the available power and energy includes the study of hydrological conditions (rainfall, runoff, and stream flow), head limitations, facilities for storage and pondage, and the conversion of the available flow and head into electrical energy.

The United States Geological Survey, the United States Weather Bureau, and many of the individual states publish much pertinent information on stream flow, climatology, geology, flood flows, and similar subjects.

When records of stream flow are not available for the vicinity of the particular site under consideration they may be obtained or approximated by one or more of the following methods:

1. Establishment of a gaging station at the site.
2. Deduction from local rainfall statistics.
3. Comparison with flow of adjacent or similar watersheds where records are available.

Stream flow data usually are summarized by the preparation of **hydrographs**, for which daily averaged flows are plotted chronologically, and **flow duration curves**, for which flow quantities are plotted against percentage of time of occurrence. Where storage is a factor, use frequently is made of the **mass diagram** for which the summation of daily or monthly flows is plotted chronologically for the entire period under study. The slope of the mass curve at any point represents the rate of flow, and from this curve the amount of storage required to regulate the flow to a definite minimum may be determined graphically. Particular attention should be given to data for years of maximum and minimum stream flow.

The **head** to be developed is subject to headwater and tailwater limitations. Headwater elevation is usually controlled by the cost of reservoir lands, hydraulic structures, and water rights, and by limitations due to the backwater influence of water impounded by the dam. The range of **headwater elevation** is influenced by the type of spillway, the reservoir operation, and flood flows. The range of **tailwater elevations** is usually established by the natural river levels at the lower end of the tailrace. In the case of overlapping developments the backwater influence of the lower development controls the tailwater levels of the upper development.

From the various combinations of headwater and tailwater conditions a **duration of head curve** may be plotted, which shows gross or net head plotted against time.

On the amount of **storage** that can be economically provided depends the extent to which the stream flow can be equalized, and the amount of installed capacity which can be justified. A run-of-river plant has no storage, and the stream flow must be used as it occurs. Sometimes, storage can be provided economically in a separate storage reservoir, particularly if the same storage would serve a series of developments on the same stream.

After the stream flow, head, and storage conditions have been analyzed, the available power and energy for dry, average, and wet years can be computed, and its conversion into electrical energy and absorption by available markets can be studied.

AVAILABLE MARKET. Since hydroelectric plants usually feed into power systems, it is necessary to analyze the power market to determine whether the power and energy available can be satisfactorily utilized. As a basis for this study the following information regarding the market or power system should be compiled:

1. Seasonal generating capacities of the steam and hydro stations in the system.

2. Annual or seasonal energy and capacity available to the system through interconnection with other systems.

3. Transmission line data, including estimated transmission losses to distribution points.

4. Data to predict probable future capacity and energy requirements of the system for several years.

Based upon these data, estimates of monthly system peak loads and energy requirements should be prepared for the future period under consideration. The estimates are usually based on data and records kept by the power company for previous years, and the future growth is predicted in accordance with past growth modified to suit general business tendencies, acquisition, or development of new market, and similar factors.

ABSORPTION OF POWER AND ENERGY BY THE MARKET. The power and energy available are next studied with particular reference to the market data to see whether they will satisfy the future system requirements on any reasonable operating basis.

Usually these system requirements are for additional capacity to satisfy additional peak load requirements, additional energy to provide additional kilowatthours on the base of the load, or a combination of these two. When additional system capacity is the major requirement and the stream flow at the site under study fluctuates widely, a relatively large amount of storage should be provided. Where the system energy cost is comparatively high, energy may become more important than capacity, in which case the justification of a reservoir would depend upon the need of increasing the natural flow during low water periods. Even on large rivers the absolute prime power is so small that sites are rarely subject to economical development on the basis of prime capacity alone. Such sites are economically justified only when they can be developed for large capacities and operated during much of the year on system peak loads, or at low load factors. Pondage is essential in all cases where capacity value is of importance.

PHYSICAL CHARACTERISTICS OF THE SITE. Generally, a satisfactory, though not necessarily economical, type of dam can be constructed on about any kind of foundation, but it is imperative that the engineer have the most complete knowledge possible of all foundation conditions. Data on foundations are usually obtained from core or wash borings or from test pits.

It is also necessary to investigate the geology and topography of the entire reservoir area in order to discover possible future sources of leakage to adjoining watersheds or to the stream below the dam.

Each site should also be considered for its practical advantages for construction, including particularly such items as accessibility and transportation facilities, possibilities for stream diversion during construction, and local supplies of materials, such as sand, gravel, lumber, etc.

9. TYPES OF DEVELOPMENTS

HIGH-HEAD PLANT. The high-head plant (more than 850 ft) requires a relatively small quantity of water in proportion to its capacity. The reservoir is usually a natural lake or a basin formed by low impounding or diversion dams. The water is conducted from the reservoir to the power station by canals, flumes, tunnels, pipe lines, or a combination of two or more of these types of waterways. The waterways are relatively small. The water wheels are usually of the impulse type, direct-connected to horizontal-shaft generators. Often two wheels per unit are used, one at each end of the generator shaft.

MEDIUM-HEAD PLANT. The medium-head plant (850 to 50 ft) may have the power house at a distance from the reservoir, or adjacent to or constructed integral with the dam. A large reservoir is common with this type of development. Where the total head is less than 500 ft, most of the head is usually developed by the height of the dam. When the power station is at a distance from the dam the connecting waterways are usually penstocks, although sometimes canals or flumes are used to conduct the water from the main reservoir to a high-level forebay closer to the station. The waterways are larger with the lower heads. The water wheels are usually of the Francis, reaction type, direct-connected to vertical-shaft generators.

LOW-HEAD PLANT. The low-head plant (less than 50 ft) usually has the power station located at the dam, either behind a forebay or constructed as an integral part of the dam. The dam is low and the reservoir small, providing only limited storage or pondage. The waterways are relatively large. The water wheels are usually of the high-speed, propeller type, with or without adjustable blades, depending on the range of head and the operating conditions. The wheels are usually direct-connected to vertical-shaft generators. Owing to the importance of conserving the head, particular attention must be given to the design of the intake, draft tubes, and tailrace. Fig. 1 shows a typical low-head plant.

EFFICIENCY. The maximum overall efficiency of a hydroelectric plant from reservoir water level to bus-bar will vary from 75 to 88 per cent, depending on length of waterways, head, and type of turbine. Medium-head plants with Francis type turbines will have the highest maximum efficiency, low-head plants with propeller type turbines slightly lower,

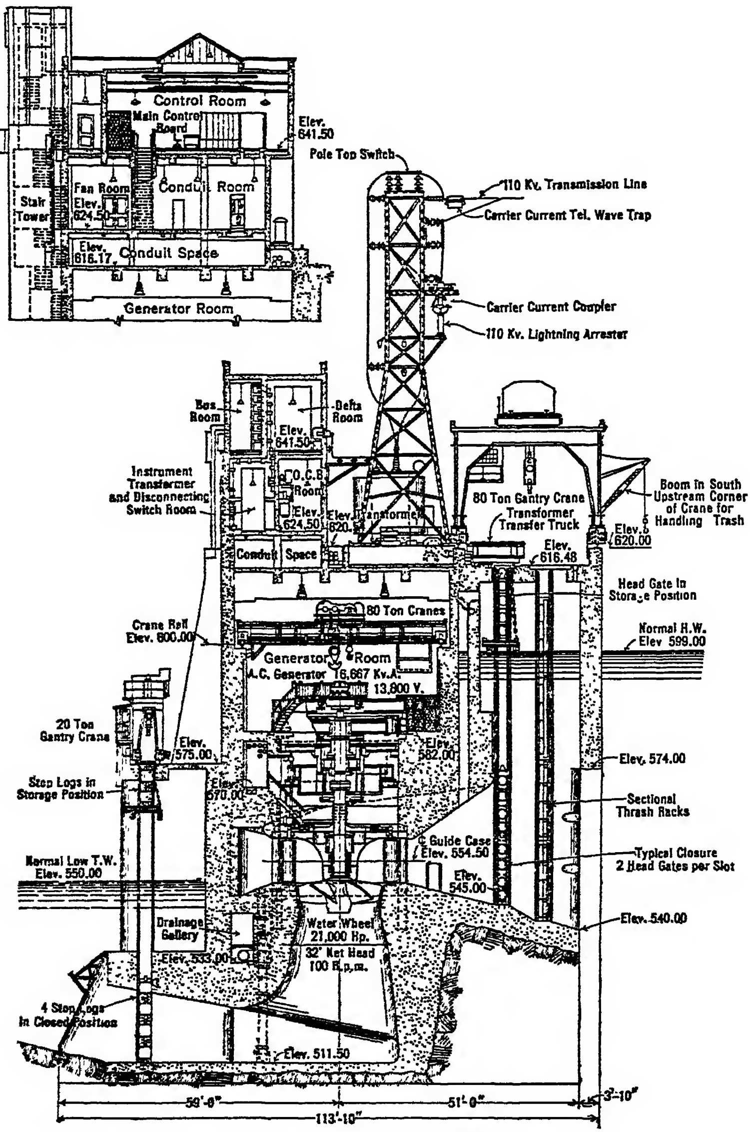

FIG. 1. Typical Low-Head Plant

and high-head plants with impulse wheels the lowest. The average overall efficiency of these plants will be somewhat less than 75 to 88 per cent and will vary over a wide range, depending on the method of plant operation, the variation in head, and the amount of wasted water.

PUMPED STORAGE DEVELOPMENT. The pumped storage development is becoming economical in special cases for peak load service. Many such plants are in successful operation in Europe and in America. An outstanding development of this type, the Rocky River Development of the Connecticut Light and Power Co., was completed in 1929. In this type of development, tidewater or water from a low-level stream or reservoir is pumped to a high-level artificial or natural reservoir during off-peak hours, the stored water being used to provide system peak capacity. Off-peak energy available from other steam and hydro plants in the system is used for the pumping operation. The maximum overall efficiency of a pumped storage plant from bus-bar ingoing to bus-bar outgoing will vary from 60 to 70 per cent. In Germany the Herdecke plant on the Ruhr River, with an installation of four 48,000-hp units under 534-ft head, develops an average overall efficiency of 65 per cent and a maximum of 68 per cent.

10. ELEMENTS OF A DEVELOPMENT

THE RESERVOIR. The chief function of the reservoir is to store water during periods of excessive stream flow in order that the surplus water may be used to advantage during periods of deficient flow.

The construction and operation of a reservoir are subject to local and federal regulations pertaining to items which involve public health and the conservation of natural resources, such as reservoir clearing, navigation facilities, fish propagation, and mosquito control.

Water stored in reservoirs is subject to losses from natural causes such as evaporation and leakage.

THE DAM. The choice of type of dam to be used in connection with the development of a particular site depends on many conditions, chief of which are the character of the foundation, the topography of the site, the height of the dam, and the availability of materials for construction. The various types of dams in common use are:

a. **Solid Masonry Dam.** Usually of mass or cyclopean concrete, but sometimes of stone masonry. May be of gravity or arch type or a combination. Requires rock foundation of unquestioned soundness and durability.

b. **Hollow Masonry Dam.** Usually of reinforced concrete but occasionally built of precast concrete slabs. Includes such special types as slab and buttress, multiple arch, and multiple dome. Ordinarily suitable for rock foundation of poorer quality than required for a solid masonry dam, although if high bearing stresses are used, the best rock foundation is necessary.

c. **Earth Dam.** Built of selected soils with or without core walls of concrete, wood piling, or steel sheet piling. Cores of sluiced material or puddled clay sometimes used. Suitable for soft foundations where adequate materials are available.

d. **Rock Fill Dam.** Built of rock fill either with concrete or timber deck or with a core wall. Suitable for rock foundation, where material is available, at less cost than concrete.

e. **Timber Dam.** May be of timber frame and deck construction or of rock-filled timber cribs. Seldom practical for heights exceeding 20 ft.

The **Spillway Section** of the dam, and sometimes all of the dam, is designed to discharge surplus and flood water. That portion not designed as a spillway is usually called a retaining or impounding section. The discharge capacity of the spillway is established so as to provide a margin of safety over the largest recorded flood. The spillway may be built with a free crest or with a controlled crest. The discharge over a free-crest spillway is controlled only by the water level in the reservoir. The discharge over a controlled-crest spillway is regulated by flashboards or crest gates.

Crest Gates of the following types are commonly used for gate-controlled spillways: sliding, roller (fixed wheels), Stoney (roller trains), radial or Taintor, drum, tilting, bear trap, and rolling. Gates may be operated by individual hoists or by traveling hoists.

Water may be discharged past the dam also through siphons or various types of sluice gates and valves.

Accessories sometimes required in connection with the construction of a dam include such structures as navigation locks, fish ladders, and log chutes.

WATERWAYS. Under this heading are classified all structures and equipment between the reservoir and the turbines, including the forebay, intakes, and water conduits.

The **forebay** is the pool adjacent to the intake. Many developments have no definite forebay, but when water is brought to the intake by canal or flume it is usually necessary to expand the section at the intake in order to reduce the velocity.

The **intake** is located at the upstream end of the conduits leading to the turbines and contains structures and equipment necessary to control the flow entering the conduits. The intake is usually provided with racks or screens to keep trash and ice from entering the conduits and with gates or valves to close off the waterways. Where the dam is of

earth or rock fill, intake towers isolated from the dam are generally used. In cold climates the intake is frequently housed to prevent freezing.

Trash Racks, in front of the intake, are usually constructed of round-edged vertical bars spaced from 1 1/2 to 8 in. on centers depending on the size and type of waterwheel runner. Water velocity at the bars is usually between 1.5 and 2.5 ft per sec.

Intake Gates of the following types are in common use: sliding, Stoney (roller trains), roller (fixed wheels), Sirnit (fixed wheels unequally spaced, resting in recesses in guide rail), caterpillar, radial or Taintor, cylinder (usually for circular intake towers). Intake valves of the following types are also used: rectangular butterfly (horizontal shaft), circular butterfly (horizontal or vertical shaft), needle or Johnson, rotary. The circular butterfly, the needle and the rotary valves and the cylinder gates are suitable for use under high heads; the remaining types are rarely used for heads exceeding 100 ft. Permissible velocities at the headgate openings vary from 2 to 10 ft per sec.

Artificial Water Conduits may be classified as: (1) open conduits; canals or flumes; (2) closed conduits; tunnels or pipes. Frequently a combination of two or more types of conduit will be found to be practical as well as economical. Long conduits are usually constructed in two portions: (1) the **high-level conduit,** which is designed for relatively low pressure and follows the topography or hydraulic gradient to a suitable location near the power house, from which point (2) the **penstock** conveys the water to the turbine, being designed for the necessary higher pressures. A **surge tank** or regulator is located at the junction of the high-level conduit with the penstock to prevent excessive changes in pressure during fluctuations in the flow.

Canals may be lined or unlined, depending upon the character of the ground through which they pass, the shape of cross-section, and the water velocity. Ordinary soils will stand velocities up to 2.5 feet per sec without erosion. Canals may be lined or paved with wood, rock, brick, concrete, or gunite.

Flumes may be of wood, concrete, or steel. In section they may be rectangular or semicircular, or they may be semicircular or semi-oval with vertical sides. The wooden flume is seldom used for permanent construction on account of its short life and high maintenance cost. In cold climates long flumes or canals are subject to ice troubles. (See Ice Prevention.)

The **tunnel** is the most permanent, but usually the most expensive, form of conduit. Whether designed as a flow or a pressure tunnel it is usually lined for additional structural safety, to minimize head losses by providing a smooth-surfaced and uniform section, and to reduce losses of water by leakage. Tunnel linings are usually of reinforced concrete, although brick linings have occasionally been used.

Pipe Lines may be of wood, concrete, or steel, although concrete pipe lines are rarely used except for very short sections.

Wood-stave Pipe is used extensively for conduits under moderate heads in locations where the topography is favorable. It is relatively cheap in first cost, and if continuously filled has fairly long life. It is particularly adaptable for use in inaccessible locations. Two types of wood-stave pipe are in general use: (1) machine-banded pipe, and (2) continuous wood-stave pipe. The former is used for heads up to 500 ft and in diameters up to 42 in. The latter is built up in place and has been constructed up to a diameter of 16 ft.

Steel Pipe Conduit is usually constructed with either riveted or welded joints, certain advantages being inherent in each type. For penstocks under very high heads, forged-steel pipe has been used successfully. Steel pipe when properly painted and maintained has a long life. In the design of a steel pipe line or penstock, careful attention must be paid to such details as supporting saddles, expansion joints, and anchorages. Permissible velocities in steel pipe are as high as 20 ft per sec for high heads, but for ordinary heads usually range from 8 to 12 ft per sec. Maximum economical velocity will generally depend on the length of conduit and the load and head conditions.

TAILRACE. The tailrace is the channel or waterway that conducts the water from the discharge end of the turbine draft tubes back to the natural river channel. Except under very favorable topographical conditions it is rarely economical to obtain additional head by extensive tailrace excavation. Permissible tailrace velocities usually vary from 3 to 5 ft per sec, although somewhat higher velocities are permissible for the higher head plants.

Impulse wheels discharge above tailwater level, and the tailrace therefore has no important effect on their operation other than to reduce maximum water level and permit lower setting of the water-wheel.

SUBSTATION. Because the hydroelectric station is usually at a distance from the load-center, a step-up substation and high-voltage transmission lines are usually required. The substation is sometimes constructed as a part of the power station. This design is particularly advantageous at high-head plants in mountainous regions where level ground area is limited.

The **outdoor substation** is usually preferred where space is available. The cost of

foundations and steel structures for the outdoor substation is considerably less than that of the housing and barriers for the indoor station, and the cost of outdoor equipment is only slightly more than that of indoor equipment. The outdoor substation may be located on the roof of the power house, on the dam, or on the ground. It should be as close as practicable to the power house in order to reduce the length of main and control cables and to afford convenient access by the attendants. The substation should be adequately fenced to exclude all unauthorized persons.

MISCELLANEOUS PERMANENT STRUCTURES AND FACILITIES. Various miscellaneous structures and facilities which may be required in connection with a hydro-electric development include:

a. Permanent railroad connection for handling equipment and supplies.
b. Permanent highway connection for easy access to plant.
c. Operators' quarters (houses, clubhouse, water supply, sewage system, lighting).
d. Parking space for visitors and garages for employees.
e. Office building (occasionally provided for important stations).
f. Storage building.
g. Boats and boathouse for reservoir patrol.
h. Gage houses (for automatic recording of water levels).

The extent of these facilities will vary with the size and importance of the development and with its distance from settled communities.

11. WATERWHEELS

Waterwheels are classified broadly in three general types: impulse, Francis, and propeller. Ordinarily impulse wheels are used for high heads, Francis wheels for intermediate heads, and propeller wheels for low heads. There are no well-defined limits separating the head ranges for these three types of wheels. Generally, impulse wheels are used for heads above 850 ft, Francis wheels for heads from 850 to 50 ft, and propeller wheels for heads below 50 ft.

The relation of the waterwheel capacity to the generator capacity should be based on the expected variations in head, flow, and load requirements, since the efficiency of the waterwheel varies considerably with load and head variations. The waterwheel capacity is sometimes selected so that at normal head the "best gate" capacity, that is, the most efficient load, coincides with the rated generator capacity. If capacity under heads lower than normal is important the waterwheel may be of sufficient capacity to deliver full generator capacity at a head lower than normal.

Generally, it is economical to use the smallest number of units which can be operated to use the water economically with respect to the load requirements. However, at run-of-river plants, it may be desirable to install units of different capacities in order to use the water most economically under varying conditions of flow and head. At low-head plants a similar result may be obtained by the use of propeller runners with adjustable blades.

While it is desirable to use waterwheel speeds as high as practicable in order to keep down generator size and cost, it is also necessary to maintain a balance between head and speed to obtain smooth operation and avoid serious pitting of the runners. Wheels are selected on the basis of their specific speed, which may be defined as the revolutions per minute at which a homologous runner would operate while developing 1 hp under 1-ft head. The relation between specific speed and actual speed is expressed by the formula:

$$N_s = \frac{N\sqrt{P}}{H^{5/4}}$$

in which N_s = specific speed.
N = speed of runner in revolutions per minute.
P = capacity of runner in horsepower.
H = head in feet.

It will be seen that high-head runners have low specific speeds while low-head wheels have high specific speeds.

Creager and Justin in Hydro-electric Handbook give the following empirical formula for determining the maximum safe specific speed to avoid pitting of the runners of Francis wheels for various heads:

$$\text{Max} \quad N_s = \frac{5050}{H + 32} + 19$$

Speeds based on this formula are frequently exceeded in practice since a small amount of pitting is not objectionable, and even in cases of considerable pitting the saving in first

cost of equipment due to the higher speed may more than offset the cost of repairing the pitted runner.

The speeds derived from the specific speed formula are subject to correction to conform to the nearest synchronous speed which is determined from the equation:

$$S = \frac{120f}{p}$$

in which S = synchronous speed in revolutions per minute.
f = frequency in cycles per second.
p = number of poles of generator. always an even number.

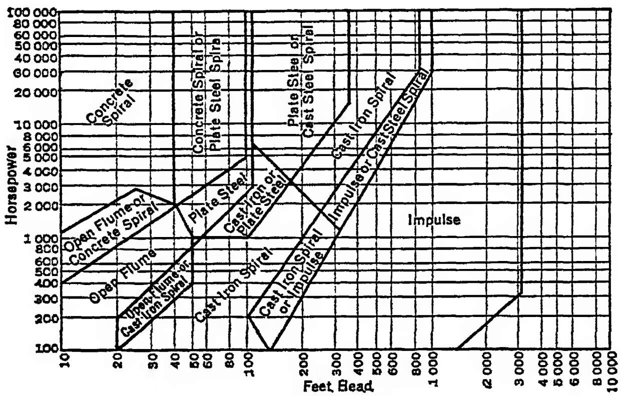

Fig. 2. Type of Unit and Setting

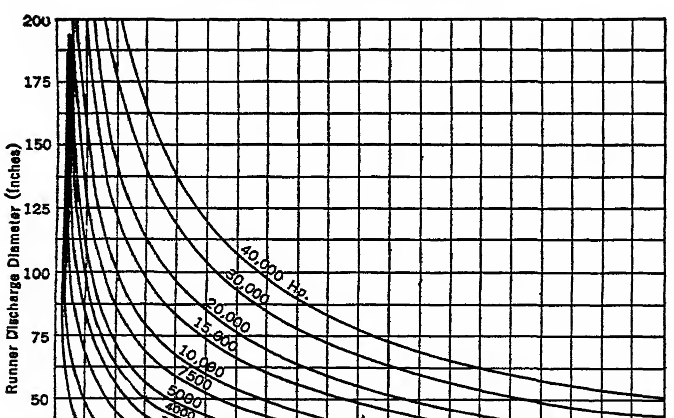

(*Courtesy of Messrs. Creager & Justin*)

Fig. 3

The selection of the type of unit and setting appropriate for various conditions of head and power is shown in Fig. 2.

For vertical-shaft units of the Francis or propeller type, the dimensions of the setting are in general a function of the discharge diameter of the waterwheel runner, and Fig. 3

gives these discharge diameters for various combinations of head and power at normal specific speeds. Various overall dimensions of the turbine setting with reference to the discharge diameter of the runner are shown in Fig. 4. This figure shows a concentric

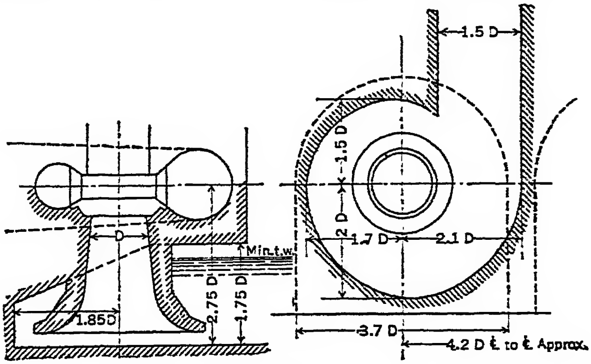

FIG. 4

draft tube. A draft tube of the elbow type would usually require some additional depth and length.

12. GOVERNORS

An approximate formula for the governor capacity required for a particular unit is:

$$C = \frac{50\,P}{\sqrt{H}}$$

in which C = governor capacity in foot-pounds.
P = capacity of unit in horsepower.
H = head in feet.

For large-sized, high-head units this value should be decreased somewhat, while for low-head, open flume units it should be slightly increased.

The governor flyballs may be directly geared to the main shaft or they may be mounted on the governor and driven by one of the following means: shaft and bevel gears from main shaft, belt drive from main shaft, or alternating current motor drive from transformer on main generator leads, from slip-rings on direct-connected exciter or from small alternating current generator on main shaft.

Governors are almost invariably operated by oil pressure, although in the past various other liquids have occasionally been used. The oil pressure required for operation is usually 150 lb per sq in. or less, and the capacity of the oil-pressure system is a function of the governor capacity and the number of units. Generally an accumulator or pressure tank is provided for each unit or pair of units, and uniform pressure during operation is maintained by use of a substantial air cushion in the top of each tank.

13. GENERATORS

TYPE. Waterwheel generators are usually revolving-field, synchronous type with salient field poles. There appears to be no immediate limit to the capacity that can be built. The speed is rarely over 720 and is sometimes as low as 60 rpm. Vertical-shaft generators are much in the majority. The vertical-shaft construction, while dictated by the waterwheel, is at the same time a distinct advantage in the design of a large-diameter, low-speed generator. Generator voltages up to 24,000 volts are feasible at the present time, but as transformers are nearly always used between the generators and the transmission line, there is usually no reason for exceeding 15,000 volts.

Runaway Speed. The runaway speed of a waterwheel with gates open, governor out of action and no load on the generator, is from 160 to 200 per cent of rated speed. When full load is suddenly dropped, with the governor in action, set to close the gates in from 2 to 5 sec, the speed will rise to 120 to 140 per cent of rated speed. A shorter time setting of the governor would cause excessive pressure in the penstock and wheel case due to inertia of the moving water. Furthermore, it is not feasible to use a quick-closing valve

ahead of the gates to trip closed in case of governor trouble, for this, too, would build up excessive pressure. As a consequence of this inability to shut off the input suddenly, as can be done with a steam turbine, the waterwheel generating unit may attain a speed of 140 per cent in case of loss of load and 200 per cent in case of accident.

The **flywheel effect** of the generator is depended upon largely to limit the speed variation with sudden load changes, since the governor action must be relatively slow, as explained above. A large flywheel effect not only gives closer speed regulation but in some cases is desired to improve system stability. Generators of standard design usually have sufficient flywheel effect for this purpose. In exceptional cases where it is not sufficient, it can be increased, at considerable cost, by increasing the diameter or massiveness of the rotor or by adding a flywheel.

STABILITY. A long transmission line, when lightly loaded or open at the far end, accepts low power factor, leading current from the generator, and this current in the armature windings tends materially to increase generator voltage. The generator field excitation may be reduced as the armature reaction increases, so as to maintain normal voltage, but if the line is long and the generator not sufficiently large, the field excitation would have to be not only reduced to zero, but even reversed in order to avoid excessive voltage. Operation with reversed field excitation is not considered good practice as the generator is likely to be unstable, lose synchronizing power, slip a pole, and build up excessive voltage. The charging of a line with two generators has also been found difficult because the machines do not always parallel easily with weak excitation. A generator of normal design can be expected to deliver satisfactorily a charging kva at zero power factor leading equal to about 75 per cent of its rated kva without instability and without developing more than rated armature voltage. If this is not sufficient to meet conditions, special generator design, involving stronger field excitation and less armature reaction, must be resorted to, although the size and cost of the machine may be considerably increased by these changes.

CONSTRUCTION. The flame-cut, welded and bolted steel frame construction, now conventional, is more reliable, mechanically, than the former cast-iron construction, is of lighter weight, can be fabricated in less time, and is more readily adapted to the ventilating and construction requirements of the turbine room. In some cases the generators have been designed for partial exposure to the weather, omitting the conventional high turbine room and serving the machines with an outdoor gantry crane.

Fig. 5 shows a cross-section through a typical vertical waterwheel-driven generator of the **overhung,** or **umbrella** type. This particular type, distinguished by having one combination guide and thrust bearing just below the rotor hub and carried by the lower bracket, offers advantages of less overall height and simpler bearing layout than the formerly more common type having two guide bearings, one below and one above the rotor, and a thrust bearing at the top of the machine, supported by the upper bracket. It has a disadvantage, for higher speeds, in the free length of shaft above the bearing. The combination guide and thrust bearing simplifies the lubrication. The heat is removed by water-cooling coils. The oil level gage and the thermometer are essential. In some overhung designs the rotor arms are sloped to bring the center line of the field more nearly into the plane of the guide bearing and further to reduce the total height of machine. The rim of the rotor is sometimes made structurally separate from the arms so that the arms are relieved of all centrifugal forces from the rim, thereby greatly simplifying the structural design. The rotor is sometimes covered with thin steel plates to reduce windage.

VENTILATION AND FIRE PROTECTION. Three general methods of **generator ventilation** are in common use. (1) Air may be taken from the room, passed through the generator, and discharged into the room by means of the fan action of the rotor and without external ducts. This allows no control of generator-room air condition and is used only in the smaller stations. (2) Air may be taken from the room or from outdoors, passed through the generator, and discharged to the room or outdoors by means of the fan action of the rotor, assisted if necessary by external motor-driven fans, and by means of external ducts and dampers. Air is often taken from a point over the tailrace where clean, moist air is available. The ducts should be short, direct, and designed to minimize friction. They are often built into the building structure. (3) Air may be recirculated through the generator and a water-cooled heat exchanger by means of the fan action of the rotor and a compact, closed duct system. Cooling water pumps are generally needed. This method has the advantage of constantly clean air, small duct space, minimum fire hazard, and minimum noise. The advantage of clean air is indicated in one case of open ventilation where a test showed 11 per cent cooler generator operation after the air passages had been cleaned. Closed ventilation has the disadvantage of requiring water pumps and of not tempering the generator-room air.

Fire Protection by means of perforated water pipes arranged to spray the windings is applicable to either system of ventilation. When carbon dioxide or other similar systems are used with open ventilation, self-closing, electrically tripped doors may be used to confine the gas in the machine in case of fire, but for these latter systems of fire protection the closed ventilating system is to be preferred.

Brakes are required on the waterwheel driven generator to bring the unit to rest. Without brakes a comparatively slight leak at the turbine gate would cause the machine to rotate indefinitely after being shut down. For vertical units the brakes act against

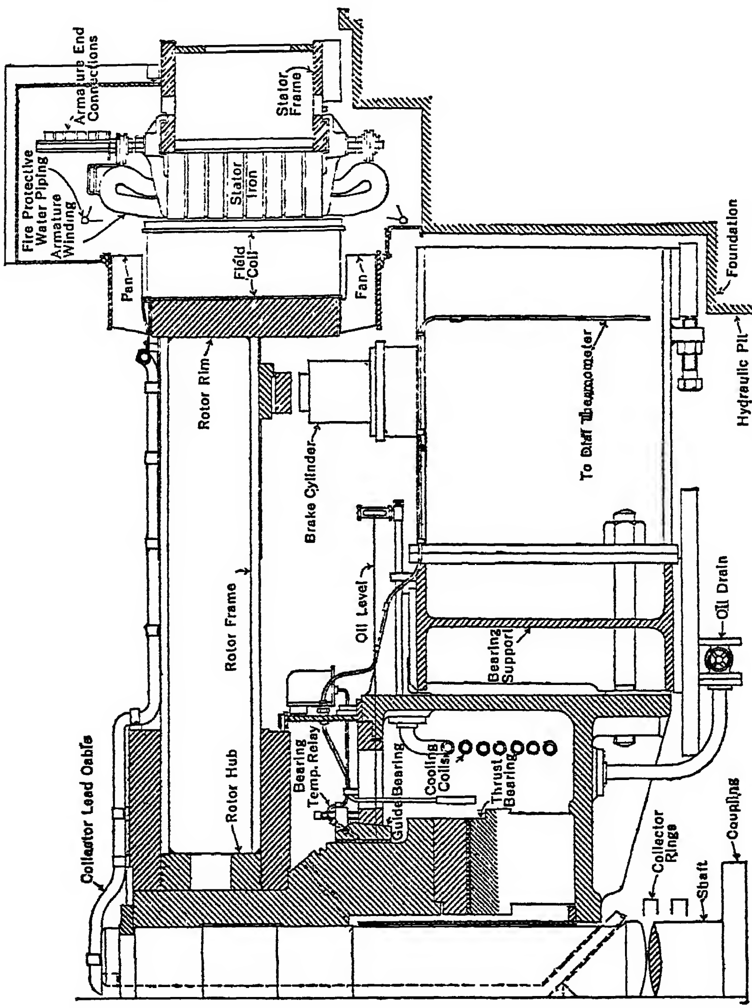

FIG. 5. Cross-section of Typical Overhung Generator

a plane surface on the lower face of the rim of the rotor. They are sometimes designed to be used also as hydraulic jacks to raise the rotating element off the thrust bearing to a position where it can be blocked for inspection. For horizontal machines the brake consists of two or more shoes in contact with a brake pulley. Brakes may be operated by magnets, oil, water, air, or mechanical linkages. The most common medium is air for braking and oil in the same cylinders for jacking.

14. AUXILIARY POWER SUPPLY

The auxiliaries of the hydroelectric station are as a rule driven by electric motors. In some cases the oil pumps and exciters are driven by the main units for maximum reliability. When oil pumps and exciters are motor driven the importance of the service justifies duplication in the source of supply and in parts of the distribution system. Normal and emergency auxiliary power is usually obtained from one or more of the following sources:

Transformer on station bus.
Transformer on generator leads.
Line from another station.
Auxiliary generator driven by main waterwheel.
Auxiliary generator driven by auxiliary waterwheel.
Auxiliary generator driven by fuel.

The transformer on the station bus has low maintenance and operating cost although it requires one or more heavy-duty oil circuit breakers, which in some cases may constitute an important item of initial cost. It is reliable during normal operation, but is not independent of main system disturbances. In many stations both the normal and the emergency auxiliary power are supplied by transformers on the bus.

The transformer on the generator leads is simple and efficient, and usually the oil circuit breakers can be omitted, thus reducing the cost. On the other hand, a larger number of small transformers is usually required than with transformers on the bus, and if this is the case the cost and efficiency may be less favorable. The scheme is reliable during normal operation but is subject to main system disturbances. Each generator may drive its own auxiliaries, independent of the others, but if this is done some common source must be provided for the several auxiliaries which are common to all units and for driving oil pumps and exciters while starting up. The common bus may be fed from one live generator at a time by means of automatically selecting switches, or from the bus through a transformer.

The line from another station is not likely to be reliable as a normal supply, but may be used to advantage as an emergency source. If it can be depended upon when needed it may be of great value when the station is shut down and the transmission lines are de-energized.

The auxiliary generator driven by the main waterwheel, or shaft generator, as it is sometimes called, is fairly simple and efficient but is quite expensive in case of a slow-speed main shaft. It is also more expensive to maintain and operate than transformers. It is reliable and independent of electrical disturbances on the main system but is subject to speed variations. In cases where exciters are driven by this source, there is a tendency for a system disturbance to become intensified owing to speed variation of the exciters.

The auxiliary generator driven by an auxiliary water wheel, or house generator, as it is sometimes called, is the most expensive in first cost, maintenance, and operation of all schemes mentioned. Its efficiency is less than transformer or shaft generator efficiency. It may in some cases be subject to disturbance from ice and trash. It has the decided advantage of being entirely independent of the main system and always available whether the main units and transmission lines are energized or not.

The auxiliary generator driven by fuel is sometimes favorable as an emergency source for use when the station is shut down and disconnected from its transmission lines. In some cases, only the supply to certain important motors such as those on spillway gates is supplemented by a small fuel-driven emergency auxiliary generator.

A source that can be depended upon when the station is shut down is essential if advantage is to be taken of the hydroelectric station's inherent quick-starting ability to support steam stations which require a much longer starting period. Head gates must be operated and in most cases governor and lubricating oil pumps must be started before the main units can be started. In some instances it is imperative that the station be started when the transmission lines are not energized. Power for this purpose may be taken from an auxiliary line from an outside source, or from a waterwheel-driven auxiliary generator.

Voltages commonly used for auxiliary power systems are 2200, 550, 440, and 220 volts. The most economical voltages to use are indicated by an analysis of the wiring and the control equipment, taking into account the locations of the transformers, buses, and motors. In many of the larger stations it is found economical to use 2200 volts for the large motors and one of the lower voltages for the smaller motors.

Among the many possible auxiliaries which may require electric power supply are the following: Head gates, sluice gates, trash rack rakes, navigation locks, forebay ice prevention, trash rack heating, gate guide heating, filler gates, fish protection. Lubricating oil pumps, governor oil pumps, lubricating and insulating oil handling and filtering pumps, house service water pumps, generator cooling water pumps and fans, air compressors, transformer oil and water pumps and blowers. Elevators, incline railway, car pullers, turbine room crane, gantry cranes, transformer hoists, building ventilating fans, water coolers, water heaters, space heaters, drying ovens, machine shop. Exciters, battery charg-

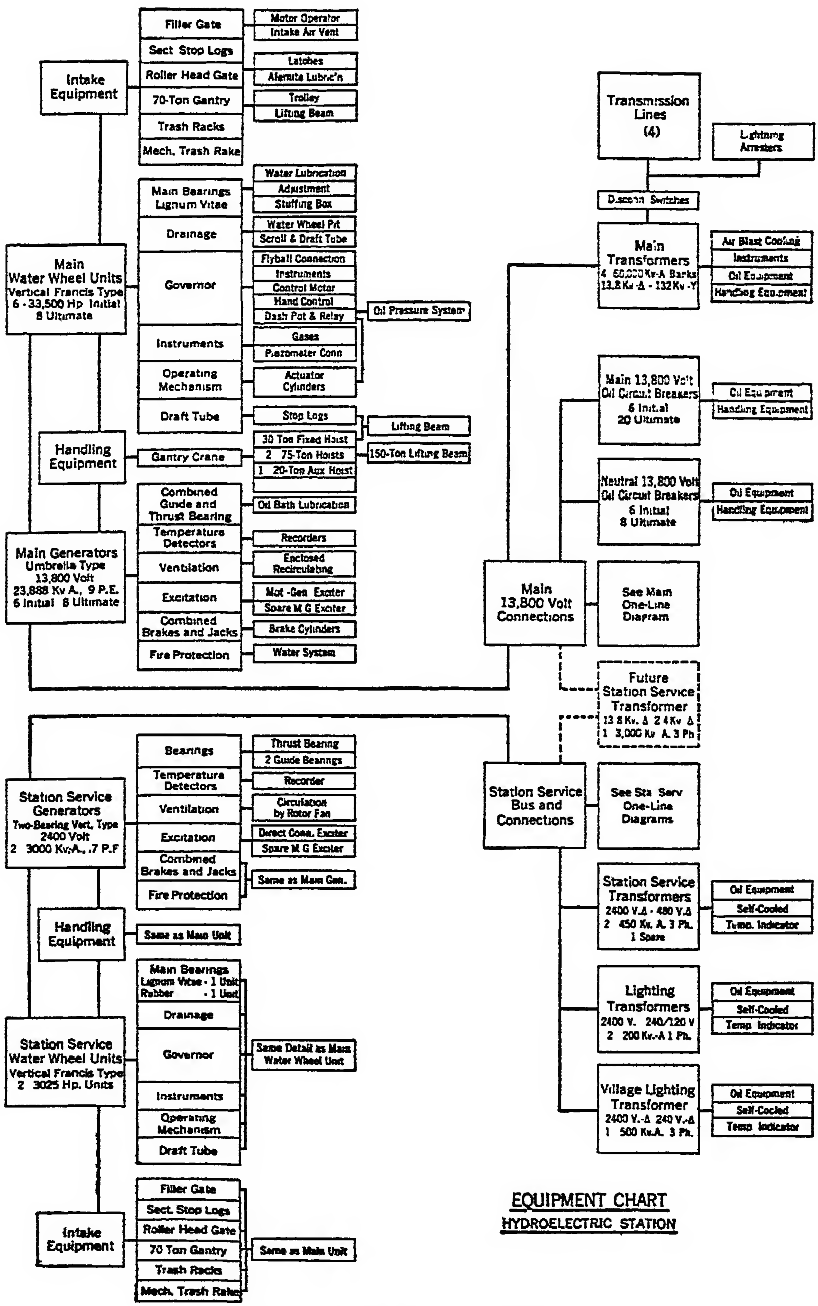

Fig. 6. Typical Equipment Chart

ing, telephones, signals, clocks, water level recorders and indicators, power receptacles, transmission line ice melting, local lines, village light and power. Lighting for power house, switch yard, grounds, storehouse, locks, employees' cottages, display signs.

It is sometimes found advantageous to diagram the various elements of main and auxiliary equipment in order to express their relation to each other in a manner similar to the better-known electrical single-line diagrams. A typical equipment chart of this type is shown in Fig. 6. This chart shows the general relation of the main equipment and principal auxiliaries. In practice, a chart of this kind is supplemented by other charts in greater detail and by flow diagrams for the various piping systems. It is also cross-referenced to the electrical single-line diagrams. These charts are useful in studying the equipment requirements and arrangement and for checking over the completed station arrangement prior to and during preliminary operation.

Excitation

POWER. The amount of excitation required by a 60-cycle, three-phase, synchronous, salient-pole, waterwheel-driven generator of normal design, operating at rated load and voltage and 0.8 power factor, may be roughly estimated by the following empirical formula:

$$\text{kw} = 10\sqrt{\frac{K}{S}}$$

where kw = excitation in kilowatts.
K = generator capacity in kilovolt-amperes.
S = generator speed in revolutions per minute.

Voltages used for the excitation system are 125 volts for smaller systems and 250 volts for larger systems.

Exciter drive should be from sources separate from the main power so that main power disturbances will not be reflected into the excitation system. At least one exciter should be driven by a prime mover to provide for starting up the station, unless a reliable source of motor drive can be assured when all main units are shut down.

15. ICE PREVENTION

The operation of hydroelectric plants located in cold climates requires definite provision for combating ice during the winter seasons. Sometimes ice is encountered in such large quantities that it must be cut and sluiced away, involving considerable expense and waste of water. Except in extreme cases, however, a plant can be kept operative by a small expenditure of energy properly applied at vital points if adequate provision is made in the original design.

Gates should be protected from excessive pressure of sheet ice, and their sills, guides, and seals should be kept free of ice sufficiently to allow operation. This has been accomplished by applying small amounts of steam or electric heat inside the gates and at imbedded parts of the guides which were made hollow for this purpose. To secure economical heating it is very important that the downstream side of the gates, exposed to the cold air, be thoroughly housed with heat-insulating material and that the heat inside the gates be evenly distributed by fans, chimneys, and other means. The data in Table I are from N.E.L.A. reports of successful installations.

Table I

Installation	1	2	3	4
Size of gate	50 × 19.5	50 × 33	40 × 24	30 × 36
Kw in gate proper	35	36	45	36
Kw at guides and seals	10	16	16	12
Total kw	45	52	61	52
Watts per sq ft	46	31.5	63	47.5

Flashboards should be protected against surface ice. The most effective method appears to be to maintain an open channel clear of ice along the upstream face about 3 or 4 ft wide. This has been accomplished by placing electric heaters or low-efficiency lamps in reflectors just above the water surface, covering them with canvas or heavy paper. Installations of this type have been reported using from 6 to 17 kw per 100 ft of flashboards.

Air Bubbler Systems have been used to maintain an open channel clear of ice along the upstream faces of gates and flashboards. A bubbler system consists of perforated pipes or groups of small nozzles installed along the lower, upstream face of the gates or flashboards, and supplied with air under pressure, which rises and creates a circulation of

warmer water from the bottom of the pond to the surface. The data in Table II are taken from N.E.L.A. reports of installations of this type.

Surge Tanks of small size are likely to freeze, especially during periods of steady load. Satisfactory performance in cold weather has been obtained by insulation alone or by insulation with steam or electric heat. When heat is applied in the air space between tank and insulating sheathing, part of it is obviously lost through the sheathing, and when applied directly to the water, part is obviously lost by exchange of water between tank and penstock. The most economical application, therefore, depends upon local conditions. It is thought by some that conditions generally favor applying the heat directly to the water. In a few cases, freezing has been prevented by anchoring a wood pole in the tank in such position that its motion breaks up any surface ice which might start to form.

Penstocks, if exposed to the weather and designed for low velocity, may partially freeze, causing loss of head, and in thawing again, the ice may pass on in sufficient quantities to clog the turbine gates. The usual precaution against this trouble is to insulate or bury the penstock. It is an advantage, in this connection, to take the water from the lower part of the reservoir so as to secure warmer water.

Trash Racks must be protected from sheet ice, the pressure of which might injure the structure, and from frazil ice, which tends to adhere to the bars and clog the passages. Protection from sheet ice is afforded in some designs by a curtain wall in front of the rack extending down well below the surface of the water. Frazil ice is usually the greatest of all ice hazards. Although it generally appears for only a short time in early winter and occasionally in the spring, it is likely to clog the racks at these times sufficiently to curtail the station output seriously. At one plant not more than 25 per cent of the available water could be used during winter months before rack heating was installed. Only where the pond or forebay is of large size and the intake is deep, can complete immunity from frazil ice be assured. Trouble from frazil ice is prevented in some cases where the waterwheels have large passages, such as with the propeller-type wheel, by raising the trash racks during the frazil ice flow, allowing the ice to pass through the plant. Air bubbler systems have been installed in front of the racks, designed to carry the frazil ice up to the surface where it can be sluiced off. In one plant a mechanical rake of special design is used successfully to clear racks of frazil ice. The method most extensively used consists of heating the trash rack bars. It is found that the bars need be raised only a fraction of a degree above the freezing temperature to prevent the frazil sticking to them. If the top of the rack extends above the surface of the water, and is enclosed, heat can be applied at this point by means of warm air fans or steam coils, and some heat will be carried down in the rack by conduction through the bars. This method has proved successful in moderately cold locations. In a number of installations, some of which are located in places where the climate is severe, the racks are heated by passing electric current through them. The energy required to keep the racks clear, in watts per square inch of bar surface exposed to the water, has been reported as 0.87, 0.88, and 0.89, respectively, from three installations which have successfully passed through one or more ice seasons. The power factor has been found to vary from 0.72 to 0.83. The impedance of the rack

Table III

Installation	1		2	
	Volts	Ohms	Volts	Ohms
A-c 60-cycle tests	15	0.078	44	0.264

	34	0.059	160	0.163
D-c test	....	0.018	.....	0.042

is subject to wide variation depending upon the quality of steel, size, and shape of bars, spacing of bars, and arrangement of bars in series-parallel circuits. It is also probably dependent to a considerable extent upon the voltage, the frequency, and the water resistance. Tests upon trash racks installed in 1930 and 1931, respectively, provide the data in Table III.

16. COSTS

The cost of hydroelectric developments probably varies more widely than that of any other class of projects. Such items as land requirements for reservoir and plant, water rights, reservoir clearing, relocation of roads and railroads, the length and height and type of dam, the necessity for and layout of tunnels, pipe lines, forebays, tailraces vary greatly for each development. The cost per kilowatt of the initial installation will usually be higher than the cost per kilowatt of the ultimate installation, where the plant capacity is increased over a period of years, since such items as the reservoir, dam, and headworks must be completed in connection with the initial development.

Accurate cost figures of hydroelectric developments are difficult to obtain for publication since the complete cost of a development includes not only the costs of the physical structures and machinery, but also the costs of preliminary investigations, surveys, foundation exploration, land acquirement, federal and state licenses, financing, and other, less tangible items. For the above reasons no attempt will be made to give overall costs of developments beyond the broad statement that the cost per kilowatt will range from about $90 under exceptionally favorable conditions or $125 for more general conditions for a large plant to $250 for a small plant constructed under disadvantageous conditions. Unit costs for individual items of construction will likewise vary over a wide range depending on location, distance from material supply sources, prevailing wage scales, and so forth.

The procedure suggested for obtaining a preliminary cost estimate for the development of a proposed site is to prepare a preliminary design of the project and base the estimate on this preliminary design and the best information available on local unit costs of structures and equipment.

A suggested outline for the preparation of a complete project estimate is as follows:

1. **Preliminary and General Expense.** Includes cost of preliminary investigation and exploration, organization and legal expenses, franchises, federal and state licenses, financing, and interest and taxes during construction.

2. **Engineering.** Includes studies of economical development of the site, preparation of general and detailed plans, specifications for structures and equipment, purchase, inspection and expediting of equipment and material, and general consulting services.

3. **Hydraulic Work.** Includes land and water rights, surveys and borings, reservoir basin clearing, relocation of railroads and highways, removal of buildings, river diversion, cofferdams, dams, dikes, headworks, forebay structures, waterwheel settings, intake gates, crest gates, stop logs, hoists and handling equipment, canals, flumes, tunnels, pipe lines, penstocks, surge tanks, turbine equipment, tailrace.

4. **Electrical Work.** Includes generating and excitation equipment, transformers, switch gear, auxiliary power supply, station wiring, electrical control, signal and telephone systems.

5. **General.** Includes power station building, station yard, private roads, railroad serving development, auxiliary equipment, shop equipment, auxiliary buildings, permanent operators' quarters, preliminary operation and tests.

6. **Substations.** Includes land, substation buildings, equipment foundations, switching structures, electrical equipment switch gear, wiring, auxiliary equipment, preliminary operation and tests.

7. **Overhead Transmission Lines.** Includes land, right-of-way, clearing, fencing, foundations, steel and wood towers, conductors, insulators, communication and maintenance facilities, preliminary operation and tests.

INTERNAL-COMBUSTION POWER STATIONS

By W. A. Sloan

18. INTERNAL-COMBUSTION ENGINES

Applications

The Diesel engine is an excellent prime mover for electrical generation in plants up to about 10,000 kw. It has the advantages of low fuel cost, short periods for warming up, and no standby losses, and it requires little water. Small sizes are about as efficient to operate as large ones, whereas with steam engines or turbines the steam rates are often twice as great in small units as in large. However, unlike the steam turbine, the plant floor area and cost increase nearly proportionally with capacity, which fixes an economic limit of from 5000 to 10,000 kw for Diesel generating stations at present.

Except where a large supply of by-product gas is available, as in steel mills, the Diesel engine is the present choice of engine in the small power field. It is used by public utilities, municipalities, hotels, and factories.

Types of Engines

PRINCIPLE. The internal-combustion engine is a prime mover whose action depends upon the heating of air by burning fuel within the cylinder. This fundamental principle is the same regardless of the fuel, which may be a combustible gas, vapor, or oil. Pulverized coal has been used successfully but is in the experimental state. The combustion causes a rapid rise in temperature and pressure in the products of combustion, which expand behind a piston moving it forward. (Rotary gas engines or gas turbines are still [1936] in the experimental state.) In its simplest form the internal-combustion engine is similar to a reciprocating single-acting steam engine, the reciprocation of the piston in the cylinder being changed to rotation of the shaft by means of a crank and connecting rod.

CLASSIFICATION. There are two distinct methods of applying the fundamental principle of operation of internal-combustion engines, so that, with reference to the thermodynamic cycle, engines may be classified as either explosion or Diesel.

In the **explosion type**, air which has been mixed with a suitable quantity of fuel in gaseous or vaporized form is moderately compressed in the cylinder and is then ignited, giving a rise in pressure which is almost instantaneous. The ignition is accomplished by an electric spark. In this class belong all gas and gasoline engines and some oil engines. The compression must be so regulated that the temperature of ignition is not reached before the spark jumps, and the mixture of fuel and air must be of such proportions that it will burn rapidly. (See Section 17, Art. 17.)

The **Diesel engine** compresses air only, to a predetermined temperature above the ignition point of the fuel. The fuel is then forced into the cylinder in a finely atomized state and ignites spontaneously without explosion, by reason of the heat resulting from the compression of the air. In the pure Diesel the fuel is injected into the cylinder by means of a blast of high-pressure air, and the timing of injection is such that there is no rise in pressure during combustion. The development of engines using mechanical means of injecting fuel into the cylinder (commonly called solid-injection Diesel) gives rise to a cycle somewhat different from the constant-pressure combustion of the pure Diesel. The recognized definition of a Diesel now is: an engine in which the fuel, injected after compression is practically completed, is ignited solely by the heat resulting from the compression of the air supplied for combustion.

There is one type of solid-injection engine, commonly called **semi-Diesel**, which has lower compression than the Diesel, so that the temperature is below that required for ignition, and in which sufficient additional heat is supplied by a hot plate or bulb forming part of the combustion chamber. The plate or bulb must be heated for starting, after which the heat of combustion will keep it at the required temperature, unless the load is too light. These engines are less efficient than those having compression ignition and are rough running in multicylinders because of the uncertainty of ignition.

Any of the thermodynamic cycles for internal-combustion engines may be mechanically performed in an engine giving an impulse in one end of each cylinder in either one or two revolutions of the crankshaft.

An engine requiring two revolutions of the crankshaft to complete its working cycle is called a four-cycle engine, having reference to the four piston strokes in two revolutions. The following sequence of operations takes place during four consecutive strokes: (*a*) inspiration of a mixture of gas and air during an entire stroke, or air only in the case of a

Diesel; (*b*) compression during the second (return) stroke; (*c*) ignition or injection causing combustion at or near the dead center and expansion during the third stroke; (*d*) expulsion or exhaust of the products of combustion during the fourth (return) stroke.

In the two-cycle engine the working cycle is completed in one revolution of the crankshaft or two strokes of the piston. Starting with the combustion, at or near dead center, the piston moves toward the crankshaft with the gases expanding behind it. Toward the end of this first stroke the piston uncovers an exhaust port and the burned gases escape. Shortly after, an inlet port opens, admitting a mixture of fuel and air (air only in the case of a Diesel) from a reservoir in which it has been slightly compressed. The inlet and exhaust ports close early in the return stroke, and during the remainder of this second stroke compression occurs. In some designs admission is accomplished through mechanically operated valves in the cylinder head. Large engines have separate compressors to furnish the small pressure required for forcing in the air or mixture, but many small engines have a closed crankcase which is used as the reservoir, and the piston displacement itself furnishes the pressure.

When the design is such that combustion occurs on only one side of the piston it is a single-acting engine; if on both sides, a double-acting. The majority of internal-combustion engines are single-acting, the double-acting principle being restricted mostly to very large sizes. The decision between single- and double-acting engines depends on the cost of production. When plain uncooled pistons can be used, the single-acting is cheaper; but when it becomes necessary to water-cool the pistons, it is generally desirable to use the double-acting principle.

Power and Rating

POWER. In contrast to steam prime movers the internal-combustion engine has a definite limit of power. The power depends upon the weight of air that can be passed through the engine in a given time and upon the efficiency with which it can be burned. This is evident, since, however much air is present in the cylinder, sufficient fuel can always be admitted to combine with it, but further addition of fuel will be useless unless there is sufficient oxygen for its combustion.

The power developed in one end of a single cylinder of an internal-combustion engine may be calculated by the following formula:

$$\text{ihp} = \frac{P\,L\,A\,N}{33{,}000}$$

where ihp = indicated horsepower.
P = indicated mean effective pressure in pounds per square inch.
L = length of stroke in feet.
A = area of cylinder bore in square inches.
N = number of impulses per minute;
= revolutions per minute for two-cycle engines;
= revolutions per minute/2 for four-cycle engines.

The mean effective pressure can be obtained from an indicator diagram and varies with the load. At full load it depends on the kind of fuel and the amount of compression.

A portion of the power developed in the cylinder is absorbed in engine friction so that the available power at the shaft is less than that developed in the cylinder and is called the brake horsepower, being that measured by a dynamometer or prony brake. Mechanical efficiency is the ratio of brake to indicated horsepower and varies from 70 to 90 per cent at full load, depending on the size and type of the engine.

RATING. Internal-combustion engines are rated on their brake horsepower usually with an allowance for overload. This overload allowance may vary from 10 to 20 per cent of rating, and the characteristic of limitation of power in such an engine makes it desirable to know either the maximum power or the overload capacity when selecting an engine for a definite service. A good criterion for the selection of an engine is the brake mean effective pressure (bmep) on which it was rated. The brake mean effective pressure is really the product of indicated mean effective pressure and mechanical efficiency and may run as high as 100 lb per sq in. or above in ordinary engines. For continuous service it is well to select four-cycle engines rated on about 70 to 80 lb per sq in. brake mean effective pressure, and two-cycle engines, with crankcase compression, rated on 40 to 50 lb sq in. The brake mean effective pressure may be calculated, when the engine dimensions are known, by putting the brake horsepower in the formula for indicated horsepower thus:

$$\text{bhp} = \frac{P_1\,L\,A\,N}{33{,}000}$$

where bhp = brake horsepower.

P_1 = brake mean effective pressure in pounds per square inch.

Other terms same as in formula for indicated horsepower.

While internal-combustion engines are mechanically somewhat limited as to size, engines have been built up to 7000 brake horsepower, the majority being of less than 3000 brake horsepower. A few years ago piston speeds of 700 to 800 ft per min were considered high for stationary engines, but recent designs are utilizing speeds as high as 1500 ft per min. This naturally helps to reduce the weight per brake horsepower.

The power of an internal-combustion engine being limited by the weight of air taken into the cylinder in a given time, altitude will have an effect on the power. Manufacturers rate their engines for sea-level operation, and allowance should be made for decrease in capacity at altitudes above 2000 ft. Altitudes of 10,000 ft will reduce the brake horsepower about 30 per cent, and other altitudes have proportional effect.

EFFICIENCY AND ECONOMY. The internal-combustion engine uses a cycle theoretically more efficient than the steam engine or turbine and consequently should give a more economical engine. Unlike the steam engine, the internal-combustion engine does not become appreciably more economical as the size is increased. Although in small powers it is far more economical than the steam engine, in very large powers it does not retain this advantage to anything like the same extent, particularly in view of recent developments of the regenerative and reheat steam cycles. Full-load test figures show thermal efficiencies above 20 per cent, referred to brake horsepower, for gas and gasoline engines, and above 30 per cent for Diesel engines.

In an explosion engine the efficiency is entirely dependent upon the amount of compression, but with the Diesel the length of time required for combustion has a decided influence. Although theoretically the explosion-type engine gives a higher efficiency for equal compressions, this advantage cannot be obtained in practice, since an explosion engine compresses a mixture which would pre-ignite if the compression were too high, while the Diesel compresses only air.

The fuel consumption of internal-combustion engines may be expected to vary somewhat with the kind of engine and the fuel, but Table I gives an idea of what might be expected on the average, in terms of Btu in the fuel.

Table I. Average Consumption in Btu per Bhp-hr

Per cent of rated load	100	75	50	25
Gas and gasoline engines	10,500	12,000	14,700	20,000
Diesel engines	8,550	8,800	9,500	11,500

The losses in an internal-combustion engine are the heat carried away in cooling water, that carried away in the exhaust gases, friction, and radiation. For explosion engines the amounts vary considerably with compression and somewhat with speed. For a Diesel the full-load heat balance will not vary much from that given in Table II.

Table II. Average Full-load Heat Balance Diesel

Brake horsepower	30%
Cooling water loss	32
Exhaust gas loss	28
Friction, compressor, radiation	10
In fuel	100

LUBRICATION. Owing to the high temperatures that prevail in the cylinder of the internal-combustion engine, the question of proper lubrication is a serious one. Cylinder oil should be of a high grade, free from acids, and composed of hydrocarbons that leave no residue after combustion. Only mineral oils, therefore, are suitable for the purpose.

The amount of oil required per horsepower-hour varies with the character of the installation and the method of operation. With a properly designed and operated lubricating system the average consumption of lubricating oil would be about 0.0005 gallon per hour per rated brake horsepower for four-cycle engines and possibly twice as much for two-cycle.

COOLING. Internal-combustion engines must be cooled by circulating water through jackets surrounding the heated parts. The quantity of water which must be circulated depends upon the initial and final temperatures.

Inlet water temperatures are usually from 80 to 90 deg fahr. In general the outlet

temperature should not be above 160 deg fahr or there may be danger of breaking down the film of lubricating oil on the cylinder walls or warping of valves. In order to avoid excessive heat stresses in large engines the temperature is usually not allowed to go above 120 deg fahr, but for engines of medium size it may run as high as 130 to 140 deg fahr. If the water contains foreign matter the temperature must be kept low to avoid precipitation and formation of scale, or a water-softening plant must be used.

Excessive circulation resulting in low final temperatures increases the fuel consumption. It is particularly undesirable with gasoline engines as it may cause precipitation of part of the fuel. Very low cooling water temperatures increase the viscosity of the lubricating oil, resulting in an increase of piston friction.

Sometimes a desirable grade of water is available in sufficient amount to allow it to be wasted after circulation through the jackets, but where water is scarce or expensive, cooling towers or spray ponds are generally employed for cooling before recirculation.

The quantity of water to be circulated depends on the thermal efficiency of the engine, the proportion of heat loss to the jackets, and the rise in temperature through the engine. The following table gives the quantity required in gallons per hour per brake horsepower for a wide range of conditions.

Gallons of Cooling Water per Hour per Brake Horsepower

Thermal Efficiency, %	Jacket Loss, %	Temperature Rise, deg fahr				
		30	35	40	45	50
15	30	20.4	17.4	15.3	13.6	12.2
	35	23.7	20.3	17.8	15.8	14.2
	40	27.1	23.2	20.3	18.0	16.2
20	30	15.3	13.1	11.5	10.2	9.1
	35	17.8	15.3	13.4	11.9	10.7
	40	20.4	17.4	15.3	13.6	12.2
25	30	12.2	10.5	9.1	8.2	7.3
	35	14.2	12.2	10.7	9.5	8.5
	40	16.3	13.9	12.2	10.9	9.7
30	30	10.2	8.8	7.6	6.8	6.1
	35	11.9	10.2	8.9	7.9	7.1
	40	13.5	11.7	10.2	9.1	8.2

19. POWER PLANTS

SELECTION OF UNITS. Division of the capacity into two or more units allows the operator to meet the load curve with units loaded to somewhere near the point of best efficiency. In addition it makes the plant more reliable, as at least partial service can be maintained in case of accident to one of the units.

High rating for a given engine lowers the cost per horsepower but shortens the life. It is better, therefore, to select engines of rather conservative rating in speed and brake mean effective pressure. The design should be as simple as possible. Details of design, workmanship, and materials as proved by the engine's record and the manufacturer's reputation are more important than the type of engine. The specifications should be drawn up by experts and contain only such points as are essential to the purchaser, such as weight and space limitations, giving the manufacturer the choice of type and details of design. It should be remembered that, though bids may be tabulated, quality cannot be tabulated, and the cheapest engine may not give the most economical service.

PLANT ARRANGEMENT. It is common practice to set the units on parallel lines. The average plant, having from two to four units, when so arranged, is a nearly square building. When steam engines are replaced by Diesels and the old building used, the arrangement will naturally depend on the shape of the old plant and engines may have to be placed with their center lines in line. Ample clearance must be allowed for the dismantling of engine, generator, and exciter.

FOUNDATIONS are a very important point in the installation of Diesel engines, as the mass must be sufficient to absorb the vibration; engines located in basements of hotels, department stores, and similar places, should be insulated from the rest of the building. In certain localities silencers are required in place of ordinary mufflers for the exhaust. The air for combustion should be free of dust and dirt.

The oil storage should be located outside the plant, either above or below ground

depending on the local conditions. The capacity of the oil storage is determined by the maximum rate of fuel consumption of the plant and the longest expected time between deliveries. The oil may be handled directly from the storage tank to the engine, or an overhead day tank may be placed inside the building.

20. ECONOMICS

INVESTMENT COSTS AND FIXED CHARGES. The average unit cost of representative Diesel electric generating plants will be found in Figs. 1 and 2, in installed capacity up to 10,000 kw. The costs are divided into four different accounts, land being omitted, since it is recognized that location would have more effect on this item than the others. The building costs are for substantial but not elaborate structures. The figures given are for each item erected, including its foundations, but no allowance has been made for overhead. Overhead costs would cover administrative expense, financing, engineering, etc., and usually runs about 10 to 15 per cent of the costs as shown.

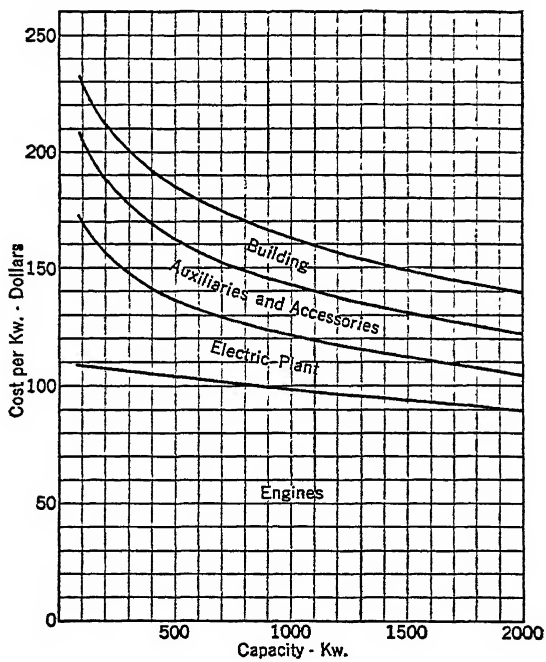

FIG. 1

The first costs of operating a generating plant which must be considered are the fixed charges on the investment. These charges include interest, depreciation, insurance, and taxes. Interest may be considered as constant for all the individual parts which make up the capital investment, but there is a difference in depreciation, insurance, and taxes between the individual parts of the plant. However, for the purpose of a rough estimate, the following average figures may be used. These figures are the yearly cost in per cent of the capital investment.

Fixed Charges

Interest	6%
Depreciation	6%
Insurance and taxes	1.5%

OPERATING COSTS. The operating costs of Diesel electric generating plants will include the cost of fuel and lubricating oil, attendance, cost of engine and other plant

repairs, supplies, and miscellaneous, including water. These items will vary with the character of load and method of operation, and the factor which they appear to follow is the plant running capacity factor, which is defined as follows:

$$\text{Plant running capacity factor, per cent} = \frac{\text{Plant output in gross kwhr} \times 100}{\text{Total rated kwhr of individual units}}$$

The expression "rated kwhr" refers to the kilowatt rating of an engine-generator set multiplied by the number of hours operated. For example, if a unit having a rating of 200 kw was operated 4000 hr, the rated kwhr equals 800,000, no matter what the actual output may have been. Total rated kilowatthours of individual units may be

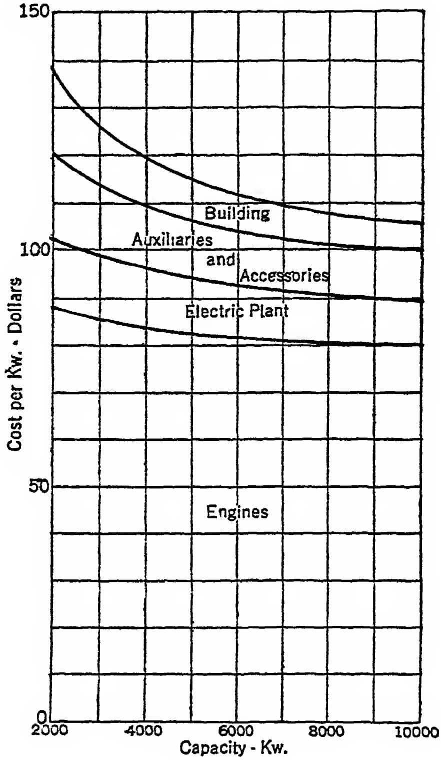

Fig. 2

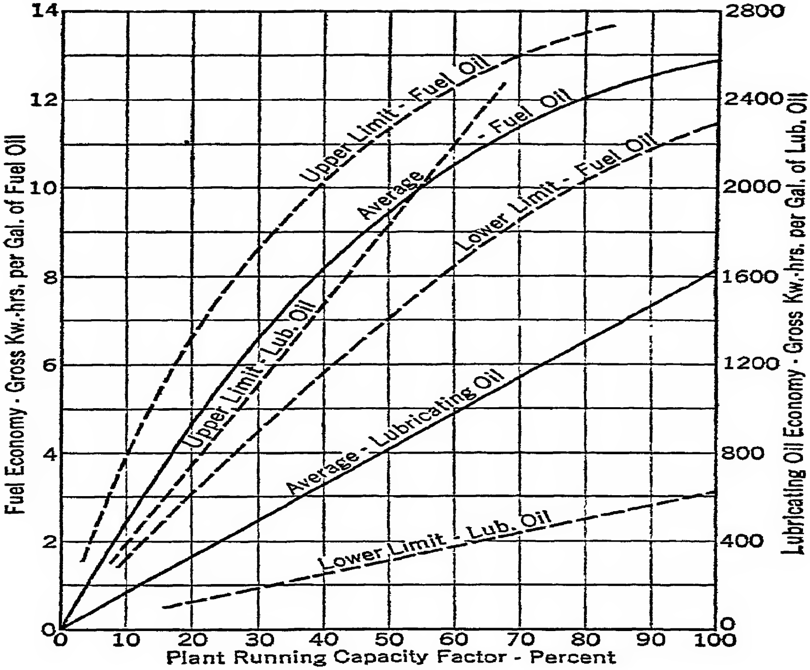
estimated by fitting the units to the expected load curve and calculating the hours of operation required for each unit.

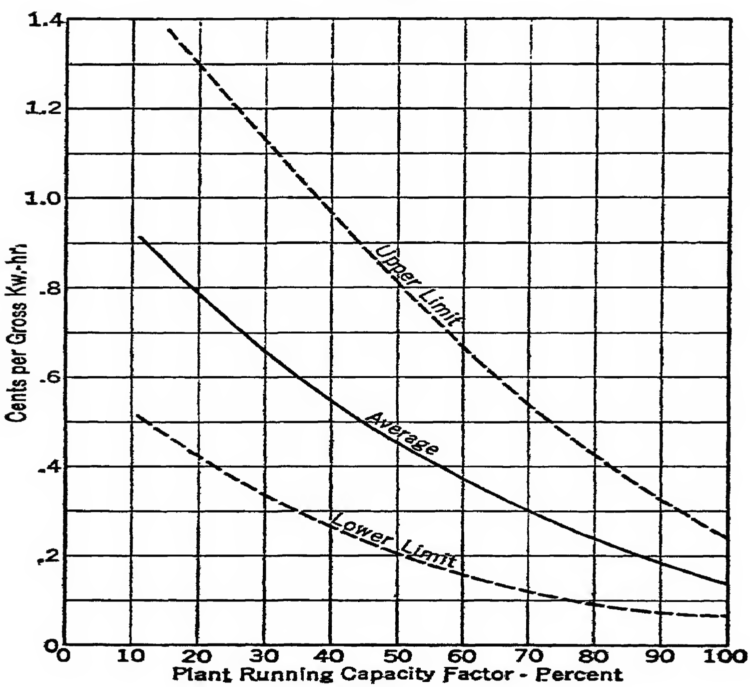
Estimating the cost of fuel and lubricating oil involves a knowledge of the quantities to be used and the price per gallon. Fig. 3 gives the fuel and lubricating oil economics of Diesel electric generating plants in gross kilowatthours per gallon of each oil, with respect to the plant running capacity factor. These curves were taken from the most recent report of the A.S.M.E. subcommittee on Oil-Engine Power Cost and represent actual performance of 120 Diesel plants for the year 1933. This same report shows that the cost of fuel oil used in these plants varied from 1.6 to 7.3 cents per gallon, the majority of cases being from 4 to 5 cents. The cost of lubricating oil varied from 21.5 to 81.8 cents per gallon, the majority of cases being from 50 to 60 cents.

The same report was analyzed for the other operating costs, and these are shown in Figs. 4 and 5, in cents per gross kilowatthour generated against plant running capacity factor. Fig. 4 gives the attendance including superintendence. Fig. 5 gives the combined cost of all repairs, supplies, and miscellaneous, including water.



Fuel Economy - Gross Kw.-hrs. per Gal. of Fuel Oil
Lubricating Oil Economy - Gross Kw.-hrs. per Gal. of Lub. Oil
Upper Limit - Fuel Oil
Average - Fuel Oil
Lower Limit - Fuel Oil
Upper Limit - Lub. Oil
Average - Lubricating Oil
Lower Limit - Lub. Oil
Plant Running Capacity Factor - Percent

FIG. 3



Cents per Gross Kw.-hrs.
Upper Limit
Average
Lower Limit
Plant Running Capacity Factor - Percent

FIG. 4

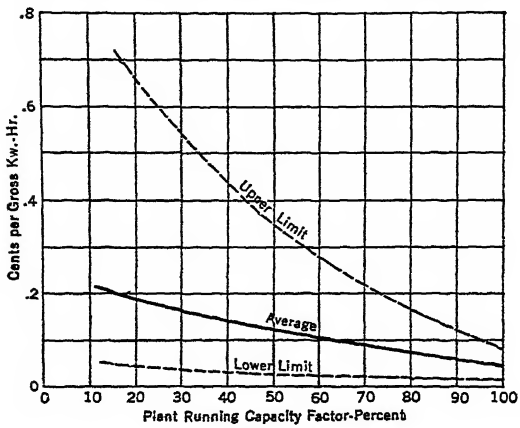


FIG. 5

The data in Figs. 3, 4 and 5 are all on the basis of gross kilowatthours generated. The net kilowatthour output is found by subtracting the power used for plant auxiliaries and station lights from the total gross output of the plant. From 1 to 10 per cent of the gross output may be used in the plant, from 2 to 4 per cent representing a good average.

SUBSTATIONS

By W. L. Slichter

22. CLASSIFICATION OF SUBSTATIONS

A substation is an aggregation of electrical apparatus for the purpose of control, regulation, subdivision, and transformation or conversion of electrical energy. It is the connecting link between two or more sections of a transmission or distribution system.

Most substations perform two or more of these functions.

FUNCTIONAL CLASSIFICATION. Substations may be classified according to their functions as follows:

1. Interconnecting two or more transmission lines for tying together two or more sources of power. This may be a simple "switching station" or it may involve the transformation of voltage if the lines operate at different voltages. The flow of energy may be either way.

2. Transforming voltage by means of transformers from some higher voltage to a lower one, usually interconnecting the high-voltage transmission line with a primary or secondary distribution system. If it feeds directly into the low-voltage (220-volt) distribution system it is called a "distribution substation" and the energy flows only one way.

3. Regulating the voltage or power factor by means of synchronous condensers, induction regulators, or tap-changing transformers.

4. Converting from alternating current at one voltage to direct current at a lower voltage for the supply of direct current to railways or customers.

5. An industrial substation receiving power at some high voltage and transforming to some convenient voltage or converting to some other form to suit the particular needs of some large industrial establishment.

CLASSIFICATION BY INDOOR AND OUTDOOR TYPES. Substations may be of the indoor or outdoor type, depending upon the degree of protection from the weather.

The tendency is to put the transformers, power switches, synchronous condensers, and frequency changers outdoors and the main remote control or master switchboard indoors. Converters, rectifiers, and storage batteries are usually placed indoors. For an outdoor station the bus-bars, disconnecting switches, lightning arresters, fuses, and line insulators are supported well above the ground on a truss structure of angle irons like a bridge; the transformers and oil switches, if any, are placed upon concrete slabs on the ground. For smaller stations, up to 1000 kva and for voltages up to 37,000, horn gap switches are used in place of oil switches, but the load is usually opened by the switches on the low-tension side of the transformers.

CLASSIFICATION BY CONTROL. Substations may be of the manually controlled type, in which operators are always in attendance; of the automatic type, in which all operations are performed by automatic features; or of the remote control or supervisory type, in which most operations are initiated by an operator at a distant station.

23. SUBSTATIONS FOR LIGHT AND POWER SYSTEMS

Location of Substations

SWITCHING OR INTERCONNECTING SUBSTATION. The location of a switching or interconnecting station is dictated by the engineering features of the system rather than by economics. Generally it is at one or both ends of a transmission line: at the generating end to interconnect the various generators to several outgoing lines, at the receiving end to tie one or more transmission lines to branches serving various parts of a city or district. Usually a switching station is also a transforming station, and the physical and mechanical construction of the two are similar.

DISTRIBUTING SUBSTATION. The location of a distributing station is governed by economics. The greater the number and the closer together the stations, the greater will be the first cost and maintenance of the stations, but the investment in copper in the distributing mains will be less and the voltage regulation at the customers' premises will be better. The number, location, and capacity of distributing stations are usually judged by the maximum power demand of the customers per square mile, the diversity factor of the load, and the length and cost of the low-voltage feeders to the customers. In the larger cities it is customary to have two classes of distributing substations: (*a*) those in which the voltage is stepped down from some high voltage (66,000) to some moderate voltage (4400 to 6600) and (*b*) those in which this moderate voltage is stepped down to 220 and 125 volts to serve the customers. The latter are usually placed in a vault in some cellar or in the street, have no attendants, and usually contain transformers with tap-changing control and a network protector. In the suburbs and in smaller cities the usual arrangement is to have a substation to transform from the high voltage to 2200 volts, distribute at 2200 volts, and change to 220 and 125 volts by numerous small transformers, usually installed on the poles, each serving from 5 to 10 customers.

TRANSFORMER SUBSTATIONS. A transformer substation may serve to interconnect a high-voltage (220-kv) transmission line with one or more secondary transmission lines (66 or 110 kv) which in turn supply the low-tension distribution circuits, or it may supply these distribution circuits directly. Between the main transmission line and the domestic customer there may be several voltages and several substations, for instance, 220 kv to 66 kv, 66 kv to 4000 volts, and 4000 to 220 volts. At each of these junctions there may be a substation.

Primary Substations. These substations usually transform from 13,000 or 33,000 volts three-phase to 4000 or 2300 volts three-phase, and are fed either on the "radial" system or the "primary network" system. In the former each substation is connected directly to the power station by one or more feeders in parallel, preferably taking different routes, and is called a terminal substation. In the network system the various substations are interconnected with each other as well as with the power station so that power may be routed to any particular substation through one or two other substations. In this case the transmission line is usually sectionalized at this station, each section being brought into the station and connected to the others and to the transformers by oil switches and protective devices. This is called a "tap" substation, and the elementary connections are as in Fig. 1. See also Section 14.

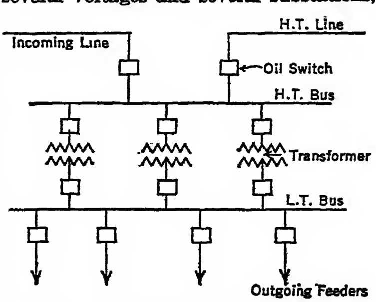

FIG. 1. Transformer Substation Diagram

These substations are located as near as possible to the center of gravity of the load, which runs from 3000 kva per square mile in the residential section of large cities to 30,000 kva per square mile in industrial sections. It is not usual to build any one substation for more than 30,000 kva, but to increase the number of substations and shorten the length of the low-tension distribution. The principal operation in such a station is to cut out the feeder when it fails and substitute a reserve feeder, and, as this is easy to accomplish by automatic means, the trend is toward the use of automatic substations because the saving in labor reduces the operating expenses by a greater amount than the increase in fixed charges and maintenance. When a circuit breaker opens it is automatically reclosed two or three times after suitable intervals, and if the trouble has disappeared it remains closed. If, after the third closing, the trouble has not disappeared, and the breaker opens again, it stays open, and an indicator in the headquarters of the power dispatcher shows which particular breaker is open.

In modern practice these lighting substations, if of the indoor type, are frequently constructed with the **truck** type switching equipment in which each panel, including its circuit breaker is on wheels and may be disconnected from the buses and moved out from its place for inspection and repair. This can be done only when the circuit breaker is open and the panel is dead so the mechanism of the truck serves as a protective interlock and disconnecting switch. For voltage regulation, tap-changing or polyphase induction regulators are used where the load is balanced and single-phase regulators on each of the outgoing lines to neutral where the load is a single-phase residence lighting load which is likely to be unbalanced. These automatic substations are inspected once a day by a trained inspector, and all troubles are reported to a repair gang. An indoor transformer station for 13,000 volts requires about 2.5 cu ft per kva, and an outdoor station from 0.25 to 0.4 sq ft per kva.

Distribution Substations. These usually transform from 6600 or 13,000 volts three-phase to a special 208-volt three-phase, four-wire system which gives 208 three-phase for motors of any considerable size and 120 volts single-phase from any wire to neutral for lighting and small motors and appliances. The low-tension side is usually connected into a "secondary network" by which any customer may receive power from more than one substation. Because of this it is necessary to provide a network protector in each substation to prevent a flow of energy from the low-tension network back into the high-tension mains in case of a fault in the latter or in the transformer. The network protector is controlled by a relay which not only opens the secondary when the flow of energy is wrong, but holds it open as long as the relative magnitude and phase of the voltages across it are such that, if connection were re-established, the flow of energy would still be wrong. This type of substation is used in large cities, and the whole equipment is usually placed in a vault under the street or in a cellar and is operated without attendants.

Equipment

A typical substation would contain: lightning arresters, disconnecting switches, oil circuit breakers, high-tension bus-bars, transformers, oil circuit breakers, disconnecting switches, low-tension bus-bars, voltage regulators, outgoing feeders and their switches metering instruments, protective devices, and a communication system.

TRANSFORMERS. The transformers are usually of the oil-cooled type (except where local fire regulations prohibit) to avoid the use of blowers and other moving auxiliary machinery. They may be of the single-phase type with three to a bank, or of the three-phase type, depending upon costs. A station of large capacity with several banks would probably have three-phase transformers whereas a small station would use single-phase transformers with only one transformer as a spare for any bank.

SWITCHING EQUIPMENT. The latest practice favors the use of the minimum amount of switching equipment consistent with reliability of operation and protection. The use of modern relays makes it possible for one switch to perform a multiplicity of functions: short circuits, time overload, reverse current, and grounds. The metering equipment depends upon local conditions, but it is the custom to have a volt, ampere, watthour, and power-factor meter on each outgoing feeder.

COMMUNICATION. Communication with the main power house, power dispatcher, and other substations may be provided in several ways: leased lines, special private line, carrier current telephony over the power wires or supervisory control, which again may be by private line or by carrier currents.

Synchronous Condenser Substation

A synchronous condenser substation will probably have the usual switching and transforming apparatus and the condensers in addition. Condensers are synchronous

motors with a very generously designed field so that they may be greatly overexcited. Overexcitation causes the condenser to draw a leading (anti-inductive) component of line current which, in passing through the inductive reactance of the transmission line or added lumped inductance, causes a rise in voltage at the receiving end. Conversely, underexcitation causes a lagging current and a lowering of voltage. By operating underexcited at light loads and overexcited at heavy loads the delivered voltage may be kept at a specified value in spite of line loss. Thus

$$E = e + (i + ji_1)(r + jx)$$

where $E \equiv$ voltage per Y phase at the sending end.
$e \equiv$ voltage per Y phase at the receiving end.
$i \equiv$ component of load current in phase with e.
$ei \equiv$ power per phase delivered.
$i_1 \equiv$ reactive component of current delivered.
$r + jx =$ impedance of one line of transmission.

E, e, and ei may be set, and i_1 will be the reactive current required of the condenser, positive for leading and negative for lagging. If the line voltage is very high, greater than 100,000, the distributed capacity of the line may cause a charging current of sufficient magnitude to help considerably.

Synchronous condensers are usually provided with a complete automatic starting equipment, including auto-transformer with 50 per cent starting tap, interlocks between speed, field closing and final closing switch.

Synchronous Converter Substations

Stations for converting from alternating to direct current are generally used for railway service and are discussed under that heading. However, in lighting service by 120-240 volts, direct current, shunt-wound converters are used instead of compound-wound. The voltage regulation or compounding is obtained by means of series boosters on the same shaft as the converter. A series booster is a three-phase generator with its phase windings independent and each in series with one of the three leads which supply the collector rings of the converter. The field of the booster is separately excited and hand controlled so that any degree of voltage control may be obtained. The Edison system substations in the large cities usually contain a large storage battery arranged in two groups to serve as a reserve to the 250-125 volt three-wire d-c distribution.

24. RAILWAY SUBSTATIONS

(See also Synchronous Converters; Energy Requirements for Railways; Switchboards; Switchgear Equipment; Transformers.) Substations are used for electric railways when the length of the road is so great that the whole road cannot be supplied by one power station at the voltage required by the motors without either an excessive drop in voltage or a prohibitive amount of copper or both. Practically all electric railways require substations. In practice there are two types of substations: (1) for transforming from alternating to direct current, and (2) for transforming from high-voltage to low-voltage alternating current.

Location and Capacity

The location, capacity, and number of substations involve not only the cost of the copper required for distribution and the cost of the substations, but also the distribution of traffic and special local conditions. The fundamental economics of the subject are expressed by the general theorem that the cost of operating the substations plus the cost of interest and fixed charges on investment in substations and line copper shall be a minimum. This is explained by the fact that if to any given arrangement an additional substation be added with the proper rearrangement of the spacing, the amount of copper used in the distributing system may be considerably decreased on account of the lesser distance between substations. If the saving in interest on the value of the copper is greater than the cost of operation of this new substation plus the interest and fixed charges on the first cost of the substation, the change is warranted.

Allowable Voltage Drop. The distance between substations depends directly upon the allowable loss in voltage and the amount of copper in the trolley and varies inversely as the load. The allowable loss of voltage is a matter of the special conditions of each road. In city roads a drop in voltage of 8 per cent with average load and 15 per cent with maximum load is frequently observed. In interurban roads a drop of 12 per cent with average load and 30 per cent with maximum load is customary.

The two conditions which determine the allowable drop in voltage are the effect

on the lights and the effect on the control circuit of the car, each of which factors requires a lesser drop in voltage than the actual operating characteristics of the motors.

Distance between Substations. For the service usually found in practice Table I shows the average distance between substations.

Table I

Volts	Type	Miles between Substations	
		Single-track Road	Double-track Road
600	Direct-current, trolley	10	15
600	Direct-current, 3d rail	13	19
3,300	Single-phase, trolley	17	23
1,200	Direct-current, trolley	19	25
1,200	Direct-current, 3d rail	38	43
6,600	Single-phase, trolley	45	50
11,000	Single-phase, trolley	..	70

Where the length of track receives its power from only one direction the allowable distance for a given drop in voltage is one-quarter the distance allowable between substations.

Capacity Required. The capacity of the substation depends upon the traffic and the size of the cars, since if many cars are operating it is probable that only a few will be starting simultaneously and it is during starting that the cars demand the maximum amount of power. It is, therefore, necessary to determine the number of cars which will be located on the section of track supplied by one substation and the frequency of starting. In interurban service the number of cars on a given section is given by the formula:

$$X = \frac{2 \times (\text{Length of section}) \times (\text{Number of cars per hour})}{\text{Schedule speed in miles per hour}}$$

The average load on the substation is equal to the average power demand of each car times the number of cars on the section divided by the efficiency of the distribution system. In a complex system the local conditions must be studied to determine how many of these cars are likely to be starting at once. In other than city roads a load factor of 0.3 to 0.5 may be used to determine the maximum load on a substation, and in single-track interurban roads it is customary to assume one car starting and one car running. See Energy Requirements for Railways, Section 17.

Converter and Motor-Generator Substations

Substations may convert alternating into direct current by means of synchronous converters, mercury rectifiers, or motor-generator sets. Converters have been in vogue longest and are most common. They are particularly adapted for operation on 25-cycle alternating current and delivering 600 volts direct current. At 60 cycles they do not operate as well as the other types but are still satisfactory. For delivering 1200 volts or higher they are not as desirable as the motor-generator or the rectifier because of commutation difficulties. However, the converter has the advantage that it readily lends itself to power-factor and voltage control. For 1200 to 3000 volts, the rectifier is more efficient, because the principal loss is due to the counter emf of the arc, which is about 20 to 30 volts irrespective of the delivered voltage. The rectifier has a higher all-day efficiency than the other types because of the small losses at light load.

EQUIPMENT. A standard a-c to d-c railway substation usually contains the following pieces of apparatus: converters or motor-generators, transformers, reactances, blowers, cables, and switching equipment.

Arrangement of Apparatus. (See also Switchgear Equipment.) It is customary to arrange the apparatus in a substation so that the current travels in as nearly as possible a straight line across the station. Thus, with the incoming line on one side there are, in the order mentioned: the lightning arresters, oil switches, transformers, a-c switchboard, reactance coils, converters, d-c line panel. A typical arrangement for a small station is shown in Fig. 2; see also article on Switchgear Equipment.

Floor Space Required. For substations with all apparatus on one level the floor space required is about 0.20 sq ft per kw. In cities where real estate is expensive, it may be desirable to put the oil switches and lightning arresters in a gallery on the upper level and the transformers on a floor above, but this involves more expense for attendance.

Converters. (See Synchronous Converters for data regarding converters.) Compound-wound commutating-pole converters are used where the load is variable to provide

automatically any desired voltage regulation. The converter by means of its series winding is made to take a leading current which, in passing through the reactance

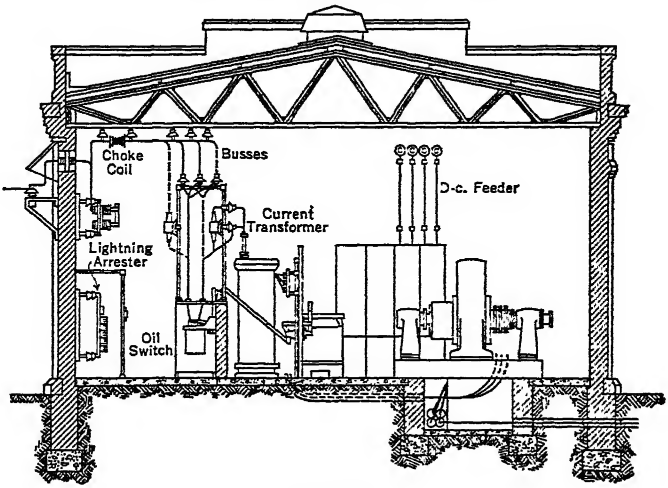

Fig. 2 (a)

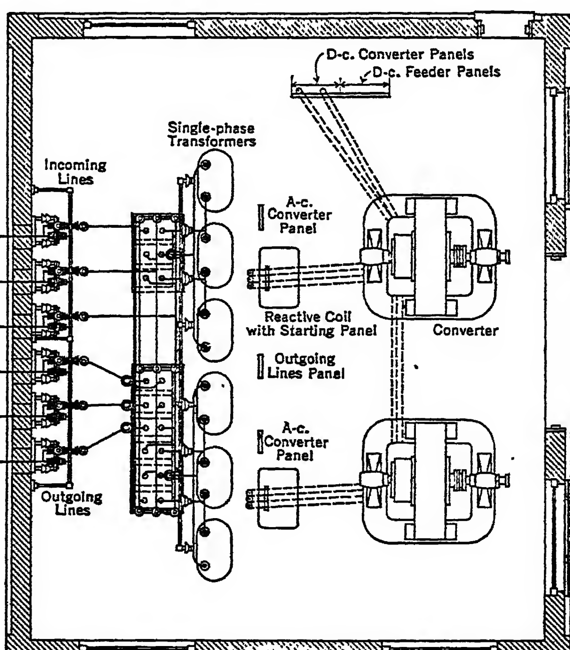

Fig. 2 (b)
Typical Arrangement of a Small Substation

of the line, the transformers, or an additional reactance introduced for the purpose, tends to neutralize the line drop. (See Transmission Lines.) In city service where a

large number of cars are operating on one section, the load is fairly constant and shunt-wound converters are generally used.

Both three-phase and six-phase converters are used, the three-phase for the smaller and the six-phase for the larger capacities. In a three-phase converter for a direct emf voltage of 600 at no load, the transformers should supply the converter with 370 volts between rings or between lines. In the six-phase converter it is customary to use the diametrical connection, in which each transformer secondary supplies 430 volts to the converter, giving 600 volts at the commutator. Each converter for railway work is customarily supplied with a "speed-limiting" device on one end of the shaft and an "end-play" device on the other end. (See Synchronous Converters.)

Transformers. (See Transformers.) The transformers used in railway substations may be either of the oil-cooled, air-blast, or water-cooled type. The oil-cooled type is used where the expense of the complications for air blast or water cooling are not warranted. Air-blast transformers may be used for voltages up to and including 33,000; the objections to them are the necessity of providing a pit, air ducts, and blower to supply the ventilation. Water-cooled transformers (which are oil-insulated transformers with water circulating in a special coil submerged in the oil) are built in sizes from 500 kw upwards and for all voltages. Their use depends upon the availability of water for cooling purposes. The usual aggregate capacity of transformers for the various sizes of synchronous converters is about the same as the converter capacity.

The transformers may be either of the single-phase or three-phase type. For small or moderate installations the single-phase type in banks of three is preferable on account of the economy of maintaining only one single-phase transformer as a spare for a whole station. In railway work it is customary to connect the secondary of the transformers in delta for three-phase, because of the possibility of operating at reduced output on open delta in case of failure of one transformer. The primary windings of the transformer are usually connected Y with grounded neutral. It is common practice to provide transformers for railway work with four $2\,^1/_2$ per cent taps on the high-potential winding, in order to use similar transformers in all substations and yet make allowances for the difference in the line drop between the power station and the various substations. Either $^1/_3$- or more generally, $^1/_2$-voltage taps are provided on the low-potential side for starting the converters.

Blowers for Air-blast Transformers are usually driven by three-phase induction motors receiving power from the low-tension side of the transformers. The amount of air required per minute per kilowatt rating of each transformer ranges from 3 cu ft in the large sizes to 5 cu ft in the small sizes. This air is supplied at a pressure of from $^3/_8$ to 1 oz per sq in. The blowers must be capable of supplying this amount of air with an allowance of about 10 per cent for leakage in the air-blast chamber. It is customary to provide two blower sets each capable of supplying air for all the transformers in the station and maintaining one as a reserve unit. In a very large station three blower sets are sometimes provided, two of which are together capable of supplying the service and the third is a reserve. A rough idea of the size of the motor necessary to drive a blower for a given purpose may be obtained from the following formula:

$$\text{Horsepower} = \frac{(\text{Cu ft air per minute}) \times (\text{Pressure in ounces})}{1200}.$$

Reactances for Voltage Regulation. The voltage at the d-c bus-bars is regulated automatically by means of line compounding which consists in adjusting the shunt-field excitation of each converter so that the converter takes lagging current at no load, operates at unity power factor at about $^3/_4$ load, and takes leading current at all loads greater than $^3/_4$ load. To accomplish this compounding, it is necessary that there should be a certain amount of reactance between the power-station bus-bars and the converters. (See Synchronous Converters.) There is seldom enough reactance in the transmission line for this purpose, so that additional reactance is inserted either by the use of special transformers having considerable leakage reactance, or by means of reactance coils. The usual reactance coil has a capacity in kilovolt-amperes equal to 15 per cent of the kilowatt rating of the converter, i.e., with full-load current passing through the reactance the voltage measured across its terminals would be 15 per cent of the voltage to neutral on the a-c side of the converter.

Reactance coils are either oil cooled or air blast depending upon the transformers used and are generally built with the three circuits in one unit, with the starting switches for the converters mounted upon the frame. For six-phase converters a three-phase reactance coil is used, but since the current per wire is one-half that of the current of a three-phase converter of the same rating, the reactance per line must be twice as great for the six-phase converter.

Switchboards. (See also Section 12.) The following switchboard panels are standard for converter substations.

1. Incoming a-c line panel.
2. Outgoing a-c line panel.
3. High-tension a-c converter or rectifier panel.
4. D-c converter or rectifier panel.
5. D-c feeder panel.
6. Equalizer and negative panel (on the converter).

Where a substation is tapped off a transmission line at an intermediate point it is good practice to bring the transmission line into the substation, interpose control switches, and then carry the circuit out of the substation on to the next substation. For this reason, in all but terminal substations, it is customary to provide both an incoming and an outgoing a-c line panel. In connection with the a-c panel of the switchboard there are a line switch, lightning arrester, choke coil, current transformers, and main oil switch, by means of which potential may be removed from all transformers. Between the transformers and the converter are the starting switches, reactance coil, and possibly measuring devices.

Single-pole switchboard panels are used for the direct current, the positive main bus-bar being the only one on the board. The negative terminals of the converters are connected with switches to the negative or ground return bus-bar, which is frequently located beneath the converter. The series field is connected on the negative side, and the equalizer, series-field-shunt, and field break-up switches are frequently placed on the machine itself. The equipment of a standard d-c converter panel comprises one of each of the following:

Carbon break circuit breaker with overload and low-voltage release, the latter interconnected to the speed-limit device.
Illuminated dial ammeter with shunt.
Field rheostat.
Two-point receptacle.
Single-pole main switch.
Single-pole double-throw station lighting switch.
Watt-hour meter.

Crane. Where ground space is limited it is good economy to provide a crane in order that the various pieces of apparatus may be lifted over each other when they are taken apart for repairs, as otherwise considerable space must be left to move them about to and from the entrance.

Methods of Starting Converters. There are several methods of starting converters, as is explained under Synchronous Converters. Starting from the a-c end as an induction motor is most desirable for railway work, as it avoids the necessity of synchronizing and requires less time. The ability to start a machine quickly and get it on the line in the shortest possible time is very important in railway work, and is an advantage inherent in this method of starting. Three-phase converters are started, by means of suitable starting switches, from $1/2$ voltage taps on the transformer secondaries and take approximately full-load current from the line. Six-phase converters are started from $1/2$ voltage taps and take $3/4$ full-load line current. Since 60-cycle converters usually take a greater starting current than 25-cycle converters and are usually operated on a system supplying power for other purposes, where voltage disturbances are objectionable, special means of starting 60-cycle converters are frequently employed.

The usual method of starting a synchronous converter from a-c supply is as follows:

1. Open all switches except main negative (on machine).
2. Close a-c line switch feeding buses.
3. Close high-tension transformer switch.
4. Close starting switch on low-voltage taps.
5. When converter reaches synchronism as shown by low frequency of swings of d-c voltmeter, close equalizer switch.
6. Close switch between series field and the shunt to series field.
7. Correct polarity if necessary by throwing shunt-field break-up switch to reverse position, leaving it closed only momentarily, then throw to running position.
8. Connect a-c terminals of converter to full voltage of transformers by throwing starting switch to running position.
9. Close d-c circuit breaker.
10. Adjust field rheostat.
11. Close main d-c switch.
12. Adjust for correct division of load, power factor, and voltage.

(See also below under Automatic Substations.)

LOAD FACTOR AND EFFICIENCY. The load factor (q.v.) of a converter substation is usually low, from 30 to 50 per cent, i.e., the load on the station is relatively light except during the morning and afternoon rush-hours, 7 to 9 A.M., and 5 to 7 P.M. respectively. The all-day efficiency of the station itself, or the ratio of the kilowatthours output to the kilowatthours input, is less than the efficiency at maximum or rated load; but the overall efficiency between the a-c generators in the power house and the cars is about constant throughout the day, since the efficiency of a transmission line increases with decrease of load, thus offsetting the low light-load efficiencies of the transformers and converters. In general practice in interurban 600-volt railways the maximum and all-day efficiencies of the various apparatus are approximately as given in the following table:

Apparatus	Full-load Efficiency, Per Cent	All-day, Efficiency, Per Cent
Step-up transformers	98	97
High-tension line	95	98
Step-down transformers	97	94
Converters	90	88
Low-tension distribution	85	88
Overall, a-c generator to motors	69	69

AUTOMATIC SUBSTATIONS. To decrease the cost of operation, by eliminating the need of attendants, substations are now equipped so that the entire control and operation are accomplished mechanically and automatically. When the voltage on the adjacent section of the trolley falls below a specified value (450 volts), a contact-making voltmeter closes a control circuit which starts a motor-driven controller operating a large gang of switches and contactors. These switches automatically and consecutively accomplish the various starting operations. The converters are started from the a-c side so there is no synchronizing, but the polarity of the d-c end is regulated, the field excitation adjusted at the proper time, and the several converters connected in parallel. Protection against overload, low-voltage, and overspeed are provided.

When the load falls below a specified value, a contact-making ammeter closes a circuit which opens all switches and shuts the converters down. A large number of these automatic substations have been installed containing up to three converters per station and in sizes up to 2000 kw units of converters.

Rectifier Substations

APPLICATION. The great majority of the older 600-volt railroads use synchronous converters, but many of the newer 600-volt roads and the 1500-volt roads use rectifiers. Some roads using 3000 volts (e.g., St. Paul) have motor-generator sets with two 1500-volt generators in series electrically, both driven by one synchronous motor; others (e.g., Lackawanna) use rectifiers for 3000 volts direct current.

TRANSFORMERS. Mercury-arc rectifiers are usually constructed with six anodes and are supplied by three-phase transformers with double secondaries giving six phases. Larger sizes may be constructed with twelve anodes and supplied from three-phase transformers with specially designed secondaries. Ideally the voltage on the d-c side is equal to the peak voltage of the a-c side ($\sqrt{2} \times$ the rms value), but owing to the drop in the arc and the transformers d-c voltage obtained is less by some 30 or 40 volts. Six-hundred volt rectifiers have an overall efficiency at rated load of about 94 per cent, including the losses in the auxiliaries. For 1500 volts the efficiency is about 96 per cent and for 3000 volts it is 97 per cent.

EFFICIENCY. The efficiency at $1/4$ load is usually above 92 per cent as compared to 88 per cent in a converter. The power factor is from 92 to 95 per cent (higher at overloads) within the working range. The cause of the low value is primarily wave distortion; it is not due to a lagging current of fundamental frequency. This wave distortion, common to all rectifiers, may cause interference in nearby telephone circuits, in which case the offending harmonics may be suppressed by a special wave filter.

AUXILIARY APPARATUS. Each rectifier requires the following auxiliary apparatus: transformers, vacuum control and pumps, temperature control and water circulation, ignition and excitation equipment, heater for starting, voltage control for compounding if required, usual overload protection, and protection against arc-back (Fig. 3).

Many rectifier substations are entirely automatic in their operation and require no attendants, as in the New York Independent Subway. Since there are no moving parts very light foundations may be used.

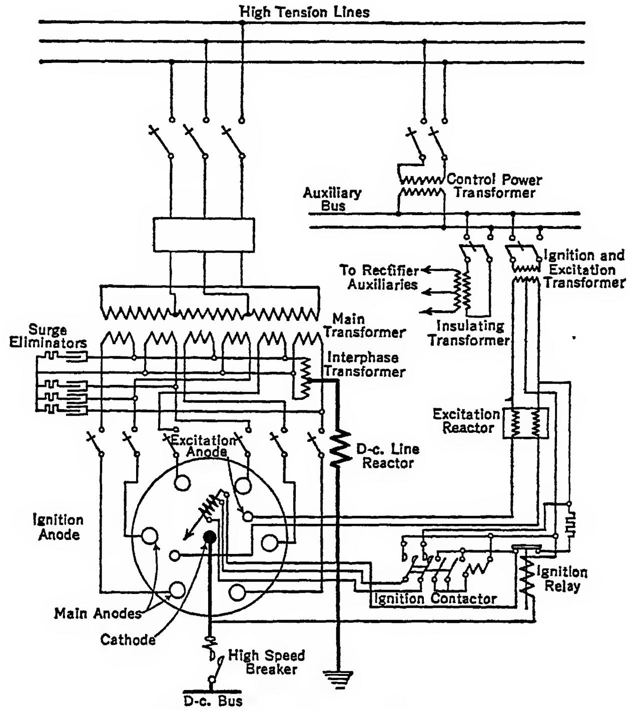

Fig. 3. Rectifier Substation Diagram

SPACE. A rectifier substation usually requires slightly more space for a given power than a converter substation, but as there are no moving parts very light foundations may be used and there is no vibration or noise. They may be adapted for regeneration on the train by a special arrangement to provide for the flow of energy from the d-c to the a-c side. Rectifier substations cost about 30 per cent more than converter substations.

PORTABLE SUBSTATIONS. Circumstances frequently occur under which the traffic on a certain branch of a railway is very heavy for only a few weeks in the year, and possibly for only two or three days in the year. Moreover traffic may be exceptionally heavy on one branch for one short period and on another branch at another period. In such cases as these it would be very expensive to provide on each branch substations having a capacity to meet the heavy demand. To meet such conditions " portable " substations are used. These consist of what are practically large steel furniture cars, in which are installed one synchronous converter and the necessary transformers and control devices. Side tracks are provided at points on the branch lines, and when needed this portable substation is hauled to the place desired and its high-tension terminals are connected to the high-tension transmission line, provision for which must be made in building the line, and its d-c terminals are connected to the trolley and the rail respectively. Such a substation may be of great convenience and value for interurban roads where summer parks, circuses, and athletic games occasionally render traffic conditions difficult. The car is limited in its size by the standard clearance outlines of the roads over which it must pass. It usually weighs, with all its equipment, about 75 tons. Apparatus having a capacity of 500 kw may be installed in such a car, and the primary voltage may be as high as 33,000 volts. (See also, Section 12 on Switchgear Equipment.)

A-c Single-phase Substations

For a single-phase railway operating at a high voltage on the trolley (11,000 or 12,000) it is not necessary to place substations as near together as in d-c systems. However, even with 12,000 volts, there is a limit to the length of road which may be supplied from one feeding point. For instance, on the New Haven or Pennsylvania with heavy traffic on four

tracks, it is necessary to step-up the voltage at the power house to 44,000 or 88,000 and step-down again to trolley voltage at intervals of 10 to 20 miles. A substation for this purpose need contain only transformers and protective devices and usually has neither a building nor attendants, the circuit breakers being reset automatically or by remote control from a supervisory station. Some roads use a three-wire system with auto-transformers by which the trolley wire may serve also as one of the transmission wires. See Fig. 4.

If power is purchased by the railway from existing 60-cycle commercial systems a frequency converter substation is used, as the motors on the cars and locomotives will not operate with 60 cycles but must have 25 cycles and the commercial power companies will not allow a single-phase load to be connected to the same lines as supply the other customers. A frequency converter consists of a 60-cycle, three-phase synchronous motor driving a 25-cycle single-phase (in this case) generator, the usual combination being a 24-pole 60-cycle machine and a 10-pole 25-cycle machine, both running at 300 rpm. A synchronous frequency changer ties the two systems together rigidly so that the slightest change in frequency or phase in one system reacts upon the other system. One of the two machines has its stationary part (stator) in a cradle so that it may be rotated a few degrees in order to adjust the load. In modern practice these frequency converters are totally enclosed and self-ventilated, and they require no building or attendant.

26. MAIN ELECTRICAL CONNECTIONS

FUNDAMENTAL REQUIREMENTS. The scheme of electrical connections to be used for generators, transformers, transmission lines, and station auxiliaries largely determines the physical arrangement of the electrical bay, the equipment, and the wiring. (See Section 12.)

Efficient Operation of the station at all loads should be provided for by suitable grouping and switching of generators, transformers, and lines. The efficiency of a steam turbine-generator varies considerably with the load, and the efficiency of a waterwheel generator varies considerably with both the load and the head. For this reason, if the load is not constant it may be necessary to switch the units from hour to hour to secure greatest economy. Switching of transformers is less important because transformer efficiency is relatively high at all loads. The lines have small loss at light load, and for this reason, as well as to safeguard continuity of service, they are usually left in service at all loads. An exception to this rule is found in long, multiple-circuit lines where one or more circuits are usually disconnected at light load to avoid overloading transformers and generators with reactive kilovolt-amperes.

Retirement of generators, circuit breakers, and other moving equipment at regular intervals for inspection and maintenance should be provided for. Where interruption of station output cannot be permitted the connections must provide for the substitution of spare equipment during this routine maintenance.

Faults occurring in any part of the equipment or connections should be promptly detected and isolated with minimum disturbance to other circuits and minimum loss of load. This requires a certain amount of busing of generators and lines so that the portion of load carried by the faulted part is automatically transferred without interruption. The relay scheme should be so arranged that the retirement of a breaker for inspection does not impair any of the relay protection.

Synchronizing must be provided for. Low-voltage circuit breakers were formerly preferred for synchronizing on account of their quicker action as compared with high-voltage breakers. High-voltage breakers inherently required somewhat longer closing time on account of their longer contact travel. The time of closing of modern breakers is so well controlled and of such consistent duration, however, that synchronizing is now feasible at all voltages up to 220 kv.

Short Circuits and System Stability must be carefully investigated. (See Sections 3 and 14.) The possibility of severe short circuits requires the use of heavy bus supports, current transformers, and other equipment to withstand the mechanical stresses and of heavy circuit breakers to interrupt the current, all of which contribute materially to the cost of the installation. Low stability may cause serious rejection of load during system disturbances. Reactance in generators, transformers, and circuits reduces short-circuit severity but also lowers the stability. The amount of reactance to be used in generators, transformers, and main circuits, therefore, must be a compromise. **Sectionalizing** of the station, as opposed to busing, greatly reduces short-circuit severity, but nevertheless some degree of busing is usually demanded in order to equalize the load among the transformers and generators and to transfer load from a faulted machine. For the small and medium-size station the busing is usually provided as required, and the breakers and other devices are designed for the resulting short-circuit currents. In very large stations, solid low-voltage busing might result in short-circuit currents beyond the ratings of available breakers and other equipment, and in this case some form of high-reactance busing may be used, such as bus reactors, double-primary transformers, and double-circuit generators. These devices insert reactance between main circuits, but not directly in them, thus limiting short-circuit current without impeding the delivery of normal station output. The use of high-speed relays and fast breakers to improve stability increases breaker duty but does not affect mechanical stresses. Some of the other means of increasing stability, such as flywheel effect, damper windings, quick response excitation, quick-acting governors, and sensitive voltage regulators, may at the same time increase both mechanical stresses and breaker duty. Therefore, the studies of short circuits and stability should be conducted jointly.

Charging Current for long transmission lines at light load must be provided. Under extreme conditions this may require the connecting of two generators to one line at light load although one generator is used per line for normal load conditions. It has been found much more satisfactory, however, to be able to charge a line with a single generator.

ELEMENTARY CONNECTIONS. A few elementary connections, which may be modified and combined to meet local requirements most completely, form the basis of all connection schemes. The more useful of these elementary connections are illustrated in Fig. 1 and analyzed as follows:

Fig. 1 (*a*) shows the **single, low-voltage bus.** Any number of generators may be operated to secure best station efficiency at all loads, but the transformers cannot be operated this way unless all lines are in parallel to the same substation bus. Only the bus sectionalizing breakers can be retired for inspection without curtailing the output, and this can be done only by sectionalizing the station. A bus fault will shut down at least one generator, transformer, and line. A generator fault will not cause immediate loss of load if the bus is operated united, that is, with sectionalizing breakers closed. A transformer fault will cause immediate loss of a line. Short-circuit stresses and breaker duty are high when the bus is united. Auxiliary power may be taken from two or more sections of the bus. A large number of lines cannot be accommodated without an expensive transformer layout. Air break switches may be used in the lines since interrupting duty can be handled by the transformer low-voltage breakers. The scheme is simple, compact, and inexpensive.

Fig. 1 (*b*) shows the **single, high-voltage bus.** Generators and transformers can be operated for best station efficiency provided their individual best efficiencies are at the same load. Only the bus sectionalizing breakers can be retired without curtailing the output, and this can be done only by sectionalizing the station. A bus fault will shut down at least one generator, transformer, and line. A generator or transformer fault will not cause immediate loss of load if the bus is operated united. Short-circuit stresses and breaker duty are high when the bus is united. Auxiliary power cannot be taken from the bus without using expensive, high-voltage transformers. Any number of lines may be

accommodated. Air break switches cannot be used, as every breaker shown must be used for interrupting. Generator breakers may be omitted. The scheme is simple but, as compared with the single low-voltage bus, requires more space and the breakers are more expensive.

Fig. 1 (*c*), the **double bus**, is shown for low-voltage, but may be used also for high-voltage. Some stations have both. Selector breakers are shown for the transformers and selector switches are shown for the generators, but either construction may be used for either location. The principal advantages of the double bus are that either bus

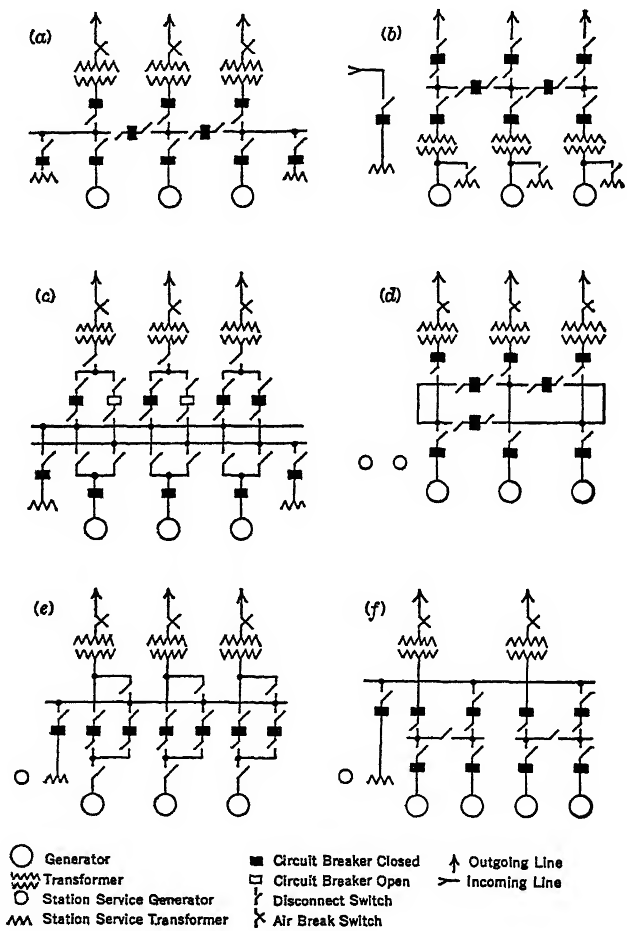

Fig. 1

with its breaker may be retired for inspection without curtailing the output or sectionalizing the station and that both buses may be operated isolated from each other with any desired grouping of generators and lines on each bus. If selector breakers are used throughout and both buses are operated in parallel, with all breakers closed, the double bus has the further decided advantage that a bus fault will not interrupt station output. Bus sectionalizing breakers are sometimes used to localize bus faults. The two buses may be tied together by closing both breakers of any two-breaker circuit, and they must be so tied together while transferring any of the circuits not having selector breakers.

Fig. 1 (*d*), the **ring bus**, is shown for the low-voltage bus but may be used also for the

high-voltage bus. Some stations have both, and in a few stations double ring buses are used. The principal advantages of the ring bus are flexibility of connections, ability to retire any bus section or sectionalizing breaker for inspection, and ability to isolate any bus section by relay action without sectionalizing the station or curtailing the output.

Fig. 1 (*e*), the **transfer bus**, sometimes called **synchronizing bus**, may be used for either the low-voltage or the high-voltage bus, and the switching facilities may be arranged in many ways other than that shown. The bus may be used to tie the station together and to transfer load from one circuit to another, but is not essential to the delivery of the station output as are all buses previously discussed. The bus or any breaker may be retired without curtailing the output. A bus fault does not cause loss of load unless load is being transferred from one circuit to another. A bus fault would shut down the auxil-

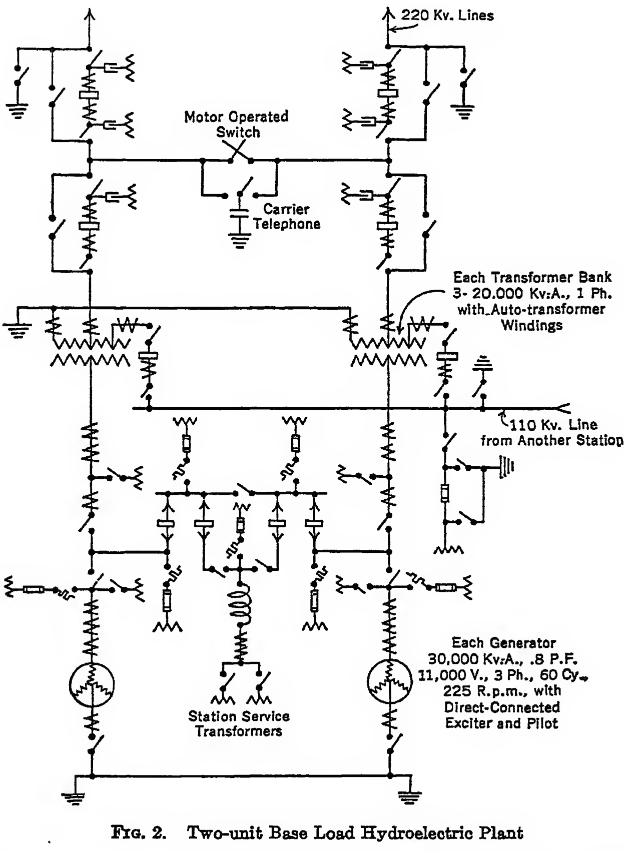

FIG. 2. Two-unit Base Load Hydroelectric Plant

iaries, however, unless a second source of auxiliary power supply were available for automatic relay. If current-limiting reactors must be used, this arrangement provides a good place for them, that is, between each generator and the transfer bus. With the reactors thus located, the station output is not delivered through the reactors under normal operation, and short-circuit current from one main circuit to another must pass through two reactors in series. Auxiliary power may be taken from the low-voltage transfer bus. The scheme may be made simple, compact, and inexpensive.

Fig. 1 (*f*), the **group bus**, is of particular value where several generators or several lines are to be connected to a transformer.

ACTUAL CONNECTIONS. Actual schemes of connections taken from the single-line diagrams of well-known recent power stations are illustrated and analyzed as follows:

Fig. 2 illustrates a two-unit base load hydro plant with two transformers and two lines

feeding a large power system. A smaller station feeds the system through the same transformers and lines. Breakers between generators and transformers are omitted. The low-voltage bus and breakers between main circuits are for providing auxiliary power and for synchronizing the two generators with each other before connecting them to the 220-kv lines. Any breaker may be retired for servicing without reducing station output. Each 220-kv breaker has a by-pass air-break switch so that the breaker can be serviced without opening the circuit. An interlock scheme is used to transfer the relay protection to the other breaker in series while one breaker is being serviced. The motor-operated tie switch provides flexibility in operating. Generators and transformers are protected individually by differential relays. Excitation is provided by direct-connected main and

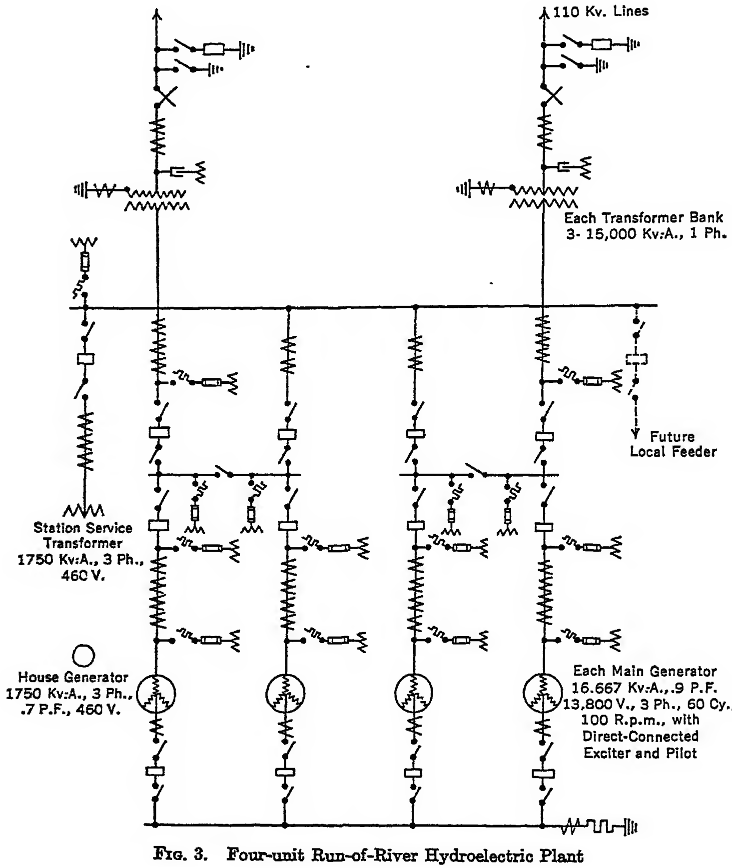

Fig. 3. Four-unit Run-of-River Hydroelectric Plant

pilot exciters on each main unit and a spare exciter which can be driven by a prime mover or by an induction motor.

Fig. 3 illustrates a four-unit run-of-river hydro plant with two transformers and two lines feeding an extensive transmission system. The main connections include two sectionalized low-voltage group buses and a low-voltage transfer bus. The number of generators in service can always be adjusted to the load to secure best station efficiency. Duplication of circuit breakers for purpose of maintenance is not considered necessary as sufficient servicing time is available during light load periods. Station service and also future local feeders are provided for by the transfer bus. A waterwheel-driven house generator also supplies station service.

Fig. 4 illustrates a four-unit peak load hydro plant with four transformers and two lines

feeding a large power system. No low-voltage bus is provided. Each generator circuit is thoroughly isolated from the others. The flexibility of two high-voltage transfer buses is obtained by the use of only one and one-half breakers per circuit. Any breaker or either bus can be retired for servicing without interrupting the output. A bus fault will not interrupt the output. Station service is taken normally from an outside source, but in case of failure of this cource, it is automatically selected from one of the generators. Stability is obtained by the use of high-speed circuit breakers, low-reactance generators, large flywheel effect, specially designed damper windings, and quick-response excitation.

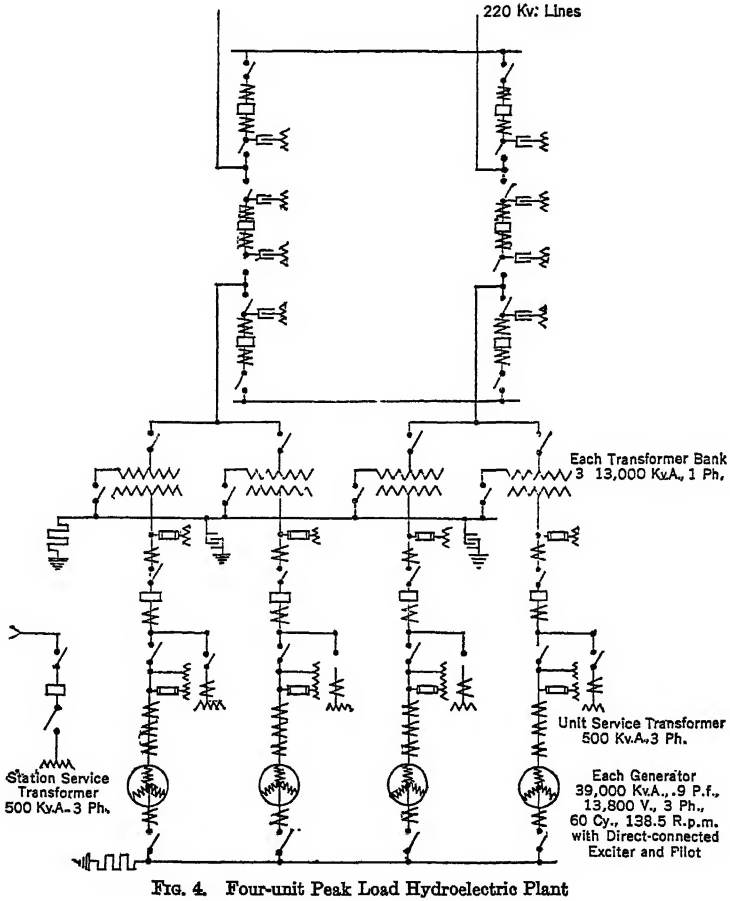

FIG. 4. Four-unit Peak Load Hydroelectric Plant

Fig. 5 illustrates a large steam plant with two or more main units, each connected through its transformer bank to the high-voltage double bus. The generator breakers are in duplicate to facilitate maintenance. The spare transformer is connected by means of removable links. Each main generator has a direct-connected auxiliary generator and also an emergency steam-driven auxiliary generator, the latter being arranged for starting and connecting to the auxiliary bus in less than 15 seconds. All unit auxiliaries are normally fed from the unit itself but in emergency may be fed from any other unit or from an outside source. The boilers are arranged in groups corresponding to the generating units, and the piping and wiring correspond in degree of flexibility. The greater importance of the auxiliaries in the steam plant than in the hydro plant demands considerably greater flexibility and duplication.

feeding a large power system. A smaller station feeds the system through the same transformers and lines. Breakers between generators and transformers are omitted. The low-voltage bus and breakers between main circuits are for providing auxiliary power and for synchronizing the two generators with each other before connecting them to the 220-kv lines. Any breaker may be retired for servicing without reducing station output. Each 220-kv breaker has a by-pass air-break switch so that the breaker can be serviced without opening the circuit. An interlock scheme is used to transfer the relay protection to the other breaker in series while one breaker is being serviced. The motor-operated tie switch provides flexibility in operating. Generators and transformers are protected individually by differential relays. Excitation is provided by direct-connected main and

Fig. 5 illustrates a large steam plant with two or more main units, each connected through its transformer bank to the high-voltage double bus. The generator breakers are in duplicate to facilitate maintenance. The spare transformer is connected by means of removable links. Each main generator has a direct-connected auxiliary generator and also an emergency steam-driven auxiliary generator, the latter being arranged for starting and connecting to the auxiliary bus in less than 15 seconds. All unit auxiliaries are normally fed from the unit itself but in emergency may be fed from any other unit or from an outside source. The boilers are arranged in groups corresponding to the generating units, and the piping and wiring correspond in degree of flexibility. The greater importance of the auxiliaries in the steam plant than in the hydro plant demands considerably greater flexibility and duplication.

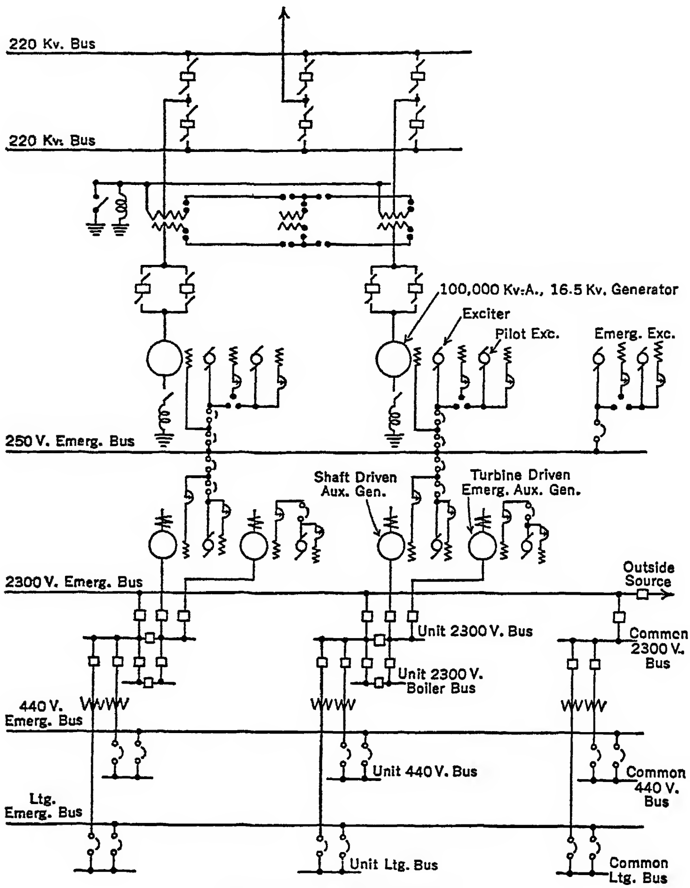

Fig. 5. Large Steam Plant

27. EXCITATION

CENTRALIZED SYSTEM. The centralized excitation system consists essentially of a group of exciters connected to an excitation bus which serves all the generators. It has the advantage of using a minimum number of large exciters, resulting in better exciter efficiency and fewer machines to maintain. The principal disadvantage is that a fault anywhere on the excitation system is likely to affect all the generators. To partially reduce this hazard the system may be divided into two parts, each serving about half the generators. One spare exciter can be made to serve either part of the system. The exciters for the centralized system may have motor drive or prime-mover drive or a combination of the two.

INDIVIDUAL EXCITATION. The individual excitation system consists of an individual exciter for each generator. A spare exciter must be provided with a bus to allow it to serve any generator. This system has the advantage that a fault in any individual excitation circuit will not affect any other generator, and for this reason alone the individual system is usually chosen for stations having a moderate number of large-capacity generators. A slight disadvantage lies in the large number of small exciters with their lower efficiency and higher maintenance cost. The main exciters for the individual system may be driven by the main units or by motors. The spare exciter may be motor driven or prime-mover driven or both.

CONTROL AND WIRING. Control and wiring for the excitation system should be simple and reliable. Overload circuit breakers are not used since disturbances on the a-c system frequently reflect back through the generator fields causing surges in the excitation system which might open automatic breakers causing loss of excitation and a-c output. Either reverse current circuit breakers or speed-limit switches are used for exciters operating in parallel with each other, to disconnect the exciter from the bus in case it should start to motorize. Short circuits, however, on the a-c system in some cases cause reverse current in the excitation system rendering reverse current circuit breakers more of a hazard than a safeguard, unless they are given high current settings. The generator field circuit should never be opened, when energized, except by means of a field switch or circuit breaker provided with an auxiliary contact and resistor to discharge suitably the energy stored in the highly inductive field winding. The **excitation wiring** should be short, direct, of ample capacity, and insulated for 8 to 10 times rated exciter voltage.

28. STATION WIRING

CIRCUITS. Station wiring circuits should be as short and direct as possible. Ample space should be allowed for adequate spacing of conductors. Substantial supports and thorough protection from mechanical injury and moisture must be provided. For heavy-current circuits ventilation is necessary. All exposed wiring must be properly guarded to safeguard employees. These requirements demand a close coordination with the building design to the end that the wiring facilities may as far as possible be built into the structures.

MAIN, LOW-VOLTAGE WIRING. Rated current is always a controlling factor and, for the larger stations, requires extremely careful consideration. Heating and mechanical effects of short-circuit currents are also of vital importance in the design of these circuits. Two general types of wiring have come into use: open wiring, having conductors supported on insulators and partially enclosed in structures; and conduit wiring, using insulated cables in conduits.

Open Wiring is generally used for the main low-voltage buses and sometimes also for the circuits. Its advantages over conduit wiring are obvious for use in buses and connections to current transformers, oil circuit breakers, and such devices located close to the bus. For the circuits to generators, transformers, and feeder outlets, open wiring is often used if the circuits are very short and the necessary space is available, but for longer circuits it is justified only with very heavy current ratings where special arrangements of conductors and ventilation are necessary.

The **conductor** for open wiring may be of tube, bar, or cable. **Tube** has the advantage of most economical shape of cross-section both for a-c carrying capacity and for mechanical stiffness. It has the disadvantage that all taps, bends, and splices must be made by accurately machined fittings. **Bar** has the advantage over tube that bends in one plane can be made by bending the bar, and other bends, taps, and splices may be either clamped or bolted, and soldered if desired, without depending upon factory-machined parts. Bar also has the advantage over tube and cable that large radiating surface is inherent in the shape of cross-section and good ventilation may be obtained by using spacers between the bars of each conductor. Bar has the particular advantages for use in buses that the bus may be tapered to suit the loads at various sections and that bars may be added as station capacity is increased. **Expansion joints** are required for long runs of either bar or tube. **Cable** has the particular advantage for circuits longer than standard tube and bar lengths that it provides continuous copper from end to end without need of splices.

Insulators for open wiring are usually of glazed porcelain with metal bases bolted to the structure and with tops provided with suitable clamps surrounding the conductor. For alternating current, the conductor clamps are made of non-magnetic metal. For heavy short-circuit conditions, two or more porcelain insulators are sometimes used at each support, arranged so that all mechanical stresses from the conductor will be delivered to the structure through porcelain in compression.

Enclosures for open wiring are usually of concrete, brick, tile, soapstone, gypsum, asbestos, steel, or other fire-resisting, structural material having sufficient mechanical strength. The structure should be of ample size to provide suitable clearances between phases and from phase to ground, should have strength to withstand safely the mechanical forces of short circuits, and should surround the circuit sufficiently to protect it from mechanical injury. Doors or grilles should be provided over all openings to a distance of at least 6 ft above the floor to prevent any person coming in contact with the conductors. The structure or the room in which it is located should be rat-proof. When more than one circuit occupies a room, it is sometimes considered an added protection to enclose each

circuit behind fireproof doors designed to prevent the spread of flame and ionized gases. Enclosed circuits should be well ventilated to prevent excessive temperature rise. Reinforcement and other magnetic material should be kept away from and should not form loops around conductors carrying heavy current as the heating caused thereby might crack the structure. Grounding of insulator bases to ground cables paralleling the circuit, though not universal practice, is commonly used by some operating companies. It provides the equivalent of a partial metallic shield around the circuit, thereby avoiding stray ground circuits.

Design of open-wiring buses and circuits should be based on (1) temperature rise of not over 30 deg cent with rated current; (2) mechanical strength at least twice the maximum stresses indicated by short-circuit analyses; and (3) insulator wet flashover strength of at least two and one-half times working voltage and clearances suitable for working voltage.

Conduit Wiring is commonly used for the low-voltage circuits except those of very heavy current rating. It is less expensive and occupies much less space than open wiring. The conductor may be soft annealed copper cable of standard stranding, rope core, hollow core, or three-phase sector design. Flexible stranding should be used if the conduit includes difficult bends. Insulation may consist of varnished cambric, high-grade rubber, or other insulating compounds having suitable characteristics under the temperature and humidity conditions in the conduits.

Conduits for the low-voltage wiring may be of rigid steel, brass, aluminum, fiber, transite, or tile, or of flexible steel or bronze. Rigid conduits are used as far as possible, the flexible types being used only where required by vibration or expansion joints in the building, or by connections to movable machinery. Steel conduit is the most universally accepted for both concealed and exposed construction on account of its superior strength and low cost. For sizes larger than 1½ in., however, fiber conduit is generally less expensive for concealed construction, but it cannot be used exposed. For circuits of such capacity that each phase must occupy an individual conduit, fiber is generally used for concealed construction and brass or aluminum for exposed work, since steel conduit would cause hysteresis losses under these conditions. Heavy current capacity circuits that must be run exposed are sometimes made up of a number of paralleled smaller circuits, each in a steel conduit. This construction has the advantage that skin effect and proximity effect are practically neutralized, but great care must be taken to make all the paralleled circuits of the same length and to equalize them thoroughly with heavy buses and tight connections at each end. Tile duct is used occasionally for power station wiring, but has the disadvantage that bends are difficult to make. Tile finds its greatest usefulness in straight duct lines. Tile and fiber must both be concealed in concrete for strength and protection.

Installation of the Conduit System in most cases must proceed with the building structure. Careful planning is necessary to avoid unnecessary bends and offsets. It generally costs less to imbed the conduits in the structure even at the expense of slightly thicker floors and walls in certain panels than to support the conduits exposed after the structure is in place. Conduits imbedded in concrete structures should have at least 2 in. clear space between them to allow the concrete to flow into place. Large groups of conduits should be installed in floor fills or wall fills, independent of the building structure. Wherever steel conduits are imbedded in cinders or cinder concrete they should be protected from the acid of the cinders by a coating of cement or other suitable material. Joints in conduits should be made water-tight and each run should be drained and vented if possible, to prevent the accumulation of condensed moisture. All metal conduits should be thoroughly grounded. Before cables are pulled, the conduits should be thoroughly cleaned and dried.

Pull boxes should be provided for long conduit runs or runs with difficult bends. A safe rule for the average case is to allow between pull boxes not over 50 ft with bends equivalent to two 90-deg bends, or not over 100 ft with bends equivalent to one 90-deg bend, or not over 200 ft without bends. Pull boxes should be of substantial, fireproof construction and of such size and shape that the cables will not have to be bent during installation to less inside radius than 6 times their outside diameters if rubber insulated or 7 times if cambric insulated or 16 times if paper insulated. The cables of these important main low-voltage circuits should be supported in the boxes by porcelain insulators, and where they enter the boxes they should be protected by fiber sleeves inside the conduit ends.

MAIN HIGH-VOLTAGE WIRING. Voltage is the chief concern in the design of this wiring. Rated current and short-circuit current should be investigated, but they do not usually control the design. Open wiring is almost universally accepted for these buses and circuits, whether located indoors or outdoors.

Two General Types of buses and connections are used: the **rigid type,** consisting of

copper tube or steel pipe supported on porcelain insulators; and the **flexible type**, consisting of stranded copper or aluminum cable supported on strain insulators. Combinations of the two types sometimes meet the conditions to best advantage. The general arrangement of the wiring and structures is materially affected by the mounting of the disconnecting switches, that is, whether with insulator stacks vertical or horizontal. Vertical stacks are generally preferred for the higher voltages on account of their greater stability; but for lower voltages, where either vertical or horizontal stacks are permitted, a more compact station can usually be arranged with disconnecting switches mounted with stacks horizontal.

Steel Structures and Supports for the flexible type of wiring are of two general types; trussed structures, suitable for the lower voltages, where spans are comparatively short; and dead-end towers, used generally for higher voltages where the bays are too large for economical trussing. For the trussed structures, the steel members may be solid rolled sections for short spans but are usually latticed. The structures should be designed for the stresses of the pull-off lines as well as those of the station buses and connections. Steel structures should be galvanized after fabrication and assembled with non-rusting bolts; or, if plain steel and riveted connections are used, the structure should be designed to facilitate routine painting.

AUXILIARY POWER AND LIGHT WIRING. The importance of these circuits justifies the highest grade of wiring available, but the voltage, normal current, and short-circuit current requirements are less severe than with the main low-voltage wiring. Conduit wiring of the general types described above is commonly used. Any open wiring should have flame-proof covering and should have insulators adequate for the short-circuit stresses.

CONTROL AND SIGNAL WIRING. This wiring should be of highest quality, and the layout should be as simple as possible to assist in quickly tracing circuits and in making extensions and additions. Color coding and systematic tagging of wires greatly assist the tracing of connections. All wires should be stranded to avoid breakage from vibration, and they should be of a design able to resist flooding or condensed water in the conduits. Current transformer secondaries and shunt leads should be of large size when the circuits are long.

Conduit Wiring is generally used. Each circuit or group of associated circuits should have a separate conduit to give utmost segregation and protection. The conduit system is generally so elaborate, particularly near the switchboards, that it is impracticable to attempt to install it in the structural slabs. The conduits are usually exposed, or concealed in a floor fill. With the floor-fill construction the structural slab is dropped from 6 to 12 in. below finished floor grade, leaving a space in which the conduits may be installed. The space is later filled around the conduits with cinder concrete or other suitable material, and the floor finish applied on top of the fill.

At the main switchboards, where most of the control wiring terminates, great care should be exercised to avoid congestion, to provide maximum flexibility for cross-connections between panels and for future work. At the same time, adequate separation and segregation of circuits should be afforded so that any fault that might develop will be confined to the circuit on which it originates. For large installations it has become usual practice to provide a **terminal room** below the switchboard room, where terminal boards, cross-overs, fuses, and other facilities can be systematically arranged and properly safeguarded.

SWITCHBOARD WIRING. This is sometimes done at the factory and sometimes at the job. The wire should have a flame-proof covering, and the insulation and covering should be so applied that it will not be injured by abrupt, right-angle bends. It should be applied neatly in vertical and horizontal runs and should be firmly supported in such a manner that each wire is accessible. To facilitate working on bench boards it is desirable to provide an opening in the floor below the bench with a platform at suitable height below floor grade so that the workman may stand below the bench or sit on the edge of the floor and conveniently reach all terminals. The wiring of gage boards containing water piping should be carefully barriered from the piping.

STATION GROUNDING SYSTEM. This includes a number of low-resistance ground connections, usually consisting of driven rods, buried plates, and water pipes all interconnected by heavy copper cables, to which the building steel and all electrical ground buses are securely connected. (See Section 14, Art. 95.)

POWER TRANSMISSION AND DISTRIBUTION

SYSTEMS

Revised by W. A. Del Mar
Previous Revision by R. A. Philip

Circuits designed for transmitting relatively large amounts of power from one fixed point to another are called transmission lines; those for delivering small amounts at numerous points are called distribution circuits. Transmission lines usually have no or few branches, while it is characteristic of distribution circuits to have many branches. The various systems of transmitting and distributing electric energy for light and power may be classified under two general heads, viz., constant-potential or multiple systems and constant-current or series systems, and each of these may be subdivided into d-c and a-c systems.

1. CONSTANT-POTENTIAL OR MULTIPLE SYSTEM

In this system, which is the one principally used for electrical distribution, the voltage between conductors is kept as constant as practicable and the current varies as the load changes.

Direct or alternating current can be used equally well for certain purposes, principally those for which the heating effect of the current is used, including the lighting of incandescent lamps, cooking, and heating. For certain purposes, where the current effects chemical or physical changes, such as charging storage batteries and electroplating, direct current is essential; for other purposes, such as operating arc lamps, it is better. For motive power, the direct current is most favorable where acceleration, variable speed, and adjustable speed are desirable, whereas alternating current gives best results where uniform unvarying speed is desired. While the fields of the two kinds overlap to such a large extent that either kind can be used for general distribution, it is found that it is often more advantageous to use both. For low-voltage, underground distribution, direct current is advantageous because the heavy currents can best be carried on single conductor cables; no subway transformers and no small, high-tension fuses are required.

Alternating current may be supplied either directly from the generators in the power station or from the secondaries of transformers in substations. Direct current may be supplied either directly from d-c generators or from converter substations supplied with high-voltage alternating current.

LIGHT AND POWER CIRCUITS. For a load consisting of both electric lamps and electric motors the same circuit may be used throughout for both classes of service or entirely or partially independent circuits may be employed. The use of the same circuit throughout for light and power service has the advantages of reduced number of wires, transformers, and meters, reduced weight of wire, and reduced capacity of transformers and meters; the use of separate circuits for light and power has the advantage of requiring less capacity of feeder regulators and, sometimes, of less weight of wire for the same perfection of regulation on the lighting circuits. It also simplifies the problem of balancing the phases in polyphase distribution. In the business districts of many cities the Edison three-wire d-c system is used, in which case light and power are equally supplied from the same circuit, the motors as a rule being connected to the outside wires. In business districts where the lighting is done by alternating current the lighting is frequently on single-phase circuits and the power on either separate polyphase circuits or on 500-volt d-c circuits. In residential districts, where the lighting is done by alternating current, small motors are usually put on the same services as the lights, whereas larger motors are put on separate meters, services, and transformers, but the same primaries are used for both services. In factory districts when the power is the predominating load the incidental lighting is sometimes taken off the same services, but generally there are separate meters and transformers. Usually the same polyphase primaries are used for power and light

with separate transformers and secondaries; in these cases the lighting transformers are commonly distributed as equally as convenient between the several phases, in order to balance the load. See Section 15, Art 2, for effects of voltage variations on lamp performance.

TWO-WIRE SYSTEM. The simplest multiple system is the two-wire system, where all devices are connected directly in multiple. This system is used very extensively for d-c light and power, from isolated plants, for power circuits (usually 500 volts), and railway circuits from central stations. It is also used for single-phase a-c distribution for both primary and secondary circuits.

THREE-WIRE SYSTEM. The three-wire system, Fig. 1, is obtained by replacing the outgoing wire of one two-wire system and the return wire of a second two-wire system by a single wire, called the neutral. The voltage between the outside wires is then double the voltage between the neutral and either outside wire. For example, 110-volt lamps may be connected between the neutral and either outside wire, and 220-volt motors may be connected between the two outside wires, and both the lamps and motors be supplied with their rated voltage. The neutral wire carries a current which depends only upon the *difference* in the loads on the two sides of the system and their distribution. As a rule the neutral of a three-wire main is made equal in cross-section to each outside wire. With perfectly balanced load the three-wire system with all three wires of the same size results in a saving in copper of 62.5 per cent as compared with a two-wire system supplying the same load at the same regulation.

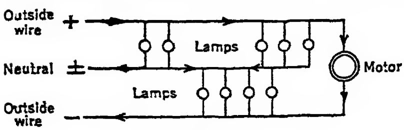

Fig. 1.

The three-wire system is used very extensively for d-c light and power distribution from central stations, also for large isolated plants and for alternating current for lighting on the secondary circuit. Three-wire systems are usually 110 volts on each side of neutral, or 220 volts between outsides, though there are several systems using 220 volts on each side and 440 volts between outsides.

The Edison three-wire distribution system, as used in the business sections of large cities, consists of a set of interconnected three-wire mains supplied by two-conductor or three-conductor feeders from one or more power houses or substations. The different feeders feed into the same set of mains at different points. At the power house or substation end the feeders are often all supplied from a common bus, though where there is a great difference in the length of the feeders there are sometimes two buses which are run in multiple when the load is light but separated when it is heavy, the short feeders on one called the low bus, and the long feeders on the other called the high bus, because of the relative voltages. As the feeders from the several substations connect to interconnected mains, the bus voltage in each is raised or lowered in accordance with the drop in its own feeders. All mains which connect feeding points supplied from a given bus are made large enough to allow large equalizing currents to flow through them, without requiring any great drop in the mains, in order to equalize the voltages at these points.

2. CONSTANT-CURRENT OR SERIES SYSTEM

The lamps or other devices are connected in series, and the current through them is kept constant, the voltages varying automatically to increase or decrease the energy delivered. It is the principal system used in the United States for street lighting, especially in the less-congested areas, but it is now little used for any other purpose. The current used for street lighting is usually 6.6 amp at voltages from 2200 to 11,000.

SOURCE OF CURRENT. Alternating current is usually obtained from a constant-current transformer on a constant potential a-c circuit.

CUT-OUTS, BY-PASSES, AND TRANSFORMERS. Switching out of lamps on series circuits is accomplished by short-circuiting them; this leaves the lamps charged to the potential of that point in the circuit. To make them safe to handle, "absolute cut-outs" are used which also disconnect both conductors to the lamp, leaving the circuit closed.

To avoid the excessively high voltage which would occur when the circuit opens, due to lamps burning out, an automatic by-pass is provided in multiple with the lamps, sometimes consisting of a piece of paper which punctures on a moderate rise of voltage, or of a choke coil which takes but little current at normal lamp voltage. Sockets for series incandescent lamps are arranged to close the circuit automatically when the lamp is withdrawn.

Transformers, one at each lamp, are sometimes used to insulate the secondary circuit

containing the lamp from the primary or for reducing the current for low-current lamps used in series with lamps taking higher current.

ADVANTAGES AND DISADVANTAGES OF SERIES LIGHTING. Constant-current or series systems have the advantage that low-voltage lamps may be used on high-voltage circuits without the expense, losses, or complication of transformation. They have the disadvantage that the lamps are dangerous to handle, the efficiency is low at light loads, and it is impracticable to distribute any large amount of power on a single circuit. In the series system, the current and consequently the loss in the conductor are the same irrespective of the load; in the multiple system, the current is proportional to the load, and the watts lost in the line therefore vary as the square of the load and the per cent loss directly as the load. For this reason the series system is not an economical one where the load varies and averages much below full load, which is the case with most commercial loads. For street lighting where all the lamps are turned on and off at once the efficiency at partial loads is of no importance. In constant-current systems the resistance of the circuit does not affect the uniformity of the voltage on the lamps at different parts of the circuit; with constant-potential systems it does. For a scattering load of lamps, such as street lamps, a uniform light can therefore be obtained from the several lamps, with a much smaller weight of copper and fewer wires, by using the series than by using the multiple system.

THURY SYSTEM. In Europe the constant-current or series system, with direct current of extra high voltage, has been used for long-distance power transmission under the name Thury sytem. The current is obtained by connecting several generators in series, and is utilized by a number of motors also in series. The advantages are simple switchboards, no transformers, and minimum strain on line insulators, the last due first to the fact that in direct current the effective voltage is as high as the maximum voltage, and second, that in a constant-current system the working voltage remains at its maximum value only during the short period when the load is also a maximum. Among the disadvantages are the necessity for insulating frames of generators and motors, need of speed governors on motors, and the necessity of converting the current by moving machinery in every case where it is used for lighting and in most cases for power. The Thury system is not used in the United States.

3. D-C SYSTEMS

Direct current has the following advantages for lighting: (1) safety, since the lines are in no way associated with high-voltage conductors; (2) freedom from power factor, reactance, and skin effect, which results in superior voltage regulation in heavily loaded low-voltage circuits; (3) the direct availability of the storage battery as a reserve and a load regulator; (4) the self-exciting and self-regulating features of d-c generators; (5) the superiority of d-c motors for adjustable speed service and for the operation of elevators and cranes; and (6) the marked superiority of d-c arc lamps. Direct current is generally used in isolated plants and in congested city districts because of the greater ease with which good voltage regulation is maintained.

4. A-C SYSTEMS

The simplest form of a-c system is the single-phase system, for which the connections are exactly the same as for the d-c systems. Both two-wire and three-wire circuits are used, the former for primary circuits and small secondary circuits and branches, and the latter for large secondary circuits. The principal use of single-phase circuits is for electric lighting and auxiliary uses, such as heating or cooking, and fan motors. For delivering large amounts of power a two-phase or three-phase system is generally used.

TWO-PHASE SYSTEMS. In this system there are two single-phase currents having a difference in phase of 90 deg, or a quarter of a cycle. These currents may be distributed on the three-wire, four-wire, or five-wire system.

Three-wire Two-phase Systems. Each single-phase current has a separate outgoing wire but unites in a common return wire. Each two-phase motor has two circuits, each connected between an outside wire and the return wire. The voltage between the two outside wires is 41 per cent greater than between outside wire and return wire, and the current in the return wire is 41 per cent greater than in each outside wire. This is an unsymmetrical system and has the disadvantage that even a balanced load will cause a distortion and unbalancing of the delivered voltage of the two phases because of the unsymmetrical drop in the common return wire.

Four-wire Two-phase System. Each of the two single-phase circuits has a complete, independent two-wire circuit. There are two variations: first where the circuits are

insulated from each other, in which case a cross between either wire of one circuit with either wire of the other will change the voltage stress to ground, but will not affect the delivered voltage or cause a short circuit; second, when the neutrals of the two circuits are connected. In the latter case, from each wire of one circuit to either wire of the other circuit, the voltage is 71 per cent of the voltage between wires of the same phase. The four-wire system with insulated phases is probably the most extensively used of the two-phase systems.

Five-wire Two-phase System. This is a modification of the four-wire system, with interconnected neutral in which the common neutral is extended as a fifth wire. Lamps may be connected from each of the four wires to the neutral. The five-wire system may be considered as two three-wire single-phase systems, one for each phase, with a common neutral wire.

THREE-PHASE SYSTEMS. In this system there are three single-phase alternating currents with a phase difference of 120 deg, or of one-third of a cycle. These currents may be distributed on the three-, four- or six-wire systems.

Three-wire Three-phase System. Each single-phase current has a separate outgoing wire; the three return currents neutralize so that no return wire is required. The three wires are necessarily interconnected, the voltages are usually the same between any two and the currents equal in each of the three conductors, provided the loads on the three phases are equal, i.e., provided the load is balanced. When equally loaded the voltage drops in the three conductors are equal and symmetrical. This is the most extensively used of the three-phase systems.

Four-wire Three-phase System. This is a modification of the three-wire system in which a neutral wire is extended as a fourth wire. Lamps or transformers may be connected from each of the three wires to the neutral, which carries only the unbalanced current, due to the differences in loading of the three phases. The voltage between the three outside wires is 73 per cent greater than from each outside wire to neutral.

Six-wire Three-phase System. If to a three-wire, three-phase system, three wires are added, one with voltage midway between that of each pair of outside wires, lamps may be divided into six groups, between the three outside wires and the three adjacent middle wires. The result is the same as though there were three single-phase three-wire circuits, one for each phase, with the six outside wires combined in pairs giving three common outside wires in place of the three pairs. When connected in this way, the three middle wires cease to be neutrals, as between the three there is a three-phase voltage equal to one-half of that between the three outside wires.

SIX-PHASE SYSTEM. This is used for circuits in the interior of substations (q.v.), such as from transformers to rotary converters, but is not used for distribution.

FREQUENCIES IN USE IN THE UNITED STATES. At present the two frequencies in most general use and adopted as standards in new work are:

60 cycles per second, used by the majority of companies operating a-c lighting systems.

25 cycles per second, generally used for a-c railway work or where the alternating current is to be converted into direct current before final use.

USE OF TWO FREQUENCIES. When the bulk of the load is direct current, but a small though important part is a-c lighting, two frequencies, 25 and 60 cycles, are sometimes used. Sometimes the two frequencies are generated by separate prime movers, though sometimes all current is generated at 25 cycles and the 60-cycle current obtained from frequency changers. (See Section 11, Motor-Generators.)

5. COMBINED D-C AND A-C SYSTEMS

Three-phase transmission and d-c distribution are readily combined but require either rotary or electronic conversion equipment. (See Section 11.) Electric railways, in particular, have commonly used rotary converters for 500-600 volt systems, but the demand for higher voltages on overhead trolley systems led to the use of motor-generators and electronic converters. (See Section 13, Art 24.)

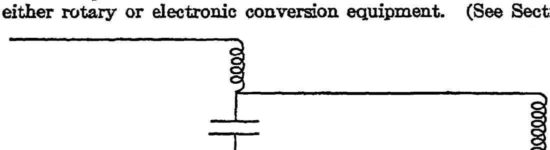

Fig. 2

A new system of transmission is being developed comprising conversion of constant-potential a-c power to constant-current d-c power, transmission of constant current d-c power, and reconversion to constant-potential a-c power.

A constant potential applied to a reactor and condenser in series may be made to yield constant current to a circuit derived from the condenser as shown in Fig. 2. This is known as the **Boucherot circuit.** (Steinmetz, Alternating Current Phenomena.)

Constant alternating current is obtained from such a circuit, transformed up, and rectified by means of inverters with grid-controlled vapor-discharge tubes. At the receiving end, the operations are reversed.

The system has the advantage that the d-c transmission line may be short-circuited without damage to line or equipment.

A description of an experimental line for 10 amp at 15,000 volts is given by Willis, Bedford and Elder, *J.A.I.E.E.*, January, 1935.

6. RELATIVE VOLTAGES AND WEIGHTS OF COPPER REQUIRED FOR VARIOUS SYSTEMS

The comparison of the various systems with respect to the weight of copper required, as tabulated below, is based upon the assumptions (1) that the energy delivered, (2) that the energy loss, and (3) that the maximum voltage strain on insulation between any wire and ground are respectively *the same* for all systems.

When the neutral or middle point of the system is grounded, then the maximum voltage strain on the insulation to ground is the maximum instantaneous value of the voltage between any outside wire and neutral. In the case of an alternating sine wave of voltage the maximum instantaneous value is equal to $\sqrt{2}$ times the effective value determined by a voltmeter. When the neutral is not grounded, an accidental ground on any leg will throw full line voltage across the insulation between any other leg and ground.

On this basis of comparison, assuming a sine wave of voltage and 100 per cent power factor for the a-c systems, the relative voltages between outside wires and the relative weights of copper are as follows:

Relative Voltages and Relative Weights of Copper

System *	Relative Voltages between Outers		Relative Weights of Copper *	
	Grounded neutral	Insulated neutral	Grounded neutral	Insulated neutral
	Per cent	Per cent	Per cent	Per cent
Direct-current (2-wire)	100	50	100	400
Single-phase (2-wire)	71	35.5	200	800
Two-phase (4-wire)	71	35.5	200	800
Three-phase (3-wire)	61	35.5	200	600

* Neutral wire not included; when neutral is added increase the figures given in the ratio of weight of neutral to combined weight of the outside wires for the system in question. For example, the addition of a neutral wire equal in size to either outside wire to a d-c 2-wire system with grounded neutral gives a relative weight of copper of $100 \times 1.5 = 150$ per cent.

EFFECT OF POWER FACTOR. To correct the above tabulation for a-c systems in cases where the power factor is less than unity, divide the relative weight of copper given by the square of the power factor (e.g., for a single-phase two-wire system with insulated neutral and 70 per cent power factor the weight of copper will be $800/0.70^2 = 1630$).

7. STANDARD VOLTAGES

Unless otherwise specified, the "voltage" of a polyphase system refers to the potential difference between phases.

VOLTAGES COMMONLY USED. The voltages most used are:

Direct current:

100 to 125 volts	Lighting, small power, and field excitation.
200 to 240 volts	Power.
500 to 600 volts	Power, electric urban railways.
1200 to 1500 volts	Interurban electric railways.
2400 to 3000 volts	Electric railway trunk lines.

Alternating current:

110–125 volts	Secondary distribution.
2,500 volts 4,500 volts 7,500 volts 15,000 volts	Primary distribution.
23,000 volts 34,500 volts 46,000 volts 69,000 volts 138,000 volts	Transmission.

The above voltages are the standard ones which are only approximated by the actual voltages in use. See also chapter on Distribution.

8. EFFICIENCY OF DISTRIBUTION

The ratio of the energy which is registered by the customers' meters, or which would be so registered if all customers had meters, to the energy supplied by the generator to the bus-bar in the generating station, may be called the overall efficiency of distribution, using the word distribution in a large sense to include transmission. The losses may be divided into several kinds: line loss, transformer loss, converter loss, meter loss and error, leakage, and unaccounted for. For some purposes it is useful to consider each loss from two points of view: (1) as a loss of energy, and (2) as a loss of power at full load; the first may be called the energy loss and the second the capacity loss. The corresponding efficiencies are usually designated as all-day or energy efficiency and the full-load or capacity efficiency, respectively.

FIXED AND VARIABLE LOSSES. The total energy loss consists of two components; (1) a fixed loss independent of load, including the core loss of transformers, the core loss, excitation, friction, and windage of rotating converting apparatus the loss in the shunt coils of meters, dielectric loss, the copper loss in constant-current circuits, and the loss in the arc of mercury-arc rectifiers for constant-current circuits; (2) a variable loss proportional to the square of the current, including the copper loss of constant-potential circuits and of transformers, the armature copper loss of rotating converting apparatus. The effect of the fixed loss on the per cent efficiency depends on the load factor of the load; that of the variable loss depends both on the load factor and the shape of the load curve.

REPRESENTATIVE LOSSES. For a lighting system, the full-load losses in primary feeders, primary mains, transformers, secondary mains, services, and meters may be expected to be as much as 17.5 per cent of the power generated, and the daily energy loss 33.3 per cent of the energy generated, giving 82.5 per cent capacity efficiency and 66.7 per cent energy efficiency respectively.

EFFECT OF NATURE OF LOAD. In making estimates of the efficiencies of particular systems, the effect of the following items should be considered: (1) relation of transformer capacity to maximum loads, (2) load factor, (3) shape of load curve, (4) power factor, (5) diversity factor.

9. REGULATION

An ideal constant-potential distribution would have one uniform, unvarying voltage, and would be said to have perfect regulation. The greater the variation from such constancy the poorer, i.e., the greater numerically, the regulation. The regulation is usually specified in percent variation, either above or below a standard mentioned. The standard is usually either the nominal voltage desired or the actual average voltage obtained.

EVIL EFFECTS OF POOR REGULATION. The evil effects of high voltage are short life of electric lamps, excessive speed of d-c motors, excessive exciting current of induction motors, and burning out of motors and other devices; on the other hand, low voltage greatly diminishes both the candlepower and efficiency of electric lamps, decreases the maximum power of motors, and increases the current which a motor will take for a fixed horsepower output. As electric lamps are much more sensitive to change of voltage than motors, separate circuits are often used for lighting and power, the former having devices for regulation which are omitted from the latter.

The following figures give roughly the quantitative effect of voltage variation between 5 per cent below and 5 per cent above normal:

Each per cent decrease in voltage decreases candlepower of tungsten incandescent lamps.................................3.5 per cent
decreases torque of induction motor......................... 2 per cent
Each per cent increase in voltage decreases the life of tungsten incandescent lamps*.. 10 per cent
increases the magnetizing current of induction motors........... 2 per cent

ORDINARY LIMITS OF REGULATION. Roughly, the maximum voltage variation at the lamps on a lighting system should never exceed 5 per cent, i.e., the regulation above or below normal should never be greater than 2.5 per cent, and should be as much less as is economically feasible; the voltage variation on power systems is usually about 10 per cent (5 per cent above or below normal) and is sometimes considerably more.

CALCULATION OF REGULATION. In order to calculate the variation in voltage at any receiving device or group of such devices from no load to full load, the voltage at the generating or substation or feeding point being assumed constant, the impedance drops in all parts of the distribution system must be calculated and properly combined. The various parts of the system to be considered are the house wiring, service wires (or leads from street mains to the house), secondaries, distribution transformers, primary mains, primary feeders, substation transformers, transmission lines, and power station transformers.

In making such calculations account should be taken of the fact that the loads or currents in the several parts of the system seldom have their maximum values at the same time. The maximum drop in house wiring will not occur simultaneously in all houses, nor will the maximum service drop occur together on all services, etc. Furthermore, the maximum house wiring drop for a given house may not occur at the same time as the maximum drop on the secondary mains, transformer or primary mains to which it is connected.

Effect of Line Reactance. The regulation of an a-c system of unity power factor will be poorer than that of a d-c system of the same copper efficiency (see tabulation above) because of additional drop due to line reactance.

Effect of Lagging Power Factor. A lagging power factor usually makes the regulation of an a-c system worse than it would be for unity power factor and therefore much worse than for a d-c system of the same copper efficiency.

Effect of Leading Power Factor. A leading power factor usually makes the regulation better than it would be for unity power factor and may give even better regulation than can be obtained from a d-c system of the same copper efficiency.

Effect of Currents in Neutral. Any current in the neutral wire of a balanced system produces a drop which tends to unbalance the voltage of the two sides. In the case of a three-wire d-c or single-phase system *1 per cent drop in neutral produces 2 per cent difference in the voltages on the two sides.* Voltage drop in the neutral therefore affects more seriously the regulation than an equal amount in the outside wires. If the currents in the neutral all have the same direction, say toward the station, the voltage drops in the various parts of it will be cumulative, and though the drop in each section may be small and no current may actually reach the station, the aggregate effect may be serious. The individual loads on the two sides of the neutral should be connected so that the unavoidable neutral currents flow alternately in each direction, thus causing drops in alternate directions thereby neutralizing each other over the total length of the circuit.

FEEDER NEUTRAL IN THREE-WIRE SYSTEMS. When the "feeder and main" system is used with a three-wire system, two-wire feeders should be used only on the outside wires, and only a single feeder neutral be used. That is, with respect to the neutral, the "tree" system gives better regulation for the same weight of copper than the feeder and main system, but with respect to the outside wires the latter system gives the better results.

10. VOLTAGE CONTROL

The more common methods of controlling the voltage at feeding points when the feeder and main system of distribution is used are the single bus system, the high and low bus system, and feeder regulators.

SINGLE BUS SYSTEM. All the feeders may be connected to a single bus and the bus voltage be raised as load increases so as to compensate for average drop of all the

* Average for 5 per cent increase in voltage; the first per cent increase in voltage decreases the life 13 per cent. (See Section 15, Art. 2.)

feeders on it. This method gives excessive voltage on such feeders as are comparatively short and low voltage on those that are long. Usually maximum voltage is carried in the evening during the lighting peak and lower voltage during the day, giving very poor regulation on power circuits having maximum load during the day and low load at night. This method is used on most small d-c and a-c distribution systems.

HIGH AND LOW BUS SYSTEM. The bus may consist of two parts which may be separated, and operated at different voltages, feeders of greater average drop connected to the "high" (voltage) bus and the others to the "low" (voltage) bus. The voltage of each bus is raised or lowered in accordance with average drop of feeders on it as in the single bus system. This method is used extensively on the Edison three-wire d-c systems, as noted above. The unequal drop of the several feeders on same bus is equalized by heavy interconnection through mains.

FEEDER REGULATORS. A feeder may have a separate regulator adjustable to compensate for its own drop. This method is sometimes used on d-c railway feeders and very extensively on a-c lighting feeders. A feeder or other distribution circuit which contains a voltage regulator is frequently referred to as a "boosted circuit." Boosted circuits are not usually interconnected but may be if the boosting is of the same nature in each. This system is the more flexible and economical for extensive distribution systems, since each feeder is independently regulated and may be proportioned in cross-section with regard to economy rather than inherent voltage regulation. Single-phase regulators are preferred for close control if the loads are subject to unbalancing.

CONTROL OF POLYPHASE SYSTEMS. In a polyphase system the load may be as equally divided among the phases as possible and the voltage regulated with respect to any one phase taken as representing the average of all; or the lighting load may be connected on a single phase and the voltage regulated for this phase alone. The former method is more common, as it permits of full output of all the phases of the generator being used and gives a more equal voltage on the several phases of polyphase motors.

TRANSFORMERS AS OUTSIDE BOOSTERS. An auto-transformer or an ordinary transformer may be connected to a feeder at any point and used as a "booster" to raise or lower the voltage. In an ordinary transformer the primary and secondary are connected in series thus converting the transformer into an auto-transformer; see Auto-Transformers. Such boosters are not adjustable and have a bad effect on the regulation as they give excessive voltage on the boosted part of line at light load.

To cut such a booster out of service without taking it off the circuit the primary coil must be open-circuited and the secondary short-circuited. *Caution:* the main circuit must be open before cutting out booster, because if the primary is opened while current is flowing in the secondary the booster becomes a step-up transformer and may give a dangerously high voltage on the primary. If, on the other hand, the secondary is short-circuited first, a destructive short-circuit current may flow through it and the primary, and when the primary is opened a dangerous arc will form.

USE OF TRANSFORMERS OF DIFFERENT RATIO. Transformers are also made with taps so that a uniform secondary voltage can be obtained with a varying primary voltage. The plan is not a good one, because if the difference in ratio is correct for uniform voltage at full load it gives unequal voltages at light load. It also has the very serious disadvantage that the haphazard changing of transformer ratios by ignorant linemen to compensate for dim light, due perhaps to lamps already blackened by excessive voltage, makes it impossible to carry out any systematic plan for securing the best average regulation for the system as a whole.

11. BALANCING OF LOAD

In three-wire d-c or single-phase systems and in all polyphase systems supplying single-phase load it is necessary to balance the load approximately between the two sides or the several phases as the case may be. Unbalanced load has two bad effects: (1) it loads the two sides or phases of the system unequally, making it impossible to get full output out of the lightly loaded side or phase without overloading the other; (2) it makes the regulation of the system worse by causing high voltage on the lightly loaded side or phase and low voltage on the other.

The first difficulty is not serious, because through the conduction of heat from the loaded to the unloaded coils of transformers and generators the machine capacity is not reduced in proportion to the unbalance; for moderate unbalancing, say up to 10 per cent greater load on one side or phase than on the other, it is doubtful if any appreciable effect could be discovered. As the total load usually consists of a great number of small parts, a very little foresight in dividing the load in the first place between the sides or phases, and in suitably distributing subsequently connected load, will give a balance

good enough for all practical purposes. When polyphase alternators were first installed for supplying existing single-phase lighting circuits, it was supposed to be important to have a close balance of load between the phases, and early switchboards were therefore provided with transfer switches for throwing single-phase feeders from phase to phase. It was later found that, instead of being necessary to transfer the load from phase to phase, following the diurnal or annual variations of load, the circuits could stay on the same phase indefinitely and that transfer switches were unnecessary and undesirable. The time when rebalancing of this kind is necessary is usually when new circuits are established, at which time the changes of connections are best made by changing the taps to the bus-bars.

MOTOR-GENERATOR BALANCER. On d-c three-wire systems the difference in current on the two sides may be balanced without taking the neutral current to the generator by a balancer consisting of two similar machines mechanically coupled and electrically connected in series. Each machine is wound for the voltage of one side of the system (110 volts for a 110/220-volt system); the common connection between the machines is connected to the neutral and the other two terminals to the two outsides; see Fig. 3 (the field windings are omitted for clearness). The unit acts as a motor-generator (q.v.), whichever machine happens to be on the light side being the motor for the time being and the other the generator. By strengthening the field of the one on the side where the voltage is low and weakening that of the other, so as to keep the same total voltage, the voltages on the two sides as well as the currents may be balanced if necessary.

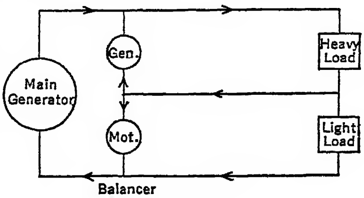

FIG. 3

The output of the balancer generator and the input of the balancer motor are practically equal to each other, neglecting the losses in the machines, and each is equal to

$$\frac{P_1 - P_2}{2}$$

where P_1 is the load on the heavily loaded side of the system and P_2 the load on the lightly loaded side. For example, if the load on one side is 110 kw and that on the other side 90 kw, the load on each unit of the balancer is 10 kw.

It would, however, be unsafe to use a balancer as small as such calculations for the normal unbalancing would indicate as correct, because in case of a short circuit on one side of the system, or of loss of a large amount of load on one side, caused, say, by the blowing of fuses, the balancer would be dangerously overloaded. This may not only destroy the balancer, but may burn out many lamps and motors on one side owing to excessive voltage. In small systems, say up to 100-kw total capacity, the balancer should be able to operate momentarily with any loading up to the capacity of the main generator, and in large systems should have capacity sufficient to burn off a short circuit on one side of the system without creating an unduly high voltage on the lightly loaded side.

DYNAMOTOR AS A BALANCER. A smaller and cheaper balancer is obtained by using a dynamotor (q.v.), which is a single machine with two windings on one armature and two commutators. The armatures are connected in series and balance the currents, but as there is only one field the voltages cannot be balanced.

A-C BALANCING COIL. On a-c single-phase three-wire systems it is usual to obtain the neutral from the middle point of the coil of the transformer supplying the current. It can, however, be obtained at any point of the two-wire circuit without going back to the transformer by using a balance coil. A balance coil is a transformer with two similar windings connected in series across the circuit and with the neutral wire connected to the common point between the windings. Whichever coil is on the lightly loaded side acts as the primary and the other as the secondary, thereby balancing the circuit by transferring one-half of the difference in load from the heavily loaded side to the lightly loaded side. Such coils, which are essentially auto-transformers with a 2:1 ratio, may be used in various ways: to obtain the neutral for an unbalanced three-wire circuit from a two-wire circuit; to supply a 110-volt load from a 220-volt circuit; to supply a large 110-volt load from a 110/220-volt circuit without connecting to the neutral. In practice balance coils are not much used as the neutral can more cheaply be obtained from the transformer.

ELECTRICAL DESIGN OF TRANSMISSION AND DISTRIBUTION SYSTEMS

Revised by W. A. Del Mar

13. DEFINITIONS AND FUNDAMENTAL RELATIONS

Previous Revision by R. A. PHILIP

The following definitions and relations apply to all types of transmission and distribution lines.

GENERATOR END AND LOAD END. By the generator end of the line is meant the end which is connected to the source of power (either directly or through transformers), and by the load end is meant the end which is connected to the load or substation which is supplied with power over the line.

PER CENT POWER LOSS (Q). By per cent power loss as used in this chapter is meant the percentage ratio

$$Q = 100 \cdot \frac{\text{Total power lost in the line}}{\text{Total power delivered at load end}} \tag{1}$$

Hence, if P is the power delivered, then the total power supplied to the line and load is

$$P_0 = P\left(\frac{100 + Q}{100}\right) \tag{2}$$

PER CENT VOLTAGE LOSS (D). By per cent voltage loss as used in this chapter is meant the percentage ratio *

$$D = 100 \cdot \frac{(\text{Voltage at generator end}) - (\text{Voltage at load end})}{\text{Voltage at load end}} \tag{3}$$

Hence calling E the voltage at the load end, the voltage at the generator end is

$$E_0 = E\left(\frac{100 + D}{100}\right) \tag{4}$$

The per cent voltage loss allowed under various conditions is discussed in detail in Article 9; the allowable voltage loss is usually between 2 and 20 per cent, the most common figure, for transmission lines, being 10 per cent.

In a d-c line with a single load at its far end, the per cent power loss and the per cent voltage loss are always equal, but in an a-c line the per cent voltage loss may be either greater or less than the per cent power loss, depending upon the constants of the line and the power factor of the load, or may even be negative, i.e., there may be an actual rise of voltage at the load end above the voltage at the generator end; see below.

EFFICIENCY OF TRANSMISSION. By the efficiency of transmission is meant the percentage ratio

$$100 \cdot \frac{\text{Power output of line at load end}}{\text{Total power input to line at generator end}} \tag{5}$$

The per cent efficiency is related to the per cent power loss Q as follows:

$$\text{Per cent efficiency} = \frac{10{,}000}{100 + Q} \tag{6}$$

14. ELECTRICAL DESIGN OF D-C LINES

Previous Revision by R. A. PHILIP

Two types of problems arise: (1) given a definite line with known constants, what is the power loss and voltage loss for a given load; and (2) to transmit a given amount of power a given distance with a given allowable loss, what will be the size and weight of the conductor required? In the following paragraphs are given the necessary formulas for the several cases. (See also Section 17.)

TWO-WIRE LINE; CONCENTRATED LOAD AT FAR END. Let

E = volts between wires at the load end of the line.

$P = \dfrac{EI}{1000}$ = kilowatts taken by load.

* In an a-c line the difference in the numerator of this ratio is the algebraic difference between rms values of the two voltages, not the vector difference.

$I = \dfrac{1000\,P}{E}$ = amperes taken by load.

l = length of each line wire in feet.

r = ohms per 1000 feet of conductor; see tables in chapter on Bare Wires and Cables.

$R = \dfrac{rl}{500}$ = total resistance of line (both conductors), in ohms.

The following relations then hold:

$$\text{Total kilowatts lost} = p = \frac{RI^2}{1000} = \frac{rlI^2}{500{,}000} = \frac{2\,rlP^2}{E^2} \tag{7}$$

$$\text{Total volts lost} = v = RI = \frac{rlI}{500} = \frac{2\,rlP}{E} \tag{8}$$

$$\text{Per cent power loss} = Q = \frac{100\,p}{P} = \frac{rlI^2}{5000\,P} = \frac{200\,rlP}{E^2} \tag{9}$$

$$\text{Per cent voltage loss} = D = \frac{100\,v}{E} = \frac{rlI}{5\,E} = \frac{200\,rlP}{E^2} \tag{10}$$

$$\left.\begin{matrix}\text{Resistance of each con-}\\ \text{ductor per 1000 ft}\end{matrix}\right\} = r = \frac{500\,v}{lI} = \frac{QE^2}{200\,lP} = \frac{DE^2}{200\,lP} \tag{11}$$

CALCULATION OF SIZE AND WEIGHT OF CONDUCTOR FOR CONCENTRATED LOAD. From the value of r calculated from any one of the relations given in eq. (11), the size of wire may be found from the tables in the chapter on Bare Wires and Cables; the next larger size of wire (next smaller gage number) should usually be chosen when the calculated resistance lies between that of two commercial sizes. The wire selected must also have sufficient current-carrying capacity; see Arts. 51 and 60. For outside lines, however, the current-carrying capacity will in general be ample unless the allowable voltage loss is excessive. For an outside overhead line a wire smaller than No. 6 A.W.G. (or B. & S.) gage is seldom used, chiefly on account of its lack of mechanical strength.

Let w = weight per 1000 ft of the wire finally selected; then

$$\text{Total weight of conductor in pounds} = W = \frac{wl}{500} \tag{12}$$

DIRECT CALCULATION OF TOTAL WEIGHT OF CONDUCTOR (W); TWO-WIRE LINE. For preliminary estimates it is sometimes convenient to calculate the total weight of conductor directly, without reference to a wire table. The total weight of conductor for a two-wire line with concentrated load at its end is given by the formula

$$W = \frac{KP}{Q}\left(\frac{l}{E}\right)^2 \text{ pounds} \tag{13}$$

where P is the power taken by the load, l the length of the line (length of each wire), E the voltage at the load, Q the per cent power loss (= per cent voltage drop for 2-wire d-c line), and K a constant depending upon the material of the conductor and the units in which P, l, and E are expressed, as given in Table I.

Table I. Values of K in Formula 13

Material	E in volts, l in feet, P in kilowatts	E in kilovolts, l in miles, P in kilowatts
Copper (98 per cent conductivity)	13.5	380
Aluminum (61 per cent conductivity)	6.5	185
Any material of specific gravity δ having a conductivity of c per cent at 20° C	$\dfrac{141\,\delta}{c}$	$\dfrac{3940\,\delta}{c}$

NOTE: The values of K given for copper and aluminum are about 5 per cent greater than their theoretical values to allow for stranding, higher working temperature, etc.; 100 per cent conductivity corresponds to 1.724 microhms per centimeter cube at 20 deg cent.

Example: Two-wire D-c Line, Concentrated Load. A load of 100 kw is to be transmitted over a two-wire line to a motor operating at 230 volts, the motor being 1000 ft from the power-house switchboard. For a 10 per cent power loss or voltage drop in the line, the approximate total weight of copper required is, from eq. (13),

$$W = \frac{13.5 \times 100}{10}\left(\frac{1000}{230}\right)^2 = 2550 \text{ lb}$$

From eq. (11) the resistance per 1000 ft is

$$r = \frac{10 \times (230)^2}{200 \times 1000 \times 100} = 0.0264 \text{ ohm per 1000 ft}$$

The nearest even circular mil size is 400,000 cir mils (stranded), which has a resistance of 0.0270 ohm per 1000 ft at 77 deg fahr (see Bare Wires and Cables), and a weight of 1240 lb per 1000 ft. From eq. (12) the total weight of conductor is then

$$W = \frac{1240 \times 1000}{500} = 2480 \text{ lb}$$

This wire, if bare, weatherproofed, or insulated with paper or varnished cambric, will safely carry the required current of 100,000/230 = 435 amp, but if rubber insulated and mounted indoors, a larger wire should be required, viz., 600,000 cir mils, according to the National Electric Code (see Arts. 51 and 60).

CALCULATION OF TWO-WIRE D-C LINE IN TERMS OF VOLTAGE AT GENERATOR END. When the volts E_0 at the generator end are given instead of the volts E at the load end, the calculations for a line of given total resistance of R ohms with a concentrated load of P kilowatts at the load end may be made in the same manner as above by first finding the volts E at the load by the formula

$$E = \frac{E_0}{2}\left[1 + \sqrt{1 - \frac{4000\, RP}{E_0^2}}\right] \tag{14}$$

For an efficiency of transmission of less than 50 per cent, the sign before the radical should be − instead of +, but an efficiency of less than 50 per cent practically never occurs in power transmission. It is of interest to note that for an efficiency of 50 per cent $P = E_0^2 \div (4000\, R)$ which is the maximum power which can be delivered at the far end of the line for a given impressed voltage at the generator end.

When E has been calculated by this formula (14), the formulas (7) to (13) above may be applied directly.

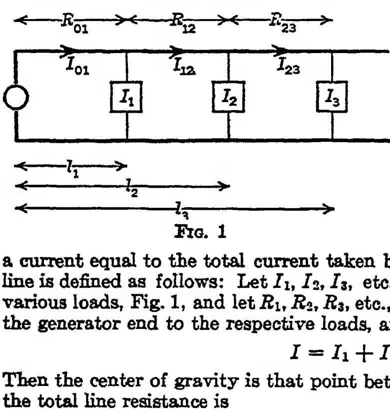

FIG. 1

TWO-WIRE LINE; DISTRIBUTED LOAD. When a line supplies a number of loads at different distances from the generator end, the voltage loss to the far end of the line is the same as would be produced by a load concentrated at the "center of gravity" of the line and taking a current equal to the total current taken by all the loads. The center of gravity of the line is defined as follows: Let I_1, I_2, I_3, etc., be the currents taken from the line by the various loads, Fig. 1, and let R_1, R_2, R_3, etc., be the total line resistances (both wires) from the generator end to the respective loads, and put

$$I = I_1 + I_2 + I_3 + \ldots \tag{15}$$

Then the center of gravity is that point between which and the generator end of the line the total line resistance is

$$R_g = \frac{R_1 I_1 + R_2 I_2 + R_3 I_3 + \ldots}{I} \tag{16}$$

When the line conductor has the same cross-section throughout its length, then the center of gravity is at the distance,

$$l_g = \frac{l_1 I_1 + l_2 I_2 + l_3 I_3 + \ldots}{I} \tag{16a}$$

from the generator end, where l_1, l_2, l_3, etc., are the distances of the respective loads from the generator end.

The total voltage loss to the far end of the line is then

$$v = R_g I = \frac{r l_g I}{500} \tag{17}$$

where the distance l_g is in feet and r is the resistance of the conductor per 1000 ft, the second relation in (17) holding only when the conductor has the same cross-section throughout its length.

The total kilowatts lost in the line are

$$p = \frac{1}{1000}\left(R_{01} I_{01}^2 + R_{12} I_{12}^2 + R_{23} I_{23}^2 + \ldots\right) \tag{18}$$

where, referring to Fig. 1, R_{01} = total resistance (both wires) from 0 to 1, R_{12} = total resistance (both wires) from 1 to 2, etc., and $I_{01} = I_1 + I_2 + I_3 + \ldots$ = the current in the line from 0 to 1, $I_{12} = I_2 + I_3 + \ldots$ = the current in the line from 1 to 2, etc. When

the cross-section of the line conductor is the same throughout its length eq. (18) may be also written

$$p = \frac{r}{500{,}000}\left(l_{01} I_{01}^2 + l_{12} I_{12}^2 + l_{23} I_{23}^2 + \ldots\right) \tag{18a}$$

where the distances l_{01}, l_{12}, l_{23}, etc., are as shown in Fig. 1, and are measured in feet, and r is the resistance of the line conductor per 1000 ft.

Calculation of Size and Weight of Conductor for Distributed Load. For a conductor of the same cross-section throughout, the required resistance per 1000 ft for a given voltage loss of v volts to the end of the line may be calculated from the formula

$$r = \frac{500\, v}{l_g\, I} \tag{19}$$

where l_g, expressed in feet, and I are given by formulas (16a) and (15). The size and weight of conductor can then be found by reference to the wire tables in the chapter on Bare Wires and Cables.

When the loads are far apart and the smaller loads are farthest from the generator, it is sometimes advisable to use different sizes of conductors for the various portions of the line. For a given voltage loss v to the end of the line, the minimum weight of conductor is obtained when the volts lost per unit length of conductor in each section of the line is proportional to the square root of the current in this portion of the line. For minimum total weight of conductor then, referring to Fig. 1, the resistance per 1000 ft *of wire* for the section between 1 and 2, say, must be

$$r_{12} = \frac{1}{\sqrt{I_{12}}} \cdot \frac{500\, v}{l_{01}\sqrt{I_{01}} + l_{12}\sqrt{I_{12}} + l_{23}\sqrt{I_{23}} + \ldots} \tag{20}$$

where the lengths are in feet; and similarly for the other sections. The weight of wire for each section may then be found by reference to the wire tables in the chapter on Bare Wires and Cables, and the total weight W can then be computed. Vice versa, for a line proportioned in this manner the voltage loss to the end of the line for a given total weight of copper will be a minimum.

A line proportioned in this manner, however, does not give minimum power loss for the total weight of conductor used. For a given total weight of conductor the total power loss will be a minimum when the power loss per unit length of conductor in each section of the line is directly proportional to the current in this section, i.e., when the voltage loss per unit length in each section is the same, which means that the weight per unit length of each section must be proportional to the line current in this section. Whence letting W be the total weight of the conductor in pounds, then the power loss will be a minimum when the section from 1 to 2, say, has a weight in pounds per 1000 ft of

$$w_{12} = I_{12} \frac{500\, W}{l_{01} I_{01} + l_{12} I_{12} + l_{23} I_{23} + \ldots} \tag{21}$$

where the lengths are in feet; and similarly for the other sections. The size of wire for each section may be obtained from the wire tables in the chapter on Bare Wires and Cables. When the sizes as found by the two formulas (20) and (21) differ considerably, the choice will depend upon which is the more important, minimum power loss or minimum voltage loss.

THREE-WIRE D-C LINE. When a three-wire circuit is exactly balanced, i.e., when the loads between each of the two outer wires and the neutral are the same and are connected to the neutral at the same point or points, no current flows in the neutral wire. The formulas given above for a two-wire line then apply directly to the case of a balanced three-wire line, noting however that the E (= volts between wires) in these formulas is to be taken as the volts between the *outer* wires, and that the weight as calculated by the above formulas is the weight of the two outer wires. The neutral wire is usually made equal in size to each outer wire, but when only slight unbalancing is expected it is sometimes made smaller. When the neutral is made equal in size to the outer wire the total weight of the three conductors will be 50 per cent more than that given by formula (13), when E in this formula is taken equal to the volts between the outer wires.

The exact calculation of the voltage loss and power loss when the loads on the two sides of the system are different and are connected at different points is somewhat complicated, but can always be effected by the application of Kirchhoff's laws for an electrical network; see Section 3.

15. ELECTRICAL DESIGN OF A-C LINES

Previous Revision by R. A. Philip

As a rough guide in fixing upon a preliminary design, the following facts should be noted; complete formulas for the various calculations required are given later.

1. A power loss of approximately 10 per cent of the delivered power is usually allowed.
2. A line voltage of approximately 1000 volts per mile of line is common practice for long-distance lines not over 150 miles in length; that is, for a 10-mile line a line voltage of 10,000 volts would be employed; for a 100-mile line a line voltage of 100,000 volts would be used. The maximum line voltage at present (1936) employed is 238,000 volts, and the maximum distance of transmission is 350 miles.
3. On the basis of 1000 volts per mile of line, unity power factor at the load, a 10 per cent power loss, and copper at 10 cents per pound, the cost of the copper required for a three-phase line is $2.66 per kilowatt delivered, and for a single-phase or two-phase four-wire line $3.45 per kilowatt delivered.

TOTAL WEIGHT OF CONDUCTOR FOR A-C LINES. The size and total weight of the conductor required for any conditions † of length, power delivered, power factor, line voltage, and power loss may be calculated as follows:

Let E = voltage between wires at the load end of the line.
P = total power taken by all phases of the load.
$\cos\phi$ = power factor of load, as a decimal.
l = length of line (= length of each line wire).
Q = allowable total power loss in per cent of delivered power.

Then the total weight of all conductors is given by the formula

$$W = \frac{KP}{Q}\left(\frac{l}{E\cos\phi}\right)^2 \text{ pounds} \tag{22}$$

where K is a constant depending upon the number of phases and wires, the material of the conductor, and the units in which the various quantities are expressed, as given in Table II.

Table II. Values of K in Formula 22

Material and Units	Single-phase or Balanced 4-wire 2-phase *	Balanced 3-wire 3-phase
Copper (98 per cent conductivity):		
E in volts, l in feet, P in kilowatts	13.5	10
E in kilovolts, l in miles, P in kilowatts	380	280
Aluminum (61 per cent conductivity):		
E in volts, l in feet, P in kilowatts	6.5	4.9
E in kilovolts, l in miles, P in kilowatts	185	140
Any material of specific gravity δ having a conductivity of c per cent at 20° C:		
E in volts, l in feet, P in kilowatts	$\frac{141\,\delta}{c}$	$\frac{106\,\delta}{c}$
E in kilovolts, l in miles, P in kilowatts	$\frac{3940\,\delta}{c}$	$\frac{2950\,\delta}{c}$

Note.—The values of K given for copper and aluminum are taken about 5 per cent greater than their theoretical values to allow for stranding, higher working temperatures, etc.; 100 per cent conductivity corresponds to 1.724 microhms per centimeter cube at 20 deg cent.

* For a 3-wire 2-phase system with the middle conductor having a cross-section equal to $\sqrt{2}$ times the cross-section of either outer wire multiply these constants by 0.85, taking for E the voltage (volts or kilovolts) between the middle wire and either outer wire.

COMMERCIAL SIZE OF CONDUCTOR AND CORRESPONDING TOTAL WEIGHT. Formula (22) takes no account of the available commercial sizes of wire. These sizes differ successively by approximately 25 per cent in cross-section. The weight can also be determined by calculating the resistance of the required conductor per 1000 ft or per mile, and taking from the wire tables in the article on Bare Wires and Cables, the nearest commercial size. Neglecting the charging current, the required resistance per unit length of wire is

$$r = \frac{K_1\,Q(E\cos\phi)^2}{lP} \text{ ohms} \tag{23}$$

† These formulas are based on the assumption that the charging current is negligible in comparison with the load current, which condition is practically realized in all but the longest high-voltage lines; formulas for power loss taking the charging current into account are given later.

where K_1 is a constant depending on the number of phases and wires and the units in which the other quantities are expressed, as given in Table III.

From the wire table the corresponding weight (w) per unit length of conductor having a resistance nearest to that calculated by formula (23) is obtained; the total weight of conductor, including all wires, is then

$$W = K_2 wl \quad \text{pounds} \tag{24}$$

where K_2 is a constant depending upon the number of phases and wires and the units in which w and l are expressed, as given in Table III.

Table III. Values of K_1 and K_2 in Formulas (23) and (24)

Units	Single-phase	Balanced 4-wire 2-phase *	Balanced 3-wire 3-phase
E in volts, l in feet, P in kilowatts, r in ohms per 1000 feet and w in pounds per 1000 ft. . .	$K_1 = 0.005$ $K_2 = 0.002$	$K_1 = 0.01$ $K_2 = 0.004$	$K_1 = 0.01$ $K_2 = 0.003$
E in kilovolts, l in miles, P in kilowatts, r in ohms per mile and w in pounds per mile. . . .	$K_1 = 5$ $K_2 = 2$	$K_1 = 10$ $K_2 = 4$	$K_1 = 10$ $K_2 = 3$

* The values of K_1 given in this column when used in formula (23) will give the resistance per 1000 ft or per mile of either outer wire in a 3-wire 2-phase system; the middle wire should, for the same energy loss per pound, have a cross-section 41 per cent greater than either outer, but when commercial sizes (A. W. G.) are used, either a wire one gage number smaller (25 per cent greater cross-section) or two gage numbers smaller (60 per cent greater cross-section) may be used; in the first case the corresponding value of K_2 is 0.81 times the values given in this column and in the second case 0.90 times the values given in this column.

Current per Wire; Heating of Line Conductors. The size of wire as determined from formula (23) must be ample to carry the required current without overheating. Heating of the line conductors is seldom a limitation in outside overhead lines, but for inside wiring or underground cables the temperature rise may set a limit to the size of wire which may be used. It is therefore always wise to determine the current which the conductor must carry, and make sure that the wire is sufficiently large not to overheat; see articles on Bare Wires and Cables, Insulated Wires and Cables, for tables of current-carrying capacity under various conditions. (Arts. 51 and 60.)

The current per line wire in amperes may be calculated from the following formulas, in which E *is the kilovolts* between wires at the load end, P *the total kilowatts* (all phases) delivered to the load, and $\cos\phi$ the power factor of the load as a fraction.

$$\left.\begin{aligned} &\text{Single-phase:} && I = \frac{P}{E\cos\phi} \\ &\text{Two-phase,* 4-wire, balanced:} && I = \frac{P}{2E\cos\phi} \\ &\text{Three-phase, 3-wire, balanced:} && I = \frac{P}{\sqrt{3}E\cos\phi} \end{aligned}\right\} \tag{25}$$

Example: Calculation of Weight and Size of Conductor for a Three-phase Line. A load of 20,000 kw is to be transmitted by means of an overhead three-phase line of copper wire to a substation 50 miles away operating at 60,000 volts between wires, the frequency being 25 cycles per second, and the power factor of the load 80 per cent with the current lagging; a power loss of 10 per cent of the delivered power to be allowed. From formula (22) the required total weight of copper is

$$W = \frac{280 \times 20{,}000}{10}\left(\frac{50}{60 \times 0.8}\right)^2 = 607{,}000 \text{ lb.}$$

From formula (23) the required resistance per mile of conductor is

$$r = \frac{10 \times 10(60 \times 0.8)^2}{50 \times 20{,}000} = 0.231 \text{ ohm per mile}$$

The nearest commercial size is 250,000 cir mils (stranded), which has a resistance of 0.228 ohm per mile at 77 deg fahr (see Bare Wires and Cables), and a weight of 4080 lb per mile. From formula (24) the total weight is then

$$W = 3 \times 4080 \times 50 = 612{,}000 \text{ lb}$$

* E is here the volts between the two wires of the same phase. This formula also gives the current in each outer of a balanced 2-phase 3-wire line, E being the kilovolts between either outer and the middle wire; the current in the middle is $\sqrt{2}$ times the current in each outer.

The current corresponding to the given load is, from formula (25),

$$I = \frac{20,000}{\sqrt{3} \times 60 \times 0.8} = 241 \text{ amp.}$$

which will give a negligible temperature rise in the wire. See Current-carrying Capacity in article on Bare Wires and Cables, Art. 51.

CALCULATION OF SIZE AND WEIGHT OF CONDUCTORS FOR A GIVEN PER CENT VOLTAGE LOSS. The voltage loss in an a-c line depends not only upon the resistance of the line, but also upon the line reactance, and in long lines upon the electrostatic capacity of the line. It is therefore impossible to express directly in a simple formula the size or weight of the wire in terms of the voltage loss. The most practical method of making such calculations is to assume first that the per cent power loss is equal to the given per cent voltage loss, and calculate the size by formula (23); then using this size of wire calculate the per cent voltage loss by the formulas given below. If this calculated voltage loss differs appreciably from the given voltage loss, choose the next larger or smaller size of wire (accordingly as the calculated loss is greater or less than the given loss) and recalculate the voltage loss, and so on, until the proper size of wire has been found.

16. FACTORS WHICH AFFECT THE VOLTAGE AND POWER LOSS IN A-C LINES

Previous Revision by R. A. Philip

Owing to the inductance and electrostatic capacity the per cent voltage loss in an a-c line is not so easily calculated as the voltage loss in a d-c line, and is in general different from the per cent power loss by an amount dependent upon the inductance and capacity of the line, the frequency, and the power factor of the load.

DETERMINATION OF LINE CONSTANTS. The four fundamental line constants are the resistance (r) and inductance (L) of the line conductors per unit length and the capacitance (C) and leakage conductance (G) per unit length. For all but the shortest transmission lines the mile is usually the most convenient unit of length, and this unit will be used throughout the remainder of this article unless distinctly stated otherwise. Tables of resistance, inductance, and capacitance both per mile and per 1000 ft are given respectively in the chapters on Bare Wires and Cables and Capacitance and Inductance Tables. From the inductance and capacitance per mile or per 1000 ft may be calculated for any given frequency the reactance $x\ (=2\pi fL)$ and the capacitance susceptance * $b\ (=2\pi fC)$ for the corresponding unit of length. In the last two chapters just mentioned are given full tables of reactance and of capacitance susceptance per mile for frequencies of 60 and 25 cycles per second; dividing the numerical values given in these tables by 5.28 will give the corresponding quantity per 1000 ft. For any other frequency of f cycles per second, multiply the numerical values given in the tables for 25 cycles by the ratio $f/25$; i.e., for 40 cycles the reactance is 1.6 times the reactance for 25 cycles.

Allowance for Skin Effect in Conductors. The skin effect is practically negligible at 25 cycles for all copper conductors smaller than 1,000,000 cir mils, and at 60 cycles for all copper conductors smaller than 450,000 cir mils. The corresponding limiting sizes for aluminum are about 30 per cent larger. The skin effect is quite appreciable in copper or aluminum cables with a steel core; it is usual to neglect the conductivity of the steel core entirely in calculating the resistance of such cables. See Arts. 50 and 61.

Apparent Resistance and Reactance in Unsymmetrical Arrangements of Wires. When the three wires of a three-phase line are so arranged that they form the three edges of an equilateral prism the reactance of each wire is the same as for one wire of a two-wire line. However, when the wires are arranged all in one plane, as is frequently done, the unequal mutual induction sets up a reactive electromotive force in each outer wire which is not in quadrature with the current in this wire; see eq. (25) in Art. 22. As a result, both the apparent resistance and the apparent reactance of each outer wire are different from its true resistance and reactance. Let r = the true resistance per mile of each wire in ohms, x = reactance per mile of each wire in ohms, as given in the tables under Inductance and Inductive Reactance; and f = frequency in cycles per second. Then the apparent resistances and reactances per mile of the three wires, No. 2 being the middle wire, are:

$$\left.\begin{array}{lll} r_1 = r + 0.00121f & r_2 = r & r_3 = r - 0.00121f \\ x_1 = x + 0.00070f & x_2 = x & x_3 = x + 0.00070f \end{array}\right\} \quad (26)$$

* The capacitance susceptance to neutral as given in the tables (i.e., in micromhos per mile) is equal to the charging current in amperes per mile per million volts between wire and neutral; the charging current for any other voltage to neutral is in proportion.

The changes in the apparent resistances do not indicate any change in the power dissipated as heat in the wires but a transfer of energy from one wire to the other by the magnetic field surrounding the wires. These relations assume sine-wave currents equal in effective value and differing in phase by exactly 120 deg. The assumption that the currents are exactly balanced cannot be strictly true, since the inequality in the apparent resistances and reactances of the three wires tends to unbalance the system, but the values just given may be taken as a fair approximation when the voltage loss in the line is not over 10 per cent, say. When the line wires are transposed these mutual-inductance effects are eliminated from the line as a whole, though the apparent impedances of the three wires in any one "exposure" of the transposition will be different; the transpositions, however, keep the currents balanced.

Leakage Conductance. The leakage current, even at very high voltages, is usually negligible in power transmission lines, but for telephone lines, the leakage is much greater, on account of the large number of small insulators used, and has a very appreciable effect on both the attenuation and distortion of the voice currents.

When the voltage is sufficiently high on a power line to cause the formation of corona an appreciable leakage current passes from one wire to the other. Even for a sine-wave voltage this leakage current is by no means sinusoidal, since its instantaneous values are practically zero except during the peak of the voltage wave, and consequently the corona loss cannot be accurately represented by a constant leakage conductance. Roughly, however, calling p_c the average value of the corona loss from each wire in watts per mile, corresponding to the given line voltage, the leakage conductance to neutral in micromhos per mile due to the corona may be taken equal to

$$g_c = \frac{p_c}{V^2} \tag{27}$$

where V is the effective (rms) kilovolts to neutral.

RISE OF VOLTAGE AT LOAD END OF LINE ON OPEN CIRCUIT. In every a-c transmission line the voltage at the load end when this end is open is higher than at the generator end, although in short low-frequency lines this rise is inappreciable. In overhead lines for which the product

$$(\text{Cycles per sec}) \times (\text{Length of line * in miles}) < 10{,}000 \tag{28}$$

this no-load rise as a percentage of the delivered voltage is, to a close approximation when the resistance of the wire is less than that of a No. 0 B. & S. copper wire, equal to $\left(\frac{fl}{4000}\right)^2$, where f is the frequency in cycles per second, and l the length of the line in miles. For example, in a 25-cycle line 160 miles long this no-load rise is 1 per cent of the delivered voltage; in a 60-cycle line of the same length the no-load rise in voltage is 5.8 per cent of the delivered voltage. The relation expressed by the above formula under the conditions stated is independent of the value of the delivered voltage and of the size and spacing of the wires, at least for all practical cases.

This rise, which is due to the charging current taken by the line, may be looked upon as present at all loads, but when the load is appreciable the voltage drop, due to the load current, unless leading, more than offsets this voltage rise. A leading current may increase the rise in voltage at the load end as the load comes on.

SYNCHRONOUS CONDENSERS (OR PHASE MODIFIERS) TO MAINTAIN CONSTANT VOLTAGE AT LOAD END. By making the line current at the load end of the line lead the line voltage by the proper phase angle, it is possible to compensate entirely for the change in the load voltage which normally takes place as the load current increases. An overexcited synchronous motor connected in parallel with the load is sometimes used for this purpose, as described in detail in the article on Synchronous Motors. A synchronous motor so used is commonly called a synchronous condenser, since the current taken by it leads the voltage impressed on its terminals.

17. METHODS OF CALCULATING VOLTAGE AND POWER LOSS IN A-C LINES

Previous Revision by R. A. Philip

The absolutely rigorous calculation of an a-c line requires that the distributed nature of the inductance and capacity be considered, i.e., that the line be considered as made up of an infinite number of sections such as shown in Fig. 4. However, simpler approximate methods may be employed for nearly all power lines such as are now used, giving results

* Length of each conductor.

sufficiently accurate for all practical purposes. The accuracy of these approximate methods depends primarily upon the frequency and length of the line; the less the value of the product of these two quantities the simpler is the method which may be employed. Accurate calculation of even a short a-c line with distributed load can be effected only by rather complicated network equations; see under Kirchhoff's laws in Section 3.

LIMITATIONS OF APPROXIMATE METHODS OF A-C LINE CALCULATIONS. The approximate methods of calculating a-c lines, in the order of their simplicity, may be designated as (1) the simple impedance method; (2) the single end-condenser method; (3) the middle condenser or " T " method; and (4) the split condenser or " π " method; the " π " method is also called the " U " method. For short low-voltage lines, the simple impedance method, which entirely neglects the charging current, is usually sufficiently accurate. The single end-condenser method takes the charging current into account in a manner usually sufficiently accurate for all but the longest high-voltage lines. The " T " and " π " methods are still more accurate, but are not given herein, as for exact calculations the rigorous method given below should be used. In fact, it is always well to check an approximate solution by this exact method.

FUNDAMENTAL ASSUMPTIONS ON WHICH FORMULAS GIVEN BELOW ARE BASED. All the formulas given below are based on the assumptions of pure sine-wave currents and voltages and a perfectly balanced system. By using the voltage to neutral instead of the voltage between wires, the formulas are also put in such shape that they may be applied directly to either a single-phase, a two-phase four-wire line, or a three-phase three-wire line, a two-phase four-wire line being considered as two separate single-phase lines. The fundamental idea in this method of treatment is that each line wire is considered as a separate circuit. The return wire shown in the various diagrams is therefore to be considered as having no impedance. This method of treatment of *balanced* polyphase circuits is strictly accurate (see Alternating Currents), but when the system is not balanced the circuit must be treated by the more general methods of network calculations; see Section 3. Also, when the voltage and current waves are not sinusoidal, each harmonic must be treated separately as described in Section 3, Art. 8.

Simple Impedance Method

This method is based upon the assumption that the electrostatic capacity of the line may be neglected entirely, and that the line may be considered simply as an impedance in series with the load, this impedance having a resistance equal to the total resistance of the line conductor and a reactance equal to the total inductive reactance of the line conductor. Fig. 2 is a diagram of the circuit, and Fig. 2a is a complete vector diagram of

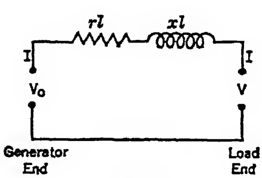

Fig. 2

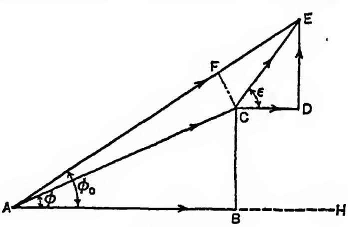

Fig. 2a

the current and voltage. When the wires are unsymmetrically arranged transpositions are assumed

$$\overline{AH} = I \qquad \overline{BC} = V \sin \phi \qquad \overline{CE} = zlI$$
$$\overline{AC} = V \qquad \overline{CD} = rlI \qquad \overline{AE} = V_0$$
$$\overline{AB} = V \cos \phi \qquad \overline{DE} = xlI \qquad \overline{FE} = V_0 - V$$

Let V = volts to neutral at load end of the line (= volts between wires divided by 2 in case of a single-phase line, and volts between wires divided by $\sqrt{3}$ in the case of a three-phase line.

I = amperes per wire; see formula (25) above.

l = length of each line wire in miles.

$Z = \frac{V}{lI}$ = " equivalent " impedance of the load per mile of line.

$\cos \phi$ = power factor of the load at end of line.

$\sin\phi = \sqrt{1 - \cos^2\phi}$ = the reactive factor of the load; $\sin\phi$ is to be taken positive for a lagging and negative for a leading current.

V_0 = volts to neutral at the generator end of the line.

r = conductor resistance per mile of line in ohms; see tables in chapter on Bare Wires and Cables.

x = conductor reactance per mile of line, in ohms; see tables in chapter on Capacitance and Inductance.

$z = \sqrt{r^2 + x^2}$ = conductor impedance * per mile of line, in ohms.

Q = per cent power loss, as a percentage of delivered power.

D = per cent voltage loss, as a percentage of delivered voltage.

From the vector diagram it is evident that the voltage at the generator end is

$$V_0 = \sqrt{(V\cos\phi + rlI)^2 + (V\sin\phi + xlI)^2} \tag{29}$$

which may also be written

$$V_0 = V\sqrt{\left(\cos\phi + \frac{r}{Z}\right)^2 + \left(\sin\phi + \frac{x}{Z}\right)^2} \tag{30}$$

where r and x are per mile of line.

The current at the generator end is the same as at the load end.

The per cent power loss is

$$Q = \frac{100\,rlI}{V\cos\phi} = \frac{100\,r}{Z\cos\phi} \tag{31}$$

and the per cent voltage loss is

$$D = \frac{100(V_0 - V)}{V} = 100\left[\sqrt{\left(\cos\phi + \frac{r}{Z}\right)^2 + \left(\sin\phi + \frac{x}{Z}\right)^2} - 1\right] \tag{32}$$

The power factor at the generator end is

$$\cos\phi_0 = \left(\frac{100 + Q}{100 + D}\right)\cos\phi \tag{33}$$

RELATION BETWEEN IMPEDANCE DROP AND VOLTAGE LOSS. The total impedance drop, which is zlI volts, should be carefully distinguished from the voltage loss, which is $v = V_0 - V$ volts. The vector diagram, Fig. 2*a*, will make the difference clear. For a given impedance drop of, say, A per cent, the voltage at the load end of the line may be anything from A per cent less than the voltage at the generator end to A per cent greater than the voltage at the generator end. The determining factor is the difference between the power-factor angle (ϕ) of the load and the power-factor angle $\left(\epsilon = \tan^{-1}\frac{x}{r}\right)$ of the line; only when $\epsilon - \phi = 0$ are the voltage loss and impedance drop the same. When $\epsilon - \phi$ is greater than 90 deg (which may occur for a leading current, since ϕ is then negative) the voltage at the load end will in general be higher than at the generator end although the impedance drop in the line may be very large. As a fair approximation, when the impedance drop is less than 20 per cent, that is, when z/Z is less than 0.2, the percentage voltage loss may be written

$$D = \frac{100\,z}{Z}\cos(\epsilon - \phi) \tag{34}$$

z and Z being the impedances of the line and load respectively, and ϵ and ϕ the power-factor angles of the line and load respectively.

EXAMPLE OF CALCULATION BY SIMPLE IMPEDANCE METHOD. Take the case of a three-phase, 60-cycle line 50 miles long, the wires being No. 0000 A.W.G. (or B. & S.) stranded copper spaced symmetrically with 6 ft between centers, and let the load be 15,000 kw at 60,000 volts between wires and at a power factor of 80 per cent with lagging current. The voltage to neutral is then $60{,}000 \div \sqrt{3} = 34{,}600$, and the current per wire $15{,}000 \div (\sqrt{3} \times 60 \times 0.8) = 180$ amp. The resistance of each wire per mile

* A convenient way of calculating an expression of the form $\sqrt{a^2 + b^2}$ is to write it $a\sqrt{1 + \left(\frac{b}{a}\right)^2}$ or $b\sqrt{1 + \left(\frac{a}{b}\right)^2}$ according as a is greater or less than b; the expression under the radical will then always lie between the numbers 1 and 2, and no difficulty will be experienced with decimal points. When b/a is less than 0.3, then the expression $\sqrt{a^2 + b^2} = a + \frac{b^2}{2a}$ with an error of less than 0.1 per cent; and when a/b is less than 0.3, then $\sqrt{a^2 + b^2} = b + \frac{a^2}{2b}$ with an error of less than 0.1 per cent. The error in the approximate expressions diminishes very rapidly as the ratio of b/a or a/b, as the case may be, decreases, being only 0.02 per cent when the ratio is 0.2.

is 0.269 ohm at 77 deg fahr, and the reactance 0.728 ohm. The equivalent impedance of the load per mile of line is $Z = 34{,}600 \div (50 \times 180) = 3.84$. Cos $\phi = 0.8$ and $\sin\phi = \sqrt{1 - 0.8^2} = 0.6$. Whence

$$\text{Per cent power loss} = Q = \frac{100 \times 0.269}{3.84 \times 0.8} = 8.76 \text{ per cent}$$

$$\text{Per cent voltage loss} = D = 100\left[\sqrt{\left(0.8 + \frac{0.269}{3.84}\right)^2 + \left(0.6 + \frac{0.728}{3.84}\right)^2} - 1\right] = 17.5\%$$

$$\text{Power factor at generator end} = \cos\phi_0 = \left(\frac{100 + 8.76}{100 + 17.5}\right) \times 0.80 = 74.1 \text{ per cent}$$

$$\text{Per cent impedance drop} = \frac{100\sqrt{0.269^2 + 0.728^2}}{3.84} = 20.2 \text{ per cent}$$

Single End-condenser Method

This method assumes that the total current at the load end is equal to the actual load current plus (vectorially) the charging current which would be taken by a single condenser shunted across the line at the load end, the capacity of this condenser being taken equal

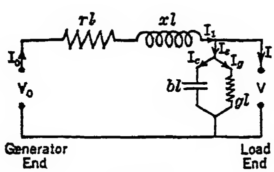

FIG. 3

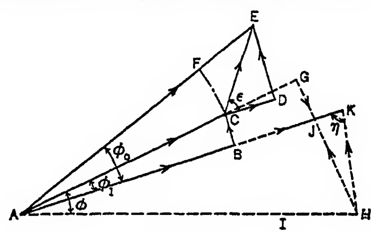

FIG. 3a

$\overline{AH} = I$

$\overline{AC} = V$

$\overline{AG} = I\cos\phi$

$\overline{GH} = I\sin\phi$

$\overline{HJ} = blV \times 10^{-6}$

$\overline{JK} = glV \times 10^{-6}$

$\overline{HK} = ylV \times 10^{-6}$

$\overline{AK} = I_1 = I_0$

$\overline{AB} = V\cos\phi_1$

$\overline{BC} = V\sin\phi_1$

$\overline{CD} = rlI_1$

$\overline{DE} = xlI_1$

$\overline{CE} = zlI_1$

$\overline{AE} = V_0$

$\overline{FE} = v$

to the total capacity of the line. This method gives too low a voltage at the generator end by approximately the same amount that the straight impedance method gives it too high, and also gives the power loss too low by approximately the same amount that the straight impedance method gives it too high. By averaging the losses obtained by the two methods a close approximation to their true values is obtained.

Fig. 3 is a diagram of the circuit, and Fig. 3a is a complete vector diagram of the voltage and current; voltages are shown by full lines and currents by dotted lines. The diagrams and formulas are for the general case of a line with leakage, but for nearly all practical cases the leakage may be neglected.

The effect of the electrostatic capacity of the line is to change both the numerical value and the phase angle of the line current. Or the condenser and the load may be looked upon as forming together an equivalent load taking a current I_1 at a power factor $\cos\phi_1$ differing from the actual current and power factor of the load. Let

V = volts to neutral at the load end of the line.
I = actual amperes per wire at the load end.
$\cos\phi$ = actual power factor at the load end.
$\sin\phi = \sqrt{1 - \cos^2\phi}$ = actual reactive factor at the load end.
l = length of each line wire in miles.
b = capacity susceptance to neutral per mile of line, in micromhos, see tables in Article 21.

g = leakage conductance to neutral per mile of line in micromhos, usually taken equal to zero in power lines, as explained above.

$y = \sqrt{g^2 + b^2}$ = dielectric admittance to neutral per mile of conductor, in micromhos. Note that for no leakage $y = b$.

The total leakage current, total charging current and total exciting current of the line are then respectively

$$I_g = glV \times 10^{-6} \qquad I_c = blV \times 10^{-6} \qquad I_e = \sqrt{I_g^2 + I_c^2} \tag{35}$$

The total line current, i.e., the resultant of the actual load current and the exciting current, is

$$I_1 = I\sqrt{\left(\cos\phi + \frac{I_g}{I}\right)^2 + \left(\sin\phi - \frac{I_c}{I}\right)^2} \tag{36}$$

On the assumptions of this method of calculation, I_1 is also the current at the generator end.

The power factor of the equivalent load formed by the actual load and the condenser is then

$$\cos\phi_1 = \frac{I\cos\phi + I_g}{I_1} \tag{37}$$

and the reactance factor of this equivalent load is

$$\sin\phi_1 = \frac{I\sin\phi - I_c}{I_1} \tag{38}$$

The formulas given above for the straight impedance method are then directly applicable, using for I, $\cos\phi$, and $\sin\phi$ in those formulas the values of I_1, $\cos\phi_1$, and $\sin\phi_1$ just calculated; i.e., the straight impedance method is to be applied not to the actual load but to the equivalent load formed by the actual load and a condenser having an admittance equal to the total admittance of the line.

EXAMPLE OF CALCULATION BY SINGLE END-CONDENSER METHOD. Three-phase line, 50 miles long, No. 0000 A.W.G. stranded copper, 6 ft between centers, frequency 60 cycles, load 15,000 kw, 60,000 volts between wires at load end, 80 per cent power factor at load. This is the same example as used above for the straight impedance method. Then $V = 34{,}600$, $I = 180$, $\cos\phi = 0.8$, $\sin\phi = 0.6$, $l = 50$, $b = 6.03$, $g = 0$, $r = 0.269$, $x = 0.728$. Then,

$$\text{Charging current} = I_c = 6.03 \times 50 \times 34{,}600 \times 10^{-6} = 10.4 \text{ amp}$$

$$\text{Resultant current} = I_1 = 180\sqrt{(0.8)^2 + \left(0.6 - \frac{10.4}{180}\right)^2} = 174 \text{ amp}$$

$$\text{Power factor of equivalent load} = \cos\phi_1 = \frac{180 \times 0.8}{174} = 0.828$$

$$\text{Reactive factor of equivalent load} = \sin\phi_1 = \frac{180 \times 0.6 - 10.4}{174} = 0.561$$

$$\text{Impedance of equivalent load per mile of line} = Z_1 = \frac{34{,}600}{50 \times 174} = 3.98$$

$$\text{Per cent power loss} = Q = \frac{100 \times 0.269}{3.98 \times 0.828} = 8.16 \text{ per cent}$$

$$\text{Per cent voltage loss} = D$$

$$= 100\left[\sqrt{\left(0.828 + \frac{0.269}{3.98}\right)^2 + \left(0.561 + \frac{0.728}{3.98}\right)^2} - 1\right] = 16.30 \text{ per cent}$$

$$\text{Power factor at generator end} = \cos\phi_0 = \left(\frac{100 + 8.16}{100 + 16.3}\right) \times 0.822 = 76.4 \text{ per cent}$$

The per cent power loss and voltage loss obtained by the straight impedance method neglecting the line capacity are respectively 8.76 and 17.6 per cent. As noted above, the single end-condenser method gives these losses too low (for inductive loads) by approximately the same amount that the straight impedance method gives them too high, whence closer approximations to the true losses are: per cent power loss = $(8.16 + 8.76) \div 2 = 8.46$ and per cent voltage loss = $(16.3 + 17.6) \div 2 = 17.0$.

CALCULATION OF EFFECT OF SYNCHRONOUS CONDENSER. Formulas (36) to (38) apply directly to the calculation of the effect of a synchronous condenser at the end of the line taking a current having an in-phase or energy component equal to I_g and a quadrature leading component equal to I_c. Fig. 3a then represents the vector relations of the currents and voltages, the vector JK being the in-phase component of the current taken by the synchronous condenser and HJ the quadrature component.

Exact Calculation of A-C Lines of Any Length and Frequency *

The charging current (and also the leakage current) for any element of a transmission line passes through only that portion of the line conductor between the given element and the generator end. The exact determination of the line current, voltage, and power at any point therefore requires that this fact be taken into account; in other words the capacity and leakage of the line are distributed and not lumped as assumed in the above methods of calculation. In Fig. 4 are shown three successive elements of one wire of a line, a return or neutral of zero impedance being also shown to complete the circuit. This method of treating separately each wire of a line is fully explained above.

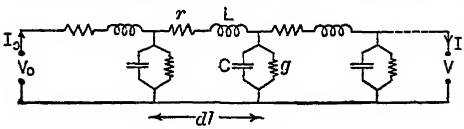

FIG. 4

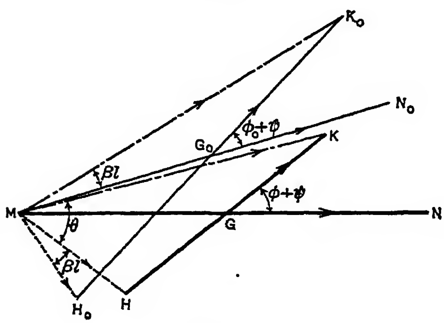

FIG. 4a

$\overline{MN} = I$	$\overline{MK_0} = A\epsilon^{\alpha l}$
$\overline{HK} = YV$	$\overline{MH_0} = B\epsilon^{-\alpha l}$
$\overline{MK} = A$	$\overline{MN_0} = I_0$
$\overline{MH} = B$	$\overline{H_0K_0} = YV_0$

In order to make clear the physical meaning of the various terms employed, the general solution is first given in terms of instantaneous values. Following this are given the working formulas (1) in terms of exponentials, viz., ϵ^x and ϵ^{-x}, (2) in terms of real hyperbolic functions, and (3) in terms of hyperbolic functions of complex angles.

GENERAL EQUATIONS OF TRANSMISSION LINE. Let l = the distance in miles of any point along a transmission line, measured from any arbitrarily chosen point (say from the load end); let i = the instantaneous current in amperes in the conductor at this point, taken positive in the direction *opposite* to that in which l is measured (i.e., positive when *toward* the load end); let v = the potential drop in volts between this point and the neutral; and let r = the conductor resistance in ohms per mile, L = the inductance of the conductor in henrys per mile, C = the capacity to neutral in microfarads per mile, and g = the leakage conductance to neutral in micromhos per mile. The following relations then hold at any point along the line, t being time in seconds measured from any arbitrarily chosen instant:

$$\frac{dv}{dl} = ri + L\frac{di}{dt} \tag{39}$$

$$10^6\frac{di}{dl} = gv + C\frac{dv}{dt} \tag{40}$$

If the circuit is composed of two or more sections of different constants (e.g., an overhead section and an underground section, or a circuit formed by a step-up transformer, transmission line, and a step-down transformer) then a similar set of equations holds for each section of the circuit, the constants r, L, g, and C being in general different for the several sections.

The complete solution of any two equations of the form given by (39) and (40) consists of an infinite series of terms for both v and i, corresponding terms in the two series having the following values:

$$i = \sqrt{2}\epsilon^{-(u-s)t}[A\epsilon^{\alpha l}\sin(\omega t + \beta l + \theta_1) + B\epsilon^{-\alpha l}\sin(\omega t - \beta l + \theta_2)] \tag{41}$$

$$v = \frac{\sqrt{2}}{Y}\epsilon^{-(u-s)t}[A\epsilon^{\alpha l}\sin(\omega t + \beta l + \theta_1 - \psi) - B\epsilon^{-\alpha l}\sin(\omega t - \beta l + \theta_2 - \psi)] \tag{42}$$

PHYSICAL INTERPRETATION AND NAMES GIVEN TO THE VARIOUS CONSTANTS. The constant ω in eqs. (41) and (42) is equal to $2\pi f$, where f is the frequency of the oscillation represented by these equations. In the most general case any change in

* This division is abstracted from the lecture notes of Dr. H. Pender.

the circuit conditions, such as closing or opening a switch, or a lightning stroke in the vicinity of the circuit, may set up an infinite number of oscillations of different frequencies, their frequency being determined by the initial conditions at the instant the change is made. The current and voltage set up by each oscillation is represented by a set of terms of the form given by (41) and (42), and the resultant current and voltage will be respectively the sum of all the current terms and the sum of all the voltage terms. The oscillation of any given frequency, however, may be considered separately, as it is uninfluenced by the presence of the other oscillations. Moreover, in the case of a composite circuit, consisting say of a step-up transformer, transmission line, and step-down transformer, if an oscillation of frequency f is set up in one part of the circuit it will also appear in all other sections of the circuit, though it may be greatly damped in these sections and therefore produce no appreciable effect.

Attenuation Constant (α), Wavelength Constant (β), Wavelength (λ), and Velocity of Propagation (U). Referring to eqs. (41) and (42), each oscillation sets up in each section of the circuit two waves, each of which has a wavelength $\lambda = 2\pi/\beta$; the constant β is therefore called the wavelength constant; it is a function of the frequency and of the constants r, L, g, and C of the circuit. The two waves travel along the line in opposite directions each with a velocity $U = \omega/\beta$; in a composite circuit this velocity U is in general different for each section of the circuit. One wave may be looked upon as the incident and the other as the reflected wave. The amplitude of each wave diminishes by the factor ϵ^{α} as the wave travels unit distance; the factor ϵ^{α} is called the attenuation factor, and the constant α is called the attenuation constant. The attenuation constant is a function of the frequency and the constants r, L, g, and C of the circuit; see below.

Surge Admittance (Y) and its Power-factor Angle (Ψ). The constant Y, which is equal to the quotient of the amplitude (or rms value) of the incident current wave by the incident voltage wave, is called the surge admittance, and its reciprocal is called the surge impedance; it is a function of the frequency and the constants r, L, g, and C of the circuit; see below. The constant ψ, which is equal to the angle by which the incident current wave leads the incident voltage wave, is called the power factor angle of the surge admittance; it is a function of the frequency and the constants r, L, g, and C; see below.

Amplitude Constants (A and B) and Phase-angle Constants (θ_1 and θ_2). The constants are equal to the amplitudes of the incident and reflected current waves at the point from which the distance l is measured, and the constants θ_1 and θ_2 give the phase of these two waves at this point ($l = 0$) at the instant from which time is measured ($t = 0$). Note that the incident current wave at $l = 0$ leads the reflected current wave by the angle $\theta = \theta_1 - \theta_2$. The determination of these constants for steady-state conditions is given below.

Natural Damping Constant (u), Energy Transfer Constant (s), and Composite Damping Constant ($u - s$). In the general case of a natural oscillation in a composite circuit the amplitude of each wave diminishes in unit time by the factor $\epsilon^{(u-s)}$; this factor is called the composite damping factor, and the constant $(u - s)$ is called the composite damping constant. The composite damping constant, like the frequency f, is the same for all sections of a composite circuit. In the case of a line of uniform constants throughout, not connected to any terminal apparatus, it can readily be shown that $s = 0$, in which case the amplitude of the oscillations diminishes in unit time by the factor ϵ^{u}; this factor is therefore called the natural damping factor, and the constant u, which for a section having the constants r, L, g, and C per unit length, is equal to

$$u = \frac{1}{2}\left(\frac{r}{L} + \frac{g}{C}\right) \tag{43}$$

is called the natural damping constant. Any section of a composite circuit for which the actual damping $\epsilon^{(u-s)}$ is less than the natural damping ϵ^{u} must receive energy from some other section; consequently a positive value of s for a given section means that energy is transferred into this section from some other section of the circuit. Similarly, a negative value of s for a given section means that energy is transferred from this section to some other section. The constant s may therefore be called the energy transfer constant. Since the voltage and current in the circuit cannot increase indefinitely the energy transfer constant s can never have a positive value greater than u.

Since the composite damping constant $(u - s)$ is the same for all sections of a circuit, it follows that the transfer of energy from one section to another by oscillations in a composite circuit will always be into the section in which u is the larger from the section in which u is the smaller. Neglecting the leakage conductance g, this means that energy will be transferred into section 1 from section 2, when r_1/L_1 is greater than r_2/L_2, that is, energy is transferred from the section of the larger time constant (L_2/r_2) to that of the smaller time constant (L_1/r_1). When the resistances are small, this means that in the limiting

case all the energy ($= {}^1/_2\, L_2 I^2$) of the magnetic field of the second section may go into electrostatic energy ($= {}^1/_2\, C_1 V^2$) in the first section, producing therefore a very high voltage at the junction point when the inductance L_2 of the second section is large compared with the capacity C_1 of the first section. This accounts for the very high voltages sometimes set up during switching operations at the junction point of an overhead line with an underground line, or in a transformer connected to a long overhead line.

STEADY-STATE CONDITIONS IN A TRANSMISSION LINE. From the above discussion it is evident that, when a sufficient time (usually a small fraction of a second) has elapsed after any change in the circuit conditions, the only terms left in the general equations of a transmission line for a given impressed sine-wave voltage of frequency f are those for which $s = u$, viz.,*

$$i = \sqrt{2}\left[A\epsilon^{\alpha l} \sin(\omega t + \beta l) + B\epsilon^{-\alpha l} \sin(\omega t - \beta l - \theta)\right] \tag{44}$$

$$v = \frac{\sqrt{2}}{Y}\left[A\epsilon^{\alpha l} \sin(\omega t + \beta l - \psi) - B\epsilon^{-\alpha l} \sin(\omega t - \beta l - \theta - \psi)\right] \tag{45}$$

The effective value of the current at any point is then equal to the sum of two vectors having the lengths $A\epsilon^{\alpha l}$ and $B\epsilon^{-\alpha l}$, the former leading the latter by the angle $(2\beta l + \theta)$, and the effective value of the voltage is equal to the difference of these same two vectors divided by Y. The phase angle between the voltage and current is equal to the phase angle between the sum and difference of the A and B vectors less the angle ψ.

Notation for Steady-state Conditions. These relations are clearly shown in the vector diagram, Fig. 4*a*, which is a complete vector diagram of a transmission line with distributed capacity and leakage. The four constants α, β, Y, and ψ are constants of the line, independent of the load, and are expressed in terms of the ordinary line constants as follows: Let

f = frequency in cycles per second.

r = conductor resistance per mile, in ohms; see tables in Article 47 of this section.

$x = 2\pi f L$ = conductor reactance per mile, in ohms, corresponding to the impressed frequency f; see tables in chapter on Inductance and Inductive Reactance.

$z = \sqrt{r^2 + x^2}$ = conductor impedance per mile, in ohms.

g = leakage conductance to neutral per mile of line, in micromhos. For power lines g is usually taken equal to zero.

$b = 2\pi f C$ = capacity susceptance to neutral per mile of line, in micromhos, corresponding to the impressed frequency f; see tables in Article 22 of this section.

$y = \sqrt{g^2 + b^2}$ = dielectric admittance per mile, in micromhos; when $g = 0$, then $y = b$.

$\alpha = 10^{-3}\sqrt{\dfrac{yz - bx + gr}{2}}$ = the attenuation constant; for r and g small compared with x and b this reduces to $\dfrac{10^{-3}}{2}\left(r\sqrt{\dfrac{C}{L}} + g\sqrt{\dfrac{L}{C}}\right)$.

$\beta = 10^{-3}\sqrt{\dfrac{yz + bx - gr}{2}}$ = the wavelength constant; for r and g small respectively compared with x and b this reduces to $2\pi f \times 10^{-3}\sqrt{LC}$, which for an overhead line equals approximately $\dfrac{2\pi f}{180{,}000}$.

$Y = 10^{-3}\sqrt{\dfrac{y}{z}}$ = surge admittance; for r and g small respectively compared with x and b, this reduces to $10^{-3}\sqrt{\dfrac{C}{L}}$. The reciprocal of the surge admittance is called the surge impedance.

$\psi = \tan^{-1}\sqrt{\dfrac{yz - bx - rg}{yz + bx + rg}}$ = the power-factor angle of the surge admittance, taken positive for $gx < br$ and negative for $gx > br$. For r and g small compared with x and b, then $\psi = 28.7\left(\dfrac{r}{x} - \dfrac{g}{b}\right)$ degrees.

---

* For steady-state conditions time may be counted from any arbitrarily chosen interval, i.e., θ_1 in eq. (41) and (42) may be put equal to zero, and for convenience $-\theta$ may be used for θ_2.

$U = \frac{2\pi f}{\beta}$ = velocity of propagation in miles per second; for a frequency f sufficiently high to make r negligible compared with x, and g negligible compared with b, this reduces to $\frac{10^3}{\sqrt{LC}}$, which for an overhead line with wires far apart is equal to the velocity of light in air, viz., 180,000 miles per second, approximately.

$\lambda = \frac{2\pi}{\beta} = \frac{U}{f}$ = wavelength of each wave in miles; for a frequency f sufficiently high to make r negligible compared with x, and g negligible compared with b, this reduces to $\frac{10^3}{f\sqrt{LC}}$, which for an overhead line is equal approximately to $\frac{180{,}000}{f}$ miles.*

In the vector diagram and in the formulas given below, let

l = length of the line in miles.
I = effective (rms) value of the amperes per wire at the load end.
V = effective (rms) value of the volts to neutral at the load end.
ϕ = the power-factor angle at the load end, i.e., $\cos\phi$ is the power factor at the load end. ϕ is taken positive for a lagging and negative for a leading current.
I_0, V_0, ϕ_0 = corresponding quantities at the generator end.

Solution by Vector Diagram (Fig. 4*a*). Having calculated the constants α, β, Y, and ψ, and knowing the current I, voltage V, and power-factor angle ϕ of the load,

Lay off $\overline{MN} = I$ as the base line, and bisect it at G.

At the angle $(\phi + \psi)$ ahead of $\overline{MN}$ lay off the line $\overline{HK}$ equal in length to YV, so that it is also bisected by G.

Then measure off $\overline{MK} = A$ and $\overline{MH} = B$.

Lay off at the angle 57.3 βl deg ahead of A the line $\overline{MK_0}$ equal in length† to $A\epsilon^{\alpha l}$.

Lay off at the angle 57.3 βl deg behind B the line $\overline{MH_0}$ equal in length to $B\epsilon^{-\alpha l}$.

Bisect H_0K_0 at G_0.

Then the line $\overline{MN_0} = 2\overline{MG_0}$ is equal to the current at the generator end; the line $\overline{H_0K_0}$ divided by Y is equal to the voltage at the generator end; the angle between $\overline{G_0N_0}$ and $\overline{G_0K_0}$ less the angle ψ is the power-factor angle at the generator end.

Note that the voltage at the load end if drawn in the diagram would be at the angle ψ behind the vector $\overline{GK}$, and at the generator end would be at the angle ψ behind $\overline{G_0K_0}$.

Algebraic Solution for Steady-state Conditions. The vector diagram may be solved algebraically as follows: Calculate first the constants A, B and θ from the formulas:

$$A = \tfrac{1}{2}\sqrt{I^2 + (YV)^2 + 2\,YVI\cos(\phi + \psi)} \tag{46}$$

$$B = \tfrac{1}{2}\sqrt{I^2 + (YV)^2 - 2\,YVI\cos(\phi + \psi)} \tag{47}$$

$$\theta = \tan^{-1}\left[\frac{2\,YVI\sin(\phi + \psi)}{I^2 - (YV)^2}\right] \tag{48}$$

Note that $\sin\theta$ has the same algebraic sign as the numerator of this fraction and $\cos\theta$ has the same algebraic sign as the denominator of this fraction; this fixes the quadrant in which θ lies.

Put
$$A_0 = A\epsilon^{\alpha l}, \quad \text{and} \quad B_0 = B\epsilon^{-\alpha l} \tag{49}$$

The current, voltage, and power-factor angle at the generator end are, then, expressing all angles in degrees,

$$I_0 = \sqrt{A_0^2 + B_0^2 + 2\,AB\cos(114.6\,\beta l + \theta)} \tag{50}$$

$$V_0 = \frac{1}{Y}\sqrt{A_0^2 + B_0^2 - 2\,AB\cos(114.6\,\beta l + \theta)} \tag{51}$$

$$\phi_0 = \tan^{-1}\left[\frac{2\,AB\sin(114.6\,\beta l + \theta)}{A_0^2 - B_0^2}\right] - \psi \tag{52}$$

Note that the quadrant in which $(\phi_0 + \psi)$ lies is determined by the algebraic signs of the numerator and denominator of the fraction in the brackets, just as in the case of the angle θ.

---

* The above formulas for z, y, α, β, Y, ψ, U, and λ also hold for the transient or free oscillations in a single circuit, and also for each section of a composite circuit, provided in these formulas $r_1 = r(u - s)L$ is substituted for r and $g_1 = g \div (u - s)C$ is substituted for g.

† See Fund. of Eng., Section 1, Table 17, for values of ϵ^x and ϵ^{-x}, where x is any number.

Solution of Steady-state Conditions in Terms of Hyperbolic Functions.* The above expressions for the current, voltage and power factor at the generator may also be put in the form,

$$I_0 = I\sqrt{\frac{\cosh(2\,\alpha l + \gamma) + \cos(114.6\,\beta l + \theta)}{\cosh\gamma + \cos\theta}} \tag{53}$$

$$V_0 = V\sqrt{\frac{\cosh(2\,\alpha l + \gamma) - \cos(114.6\,\beta l + \theta)}{\cosh\gamma - \cos\theta}} \tag{54}$$

$$\phi_0 = \tan^{-1}\left[\frac{\sin(114.6\,\beta l + \theta)}{\sinh(2\,\alpha l + \gamma)}\right] - \psi \tag{55}$$

where θ and γ are given by the formulas

$$\gamma = \tanh^{-1}\left[\frac{2\,YVI\cos(\phi + \psi)}{I^2 + (YV)^2}\right] \tag{56}$$

$$\theta = \tan^{-1}\left[\frac{2\,YVI\sin(\phi + \psi)}{I^2 - (YV)^2}\right] \tag{57}$$

The other quantities are as above defined. Note that θ is the same angle as given by eq. (48), and the quadrant in which it lies is to be determined as described in the note under (48). Also note that the constant γ given by (56) may be expressed in terms of A and B, given by (46) and (47), by means of the formula

$$\gamma = \log_\epsilon\left(\frac{A}{B}\right) = 2.302\log_{10}\left(\frac{A}{B}\right) \tag{58}$$

Formulas for Open Circuit and Short Circuit at Load End. When the line is open at the load end, $I = 0$, whence, from eq. (46) to (48), $A = {}^1/_2\,YV$, $B = {}^1/_2\,YV$, and $\theta = 180$ deg (since the denominator of the fraction is negative). When the line is short-circuited at the load end, $V = 0$, and $A = {}^1/_2 I$, $B = {}^1/_2 I$, and $\theta = 0$ deg (since the denominator of the fraction is positive). The current, voltage and power-factor angle at any point along the line may then be found in either case by substituting these values in eq. (50) to (52), which reduce to the simple hyperbolic forms:

On Open Circuit	On Short Circuit
$I_0 = YV\sqrt{\sinh^2(\alpha l) + \sin^2(57.3\,\beta l)}$	$I_0 = I\sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\,\beta l)}$
$V_0 = V\sqrt{1 + \sinh^2(\alpha l) - \sin^2(57.3\,\beta l)}$	$V_0 = \frac{I}{Y}\sqrt{\sinh^2(\alpha l) + \sin^2(57.3\,\beta l)}$
$\phi_0 = -\tan^{-1}\left[\frac{\sin(114.6\,\beta l)}{\sinh(2\,\alpha l)}\right] - \psi$	$\phi_0 = +\tan^{-1}\left[\frac{\sin(114.6\,\beta l)}{\sinh(2\,\alpha l)}\right] - \psi$

Solution of Steady-state Equations in Complex Hyperbolic Functions. Expressing all quantities other than the length l in symbolic notation, the equations of the transmission line, for *steady-state conditions only*, may be written

$$\dot{I}_0 = \dot{I}\,\frac{\sinh(l\sqrt{\dot{y}\dot{z}} + \dot{B})}{\sinh\dot{B}} \tag{59}$$

$$\dot{V}_0 = \dot{V}\,\frac{\cosh(l\sqrt{\dot{y}\dot{z}} + \dot{B})}{\cosh\dot{B}} \tag{60}$$

where the symbols other than $\dot{B}$ have the same meanings as above, except that they are all expressed as complex quantities, and

$$\dot{B} = \tanh^{-1}\left(\frac{\dot{I}}{\dot{V}}\sqrt{\frac{\dot{z}}{\dot{y}}}\right) \tag{61}$$

The real part of $\sqrt{\dot{y}\dot{z}}$ is the attenuation constant and the imaginary or "j" part is the wavelength constant.

18. STABILITY OF TRANSMISSION LINES

By John H. Palmer

General Principles and Definitions

This article should be read in connection with Section 3, Arts. 57–64 incl., where a mathematical treatment of the subject is given. In particular, Art 57 gives definitions reported by the Standards Committee of A.I.E.E.

* Tables of hyperbolic functions are given in Fund. of Eng., Section 1, Table 17.

Causes of Instability

Some of the common causes of instability of a power system are as follows:

Transient instability:

1. Line switching.
2. Sudden changes in load.
3. System faults.

Steady-state instability:

1. Overloading.
2. Highly inductive loads with subsequent low power factor of the system.

Let us assume a simple power system consisting of a generator with its prime mover supplying power to a synchronous motor over a two-circuit transmission line.

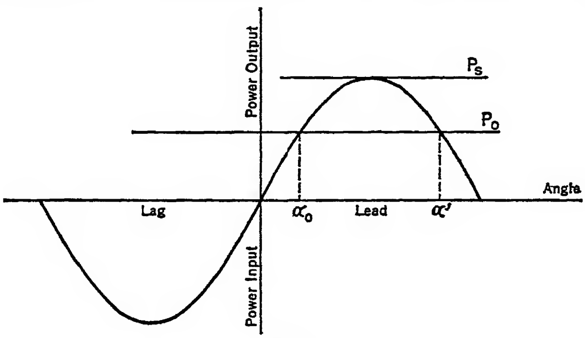

Fig. 5

For a steady-state condition there will be a phase angle between the internal emf's of the generator and motor. This angle is a function of the load and usually varies as shown in Fig. 5.

Let us now assume a mechanical power input to the generator represented by P_0. For this input α_0 is the angle between the generator and motor emf's for the steady-state equilibrium condition. P_0, the input to the generator, however, intersects the curve at another point α'. This, also, is a point of equilibrium, but at this point the system is unstable. For instance, assume that for some reason there is a slight increase in the angle α, beyond α'. This (from the curve) will cause a decrease in power output, and since P_0 is constant, the generator will accelerate, which will cause the angle α to increase. This in turn will cause a further drop in output so that the effect will be cumulative and the motor will drop out of step. By similar reasoning it will be seen that a decrease in α from α' will have the same effect. Similar analysis of the diagram at the angle α_0 shows that this is a point of stable equilibrium. It is now evident that P_s is the maximum power which can be transmitted over this system under stable, steady-state conditions. In other words, it is the stability limit of the system. However, with power input of P_0, a transient swing of the angle α from α_0 may extend as far as α' without causing instability. Under this condition, even on the descending side of the curve, the power output will be greater than the input, slowing down the generator and causing the angle to return to the stable position at α_0.

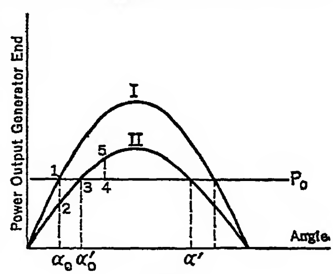

Fig. 6

LINE SWITCHING. Let us now consider again the same transmission line and determine the effect of opening one line at either end. The power-angle diagram for the system at the generator end is shown in Fig. 6, curve I representing conditions before switching, and curve II, conditions after switching.

Then if we assume the power input to the generator to be P_0, the original steady-state angle α will be at α_0. After the switching operation a new position of equilibrium will be reached at α_0'. When the system is operating at α_0 the opening of the line reduces the power that will be taken over the system at that angle by the vertical distance between

the power input curve and the new output curve II. The distance between points 1 and 2 represents the power consumed in accelerating the generator rotor. Because of this acceleration the angle α will increase along the new curve toward point 3. As it approaches point 3 the accelerating force will decrease and the velocity will increase until at point 3 the accelerating force will be zero and the velocity a maximum. As a result the rotor will overrun the position of equilibrium at 3 toward point 5, causing a retarding force to be set up which will increase as 5 is approached. At point 5 the velocity will be normal, but the angle α and the output will be too great for equilibrium, producing a maximum retarding force tending to bring conditions back to point 3. The rotor will again overrun the position of equilibrium, causing oscillation about the final position 3. The amount of overswing will be such that the area 1, 2, 3 equals area 3, 4, 5 except for the losses, which produce the necessary damping action to stop this oscillation. For this case, the system is stable since the overrun does not carry the angle beyond α'.

SUDDEN CHANGES IN LOAD. This differs from switching operations in that the circuit constants remain substantially the same and the input and output vary, whereas with switching, the input and output are substantially the same and the circuit constants are changed. Considering again the two-circuit power system, let us assume that the load is increased as indicated in Fig. 7, from P_0 to P_1. If this increase is sudden the prime-mover governor will not respond immediately and the increase in power will have to be supplied by the kinetic energy of the system, slowing it down.

But in this case the motor will slow down faster than the generator, so that the relative effect will be the same as an increase in speed of the generator, increasing the angle α. This slowing down, however, will cause the governor of the prime mover to act and restore the speed to normal by increasing the power input to the system, to correspond to the new power output. There will be some oscillation of the system as described under Line Switching, but if stable it becomes steady at the angle α_0', corresponding to the new load. The same conditions of stability apply as before.

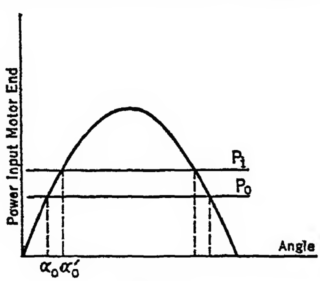

FIG. 7

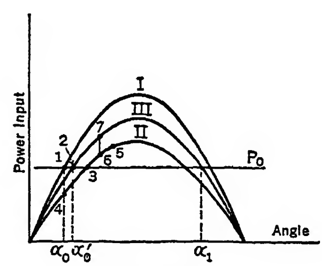

FIG. 8

SHORT CIRCUITS. Short circuits present considerably more complications than switching operations and changes in load, because three distinct networks are involved:

(*a*) The original condition prior to the short circuit.

(*b*) A second condition during the short circuit.

(*c*) A third condition after the short circuit has been cleared, usually by a switching operation.

The second condition is what makes the short circuit radically different from switching operation and load changes. The short circuit may increase or decrease the power input according to whether it is a high- or low-resistance fault. A high-resistance fault is usually in the form of a failure to ground in a grounded neutral system, and there is a certain fault resistance for which the power input will be a maximum.

Low-resistance Fault. Fig. 8 shows the power-angle diagrams for a low-resistance fault, in which curve I shows the condition before short circuit occurs; curve II, the condition during short circuit; and curve III, the condition after the fault is cleared.

Point 1 at angle α_0 represents the point of equilibrium before short circuit occurs. Immediately when the fault is applied, the operating point will jump to 4. This will cause the generator to speed up to try to reach the point of equilibrium 3 on curve II. An oscillation will then be set up between points 4, 3, and 5 as previously described, during which time the fault will be cleared, say at point 6. Conditions will then jump to point 7, curve III. This will cause a second oscillation about 2, and the system will soon become stable at 2, angle α_0', provided it does not swing beyond the maximum stability angle α_1.

High-resistance Fault. Fig. 9 shows the power-angle diagram for a high-resistance fault, with the three curves, I, II, III, representing the same respective circuit conditions as in Fig. 8. Here again the same sequence of events will take place as described for a low-resistance fault. However, in this case the electrical power input to the line is greater than the mechanical input at point 4 and will be supplemented for a short time by the inertia of the generator. This will cause a large oscillation to start about the new point of equilibrium 3 during short circuit, from 4 to 5, changing the angle from leading to lagging as shown.

The area 1, 3, 4 represents the energy given up by the generator in moving from 4 to 3 during which time the electrical input to the system is greater than the mechanical input P_0. The generator starts giving up its kinetic energy immediately, and the motor starts giving it up as soon as the angle becomes lagging. It will be noted that at point 10 the electrical power input to the system becomes negative, indicating that the *generator* has started to operate as a motor, taking energy from the *motor* as well as from its prime mover. Thus the energy given to the generator by the *motor* during the swing down to point 5 is represented by area 10, 5, 11. The energy supplied to the system by the prime mover during this swing is represented by area 1, 9, 11, 12. Of this energy, 1, 3, 10, 12 would be furnished to the motor and fault while 3, 9, 11, 10 would be used in accelerating the generator. The energy given up by the motor (10, 5, 11) would also be used in accelerating the generator. Suppose now that during the oscillation about point 3 a circuit breaker opens at point 6 clearing the line on which the fault has occurred. Conditions will immediately jump to point 8 on curve III. The generator with the load removed will accelerate very rapidly with conditions following curve III up to point 2 where it will have a surplus of kinetic energy equal to area 2, 7, 8. If this area is greater than the area enclosed between P_0 and curve III, the generator will overrun the second equilibrium point at α_1 and instability will occur. If this area 2, 7, 8 is smaller, the system will be stable.

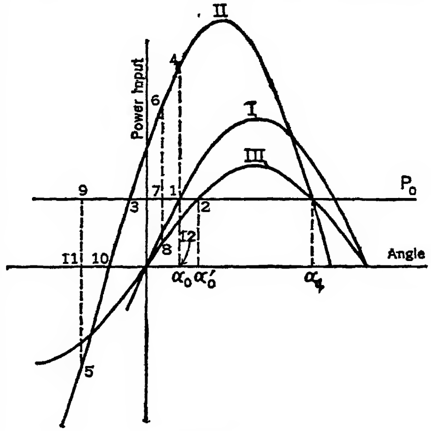

FIG. 9

From the above it will be seen that fault resistance is of great importance in the consideration of short circuits.

Assumptions Made. The preceding discussion has been given in an attempt to present a general picture of the phenomena of stability. Certain simplifying assumptions have been made which in practice will require modification; for example, the mechanical inputs and outputs of machines are assumed constant. When actual values are known as a function of time, suitable corrections can be made. Also, it is assumed above that the internal voltages of the machines are constant. The effect of this may be corrected for by drawing power-angle curves of different voltages.

Methods Used to Increase Stability

The above method of visualizing the phenomena of stability also aids in an understanding of the various methods which have been used to increase stability. These methods are as follows:

1. The use of synchronous condensers at strategic points along the line for improvement of power factor and voltage regulation, and for supplying power to the line under transient conditions.
2. Improved inherent regulation of machines.
3. The use of static capacitors in series with the line.
4. Increased speed of excitation.
5. Faster-acting prime-mover governors.
6. High-speed relays and circuit breakers to reduce the oscillations subsequent to the opening of a breaker.
7. Taking account of ground resistances, under condition of high fault current, in designing the system.

The above discussion of power-angle relations is largely from C. L. Fortescue's paper on Transmission Stability, A.I.E.E., 1925, p. 984.

Mechanical Analogies

Another excellent method of visualizing transmission-line characteristics is by means of mechanical analogies. See Mechanical Analogy to the Problem of Transmission Stability, by S. B. Griscom, *Elec. J.*, May, 1926.

The following is based on this article. Referring again to the above transmission system, the vector diagram under certain conditions might be as shown in Fig. 10, assuming

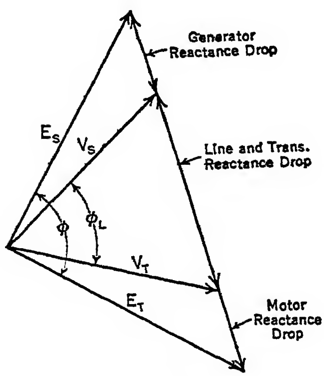

FIG. 10.

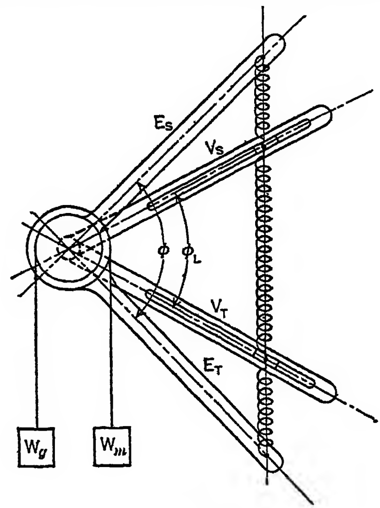

FIG. 11

a transmission line of pure reactance and zero resistance. Here:

E_s = internal emf of the supply generator.
V_s = terminal voltage of the generator.
V_t = terminal voltage of the motor.
E_t = internal emf of the motor.

This may be represented mechanically as shown in Fig. 11.

The arms represent the corresponding vectors shown in Fig. 11 with the spring representing the reactance drop.

The moment produced by W_g = the power input to the generator.

The moment produced by W_m = the power output of the motor.

Now, assuming constant internal voltages; if W_m increases slowly so that the generator governor can follow the change in load and keep the system in equilibrium, then W_g will increase correspondingly and the angles ϕ and ϕ_L will increase, lengthening the (reactance drop) springs. This will also decrease the terminal voltages V_s and V_t as shown. This will continue until angle ϕ reaches 90 deg, after which the mechanical system will become unstable and will collapse. This is due to the fact that while the force exerted by the springs is still increasing with the angle, the moments produced by this force acting on the arms at E_s and E_t starts to decrease after passing the 90-deg angle. The same will be true of the electrical system. Instability occurs when the internal emf's of the generator and motor become 90 deg out of phase.

Many other effects can be demonstrated with similar analogies, and this is very thoroughly discussed in the above reference.

19. CORONA

Original Author, F. W. Peek
Revisions by W. A. Del Mar

If a potential difference is established between smooth parallel wires, or between concentric cylinders, and gradually increased, a voltage is finally reached at which a

hissing noise is heard. If it is dark, a pale glow, called the electric "corona," will be seen to surround the wires. When wattmeters are inserted in the line a loss is noticed to start at this critical voltage. There is also noted the characteristic odor of ozone, and the air around the wires becomes ionized. These phenomena are referred to as "corona effects."

The corona starts at the conductor surface, because the voltage stress per unit distance, or "voltage gradient," is highest there. The breakdown or corona extends out to a point where the stress is below the breakdown point of air. If the wires are close together, so that the stress is fairly uniform, the breakdown immediately extends from conductor to conductor without corona, and the phenomenon is called a "spark-over." The corona does not extend to the other conductor when the separation is large compared to the wire diameter, because it reaches a point in space where the gradient is below the breakdown gradient of air. Increasing the voltage after the corona point is reached causes the corona to extend until finally a spark occurs from conductor to conductor. The power loss increases very rapidly with increase in voltage above the critical point.

Corona is caused by either a-c or d-c voltages, and starts at approximately the same maximum stress. At the critical voltage, corona occurs only at the crest of the alternating wave. As the voltage is increased above the critical point, the loss extends over a greater portion of the wave. In the a-c corona the eye sees a superposition of the corona caused by the plus and minus half-cycles of the a-c waves. If the effects of the half-waves are viewed separately, it is noticed that a reddish haze surrounds the wire while it is negative, whereas the surface of the wire glows bluish-white while it is positive. Positive and negative d-c corona have exactly the same appearance as the positive and negative corona of the corresponding a-c half-waves. When a negative wire becomes oxidized, reddish tufts appear. If there are rough spots on the wire the corona starts at these points at a lower voltage. At points the positive corona extends out as a bluish-white spray; the negative corona appears as a red tuft.

Corona is also caused by transient voltages. Corona produced by voltages lasting less than a millionth of a second can be seen by the eye and distinction can be made between a positive and negative half-wave.

CORONA VOLTMETER. For a given conductor arrangement and air density corona always starts at the same maximum voltage. Use has been made of this fact in the corona voltmeter (Whitehead and Isshiki, J.A.I.E.E., May, 1920.) For this purpose, a wire in the center of a cylinder is generally used. In one form, the voltage is applied and the air density varied until the corona appears. The voltage is then readily calculated or read from a scale. A tapered wire has also been used. The starting point can be detected by the glow, the noise, the odor, or the conducting ionized air.

LAWS OF CORONA-FORMATION. The laws of corona have been quite definitely worked out. The chief factors affecting corona formation are:

For a given spacing and air density the corona starting voltage is lowered by decreasing the wire diameter.

Increasing the spacing increases the corona starting voltage, but the effect of changing the diameter is relatively much greater.

Decreasing barometric pressure decreases air density and decreases the corona starting voltage.

Increasing temperature decreases air density and decreases the corona starting voltage.

Dirt, water, etc., on the conductor surfaces lower the corona starting voltage by increasing the stress.

The *apparent strength* of air is not constant in irregular fields but greater at the surface of small conductors than large ones. The strength at the start of corona is always constant, however, at a distance from the conductor which is a known function of the radius, known as the **energy distance.** This corresponds to the strength in a uniform field of 76 kv per in. (maximum value in case of a-c voltage), which seems to mean that the actual strength of air is 76 kv per in. In order, however, that a finite thickness only may be brought to this stress in an irregular field, the stress at the conductor surface must be higher. At a given spacing the corona always starts at a lower voltage on small wires than large ones, because, although the *apparent strength* of air at the small conductor surface is greater, the stress produced by a given voltage is relatively much higher for the smaller wires.

Corona does not start at exactly the same voltages when the wires are alternately plus and minus. The difference is at most a few per cent and is greater for small wires than large ones.

For perfectly clean, smooth wires of uniform diameter, there is no loss until the *visual critical voltage* is reached, when the loss assumes a *definite value* and increases as a function of the ratio of the applied voltage and the *disruptive critical voltage.* The *visual critical*

voltage takes into account the *apparent strength* of the air, which is a function of the wire diameter; the *disruptive critical* voltage corresponds to the constant strength of air for uniform fields, which is about 76 kv per in., maximum value. The *visual critical voltage* is always higher than the *disruptive critical voltage. Owing to irregularities there is always a loss below the visual critical voltage.*

Corona loss increases with increasing frequency being proportional to the frequency, between 25 and 60 cycles.

The formulas for calculating corona on transmission lines are given below.

Corona on Transmission Lines

It is of great importance in the design of high-voltage transmission lines to know the various factors that affect the corona formation and to be able to estimate accurately the starting voltage and loss for a given line.

The various characteristics may be calculated from the following formulas based on the work of F. W. Peek, as modified by Wm. S. Peterson, A. Nuttall, V. Siegfried, J. S. Carroll and B. Cozzens, Trans. A.I.E.E., 1933, vol. 52, pp. 55–63.

Let e = rms value of the kilovolts to neutral ($= 1/\sqrt{3}$ kilovolts between wires for three-phase; $= 1/2$ kilovolts between wires for single-phase).

e_0 = disruptive voltage in kilovolts to neutral at which the voltage gradient at the surface of the conductor is equal to the air breakdown value.

t = temperature of the conductor in degrees fahrenheit.

b = barometric pressure, in inches.

$\delta = \dfrac{17.9b}{459 + t}$ = specific gravity of air, referred to air at 77 deg. fahr and 29.9 in. barometric pressure.

r = radius of conductor, in inches.

$g_0 = 53.6$ = disruptive critical gradient, kilovolts per inch, rms value.

$g_v = g_0\,\delta\left(1 + \dfrac{0.189}{\sqrt{\delta r}}\right)$ = visual critical gradient, kilovolts per inch, rms value.

s = distance between conductor centers, in inches.

f = frequency, cycles per second.

Then, for smooth round conductors, the disruptive critical voltage, rms value of kilovolts to neutral, is

$$e_0 = 2.302\, m\, g_0\, r\delta^{2/3} \log_{10}\left(\frac{s}{r}\right) \tag{62}$$

where m is the roughness factor and has the following values.

Condition of Conductor	m
New, unwashed conductors	0.67 to 0.74
Washed with a grease solvent *	0.912 to 0.93
Scratch-brushed	0.885
Buffed	1.00
Dragged and dusty	0.72 to 0.75
Weathered (5 months)	0.945
Weathered wire at low humidity	0.92
Same, at night, as low as	0.78
For general design	0.87 to 0.90

* It is found that die grease greatly increases corona loss.

For stranded conductors having 12 or more strands in the outer layer, the disruptive critical voltage, rms value of kilovolts to neutral, is

$$e_0 = \frac{123.4\,\delta^{2/3} m\left[\log_{10}\dfrac{s}{cr_1} + (n-1)\log_{10}\dfrac{2s}{(d - 2\,cr_1)}\right]}{\dfrac{1}{cr_1} + (n-1)/(d - 2\,cr_1)} \tag{63}$$

where r_1 is the radius of an individual strand, n is the number of strands in the outside layer, and c is given by

$$c = \left[1 - \frac{\sin\left(\dfrac{\pi}{2} + \dfrac{\pi}{n}\right)}{\left(\dfrac{\pi}{2} + \dfrac{\pi}{n}\right)}\right] \tag{64}$$

For **stranded conductors** having 6 outside strands,

$$e_0 = \frac{123.4\,\delta^{2/3}\,rm\left[\left(\log_{10}\frac{s}{r}\right) + 0.0677\right]}{1.37} \tag{65}$$

The **visual critical voltage,** rms value of kilovolts to neutral, is given approximately by

$$e_v = 2.302\, m_v\, g_v\, r \log_{10}\left(\frac{s}{r}\right) \tag{66}$$

where m_v, for polished wires, $=0.72$ for local corona and $=0.82$ for decided corona all along cable.

The **power loss in fair weather,** in kilowatts per mile of single conductor, is

$$p = \frac{0.0000337\, fe^2F}{\left(\log_{10}\frac{s}{r}\right)^2} \tag{67}$$

where F is a function of $\frac{e}{e_0}$, having the values given in Table IV.

Table IV. Empirical Corona Loss Function, F

$\frac{e}{e_0}$	F	$\frac{e}{e_0}$	F	$\frac{e}{e_0}$	F	$\frac{e}{e_0}$	F	$\frac{e}{e_0}$	F
0.6	0.011	1.4	0.32	2.2	8.4	6.0	22	12	28
0.8	0.018	1.5	0.92	2.4	9.8	7.0	24	14	29
1.0	0.036	1.6	2.70	3.0	10.5	8.0	26	16	29
1.2	0.083	1.8	5.1	4.0	16.5	9.0	27	18	29
1.3	0.140	2.0	7.0	5.0	19 0	10.0	28	20	30

Methods of Increasing Size of Conductors. For equal conductivity an aluminum conductor has about a 25 per cent greater diameter than a copper conductor, and, therefore, approximately 25 per cent higher critical voltage. The advantage of aluminum may be still further increased by the addition of a steel cable core. Aluminum, however, is more easily nicked or scratched than copper, during installation, thereby losing some of this advantage.

Copper cables of large diameter are now made with tubular strands, or with ordinary strands on a twisted I-beam core, or in annular form with interlocked or keyed strands. See Art. 49, chapter on Bare Wires and Cables.

ARRANGEMENT OF CONDUCTORS. In the above formulas it has been assumed for three-phase lines that the conductors are so arranged that they form the edges of an equilateral prism. When the conductors are not so arranged, but are placed symmetrically in a plane, corona will start at a lower voltage on the center conductor than on the outside conductors. The actual critical voltage on the center conductor will be approximately 4 per cent lower, and on the outside conductors 6 per cent higher, than for the equilateral prism arrangement with the same spacing.

VOLTAGE VARIATION ALONG LINE. In practice, owing to the drop in voltage along the line, the corona loss will be different at different points on the line. This may be allowed for by calculating the loss per mile at various points, and plotting a curve with loss per mile as ordinates and length in miles as abscissas. The area of this curve then represents the total loss.

If an insulated system is operating near the critical corona voltage, and one conductor becomes grounded, the corona loss will be quite high.

THE CORONA LIMIT OF HIGH-VOLTAGE TRANSMISSION LINES. SAFE AND ECONOMICAL VOLTAGES. It will generally be found that it is safe and economical to operate a line up to, but not above, the fair-weather value of the disruptive critical voltage, that is, up to the value of e_0 given by eq. (62), (63) or (65), for average barometer and summer temperatures. This will give loss during storms, but as storms do not extend over the whole line at one time, generally it will not be serious. During cold weather the critical voltage will be higher and storm loss less.

Besides the loss of energy, corona loss may be undesirable from another standpoint, viz., since the loss occurs only on part of the wave, it may introduce harmonics if it is excessive.

Table V gives the factors by which these voltages must be multiplied to give the corresponding disruptive critical voltage at various elevations. This correction factor

is equal to the ratio of the barometric pressure at the given altitude to the barometric pressure at sea level.

Table V. Approximate Altitude Correction Factors at 25 Deg Cent

Altitude		Correction Factor	Altitude		Correction Factor
Feet	Meters		Feet	Meters	
0	0	1.00	5,000	1525	0.87
500	152	0.99	6,000	1830	0.86
1000	305	0.97	7,000	2135	0.84
1500	459	0.96	8,000	2400	0.82
2000	610	0.95	9,000	2745	0.80
2500	765	0.94	10,000	3050	0.77
3000	915	0.93	12,000	3660	0.74
4000	1220	0.91	14,000	4270	0.70

Special Calculations. For small conductors the loss, in kilowatts per mile of conductor, is given by the expression,

$$p = \frac{390}{\delta}(f + 25)\sqrt{\frac{r + \frac{0.93}{s} + 0.016}{s}}\,(e - e_d)^2 \times 10^{-5} \qquad (68)$$

where $$e_d = 2.302\, m\, g_d\, r \log_{10}\left(\frac{s}{r}\right)$$

and $$g_d = g_0\delta\left[1 + \frac{0.189}{\sqrt{\delta r}}\frac{1}{(1 + 1480\, r^2)}\right]$$

CAPACITANCE AND INDUCTANCE TABLES

By W. A. Del Mar

21. CAPACITANCE

See also Section on Electricity in Eshbach, Fundamentals of Engineering.

Overhead Wires

SINGLE ROUND WIRE PARALLEL TO THE GROUND.

H = height of wire above ground,
d = diameter of wire, in same unit as H.

The capacitance $= \dfrac{7.354 \times 10^{-3}}{\log_{10} \dfrac{4H}{d}}$ microfarads per 1000 ft (1)

$= \dfrac{38.83 \times 10^{-3}}{\log_{10} \dfrac{4H}{d}}$ microfarads per mile (2)

TWO PARALLEL ROUND* WIRES.

D = distance apart, center to center.
d = diameter of wire, in same unit as D.

The exact capacitance †

$= \dfrac{8.467 \times 10^{-3}}{\cosh^{-1} \dfrac{D}{d}}$ microfarads per 1000 ft (3)

When D is greater than $10\,d$ the following formulas for the capacitance *between wires* may be used instead of the above with an error of less than 0.1 per cent:

$= \dfrac{3.677 \times 10^{-3}}{\log_{10} \dfrac{2D}{d}}$ microfarads per 1000 ft (4)

$= \dfrac{19.41 \times 10^{-3}}{\log_{10} \dfrac{2D}{d}}$ microfarads per mile (5)

The *capacitance to neutral* in all cases is $C_0 = 2C$. Tables of capacity to neutral for various sizes of wires and various spacings are given in the tables below. Note that these tables and the above formulas are strictly applicable to ordinary overhead lines only when the distance from the wires to other conductors, particularly the earth, is large compared with their distance apart. However, the effect of the earth is usually small in most practical cases (see below), and the formulas and tables give a very fair approximation to the actual capacitances.

The capacitances of standard strands given in the following tables are calculated by the same formula as for smooth round wires using for the diameter d the diameter of the strand; see *Bare Wires and Cables.* The values as thus calculated are therefore not exact, but the error is probably less than 3 per cent for all practical cases.

Effect of the Earth on the Capacity of Two Overhead Wires. If both wires are at the same height, the effect of the earth is to increase the capacitance by an amount equal to the increase in capacitance which would result from decreasing the distance between the wires from the actual distance D to the "equivalent" distance D'. For D small compared with the height H, which is usually the case, the equivalent distance D' is practically equal to D, and the effect of the earth is therefore negligible.

$$D' = \frac{D}{\sqrt{1 + \left(\dfrac{D}{2H}\right)^2}} = \text{“equivalent” distance apart} \qquad (6)$$

* When the wires are far apart compared with the linear dimensions of their cross-section, the second group of formulas also applies approximately to wires of any shape of cross-section provided d is taken equal to the perimeter of the cross-section divided by π, i.e., equal to the "equivalent" diameter of the cross-section.

† Taking into account the non-uniform distribution of the charge on each wire; see Pender and Osborne, *Elec. World,* 1910, Vol. 56, p. 667.

THREE-PARALLEL WIRES.

Equilateral Triangle Arrangement.

D = distance apart, center to center.
d = diameter of wire in same units as D.

The normal capacitance between any two of the wires with the third wire insulated is

$$\frac{3.677 \times 10^{-3}}{\log_{10} \dfrac{2D}{d}} \quad \text{microfarads per 1000 ft} \tag{7}$$

which is the same as the capacitance between two parallel wires by themselves; see above.

Equilateral Triangle Arrangement with Balanced Three-phase Voltages. For sine-wave voltages between the wires equal in effective value to V and differing in phase by 120 deg, the following relations hold between the *effective* values of the voltages and charging currents for each of the three wires.

$$I = 2\,\pi f C_0\, V_0 \tag{8}$$

where $V_0 = \dfrac{V}{\sqrt{3}}$ = voltage to neutral.

$$C_0 = 2C_{12} = \text{capacity to neutral}$$

when the C's are in microfarads and the charging current in microamperes.

The charging current for any wire is 90 deg ahead of the voltage drop from that wire to the neutral. For the same voltage V between wires in a single-phase system as in a three-phase balanced system, the charging current per wire in the three-phase system with the equilateral triangle arrangement of wires is $2/\sqrt{3} = 1.155$ times the charging current per wire in the single-phase system.

For any other arrangement of wires and for an unbalanced three-phase system, the general equations in Eshbach, Fundamentals of Engineering may be used.

Effect of the Earth on the Capacity of Three Overhead Wires. Ordinarily the formulas given above neglecting the effect of the earth are sufficiently accurate for all practical purposes; compare with the effect of the earth on a two-wire line.

Cables

SINGLE-CONDUCTOR CABLE. Round Wire in Concentric Sheath.

D = inside diameter of sheath.
d = diameter of conductor (both in same units).
K = specific inductive capacity of dielectric.

The capacitance of a length of cable long compared to its diameter

$$= \frac{7.354 \times 10^{-3}\, K}{\log_{10} \dfrac{D}{d}} \quad \text{microfarads per 1000 ft} \tag{9}$$

Round Wire in Eccentric Sheath.

a = radius of wire.
b = inside radius of sheath.
c = distance between center of wire and center of sheath (all in same units).

The ratio of the capacitance eccentric, to the capacitance, concentric,

$$= \frac{\cosh^{-1}\left(\dfrac{b^2 + a^2}{2\,ab}\right)}{\cosh^{-1}\left(\dfrac{b^2 + a^2 - c^2}{2\,ab}\right)} \tag{10}$$

TWO-CONDUCTOR CABLE.

D = inside diameter of sheath.
a = distance between centers of wires.
d = diameter of wires (all in same units).

Assuming the entire space between conductors and sheath to have uniform specific inductive capacity K, the capacitance from conductor to conductor

$$= \frac{3.677 \times 10^{-3}\, K}{\log_{10}\left(\dfrac{2a}{d} \cdot \dfrac{D^2 - a^2}{D^2 + a^2}\right)} \quad \text{microfarads per 1000 ft} \tag{11}$$

THREE-CONDUCTOR CABLE.

D = inside diameter of sheath.
a = distance between centers of wires.
d = diameter of wires (all in same units).

Assuming the entire space between conductors and sheath to have uniform specific inductive capacity K, the capacitance between one conductor and any other one will be

$$\frac{3.677 \times 10^{-3} K}{\log_{10} \frac{2a\rho}{d}} \quad \text{microfarads per 1000 ft} \tag{12}$$

where

$$\rho = \sqrt{\frac{(3D^2 - 4a^2)^3}{(3D^2)^3 - (4a^2)^3}}$$

That is, the capacitance is the same as that of two parallel wires by themselves but at a distance ρa between centers instead of the actual distance a.

Relations between capacitances of various combinations of conductors and sheath will be found in *Alternating Currents*, by Alex. Russell, and in *Electric Cables*, by W. A. Del Mar.

Capacitance to Neutral* of Smooth Round Wires

* The susceptance *between* conductors equals one-half the values given in this table.

22. INDUCTANCE

SELF-INDUCTANCE OF A SINGLE STRAIGHT ROUND WIRE, RETURN NEGLECTED.

Let l = length of wire, in centimeters.
d = diameter of round wire, in centimeters.
$r = \frac{d}{2}$ = radius of round wire, in centimeters.
L' = inductance, in millihenrys.

Then for a round wire the self-inductance is

$$L' = 2\left[l \log_\epsilon \frac{l + \sqrt{l^2 + r^2}}{r} - \sqrt{l^2 + r^2} + \frac{l}{4} + r\right] \times 10^{-6} \tag{13}$$

$$= 2l\left[\log_\epsilon \frac{2l}{r} - \frac{3}{4}\right] \times 10^{-6}, \text{ approximately} \tag{14}$$

Where the permeability of the wire is μ and that of the medium outside is unity, and the frequency is low, eq. (2) appears in the form

$$L' = 2l\left[\log_\epsilon \frac{2l}{r} - 1 + \frac{\mu}{4}\right] \times 10^{-6} \tag{15}$$

This last formula is of theoretical interest only, as the value to assign to μ is doubtful and when such wires are used even for currents of moderate frequencies, the skin effect is appreciable; see Article 50.

The self-inductance of a round wire may be considered as made up of two parts, viz., the inductance due to the flux *external* to the wire, and that due to the flux *within* the wire. The first or "external" inductance is

$$L_e = 2l\left[\log_\epsilon \frac{2l}{r} - 1\right] \times 10^{-6} \tag{16}$$

and the "internal" self-inductance is

$$L_i = l\frac{\mu}{2} \times 10^{-6} \tag{17}$$

both being in millihenrys.

SELF-INDUCTANCE OF A HOLLOW TUBE OF CIRCULAR SECTION, RETURN NEGLECTED. The *external* inductance is the same as for a solid wire, i.e., eq. (4), taking for r the external radius of the tube. The *internal* inductance of the tube, putting r_2 = external radius and r_1 = internal radius, is

$$L_i = 2\,\mu l\left[\frac{r_1^4}{(r_2^2 - r_1^2)^2}\log_\epsilon \frac{r_2}{r_1} - \frac{1}{4}\,\frac{3r_1^2 - r_2^2}{r_2^2 - r_1^2}\right] \times 10^{-6} \tag{18}$$

The term in the square brackets is always less than ¼, i.e., the internal inductance of a hollow tube is always less than the internal inductance of a solid wire; see eq. (5). In the limit, where $r_1 = r_2$ (tube with infinitely thin walls), the *internal* inductance is zero.

MUTUAL INDUCTANCE OF TWO PARALLEL STRAIGHT WIRES OR BARS. See Fig. 1. Same notation as above, and in addition let D = distance between centers of the two wires, in centimeters.

Then the mutual inductance between the two wires AC and BD is

$$M = 2\left[l\log_\epsilon \frac{l + \sqrt{l^2 + D^2}}{D} - \sqrt{l^2 + D^2} + D\right] \times 10^{-6} \tag{19}$$

$$= 2l\left[\log_\epsilon \frac{2l}{D} - 1 + \frac{D}{l}\right] \times 10^{-6}\text{, approximately} \tag{20}$$

when the length l is great in comparison with D.

Eq. (7), which is an exact expression when the wires have no appreciable cross-section, is not an exact expression for the mutual inductance of two parallel cylindrical wires, but is not appreciably in error even when the section is large and D is small if l is great compared with D.

Eq. (7) is also applicable, with a practically negligible error, to bars of rectangular section, and in fact to the mutual inductance between any two parallel conductors of any section and external to each other, e.g., between an overhead wire and a rail, the distance D being the distance between the centers of gravity of the two sections.*

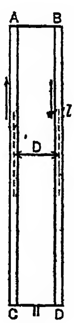

Fig. 1

MUTUAL INDUCTANCE BETWEEN A TUBE AND AN INTERIOR WIRE. Using the same notation as for eq. (6) above, the mutual inductance in this case is

$$M = 2l\left[\log_\epsilon 2l - \frac{r_2^2\log_\epsilon r_2 - r_1^2\log_\epsilon r_1}{r_2^2 - r_1^2} - \frac{1}{2}\right] \times 10^{-6} \tag{21}$$

TOTAL INDUCTANCE OF A TWO-WIRE TRANSMISSION LINE. For a length so great that d and D are negligible compared with l, this total inductance per wire for equal round wires is

$$L = 2l\left[\log_\epsilon \frac{2D}{d} + \frac{\mu}{4}\right] \times 10^{-6} \tag{22}$$

where d is the diameter of each wire. The total inductance of the line per unit length of *wire* of unit permeability is

$$\left.\begin{aligned} L &= 0.01524 + 0.14037 \log_{10}(2\,D/d) \quad \text{millihenrys per 1000 ft} \\ &= 0.08047 + 0.74113 \log_{10}(2\,D/d) \quad \text{millihenrys per mile} \end{aligned}\right\} \tag{23}$$

where D and d may be expressed in any units of length provided they are both expressed in the *same* units. To obtain the total inductance of both wires multiply by *twice* the

* Accurately, the geometrical mean distance between the two areas; see *Bull. Bur. Stand.*, 1912, Vol. 8, pp. 125 and 126. For round wires, solid or tubular, the geometrical mean distance between them is exactly the distance between their centers.

length of the line. The formulas given in eq. (23) also apply approximately to stranded wires, provided d is taken as the diameter of the solid wire having a cross-section equal to that of the copper in the stranded wire; i.e., the inductance of a No. 0000 stranded wire on a given spacing is approximately the same as that of a No. 0000 solid wire on the same spacing.

Tables of L and the corresponding reactances for 25 and 60 cycles for various sizes of wires and various spacings are given below.

The above formula is not applicable to conductors at close spacing when the frequency is high; see F. B. Silsbie, *Elec. World*, Vol. 68, p. 125, July 15, 1916.

INDUCTANCE DROP IN A THREE-WIRE TRANSMISSION LINE. The value of L to be used in the following equations is that to be derived from eq. (23).

Equilateral Triangle Arrangement. For a sine-wave current of effective value I and frequency f, the inductive drop in each wire per unit length of line has the effective value

$$V = 2\pi fLI \tag{24}$$

and leads the current in this particular wire by 90 deg, irrespective of whether the load be balanced or not, the only condition being that no current returns to the generator through any other conductor than the three line wires.

Three Parallel Wires in the Same Plane. Let the three wires of the three-phase system have equal diameters d, let No. 2 be the middle wire, and let Nos. 1 and 3 be at equal distances (D between centers) from No. 2 and on opposite sides of No. 2. Under these conditions, considering unit length of line, put

L = same values as in (23), taking D as the distance between either outer and the middle wire,

and M = 0.04225 millihenry per 1000 ft
= 0.2231 millihenry per mile

Then

$$\left.\begin{aligned} V_1 &= 2\pi f[LI_1 - MI_3] \\ V_2 &= 2\pi f I_2 L \\ V_3 &= 2\pi f[LI_3 - MI_1] \end{aligned}\right\} \tag{25}$$

TOTAL INDUCTANCE OF A CONCENTRIC CABLE. The total inductance of a concentric main per unit length of *cable* is

$$L = 2\left[\log_\epsilon \frac{d_2}{d_1} + \frac{d_3^4}{(d_3^2 - d_2^2)^2}\log_\epsilon \frac{d_3}{d_2} - \frac{d_3^2}{2(d_3^2 - d_2^2)}\right] \times 10^{-6} \text{ millihenry per cm.} \tag{26}$$

where d_1 = diameter of internal conductor, assumed solid; d_2 = internal diameter of outer conductor; and d_3 = external diameter of outer conductor.

INDUCTANCE OF OVERHEAD WIRES WITH EARTH RETURN. This case is not susceptible of a definite solution, since the inductance depends upon the distribution of the return current in the earth. When the current returns through one or more rails immediately below the wire, the leakage current to the earth may be neglected and the wire and rails treated as linear conductors, applying the formulas given above. When there is no metallic return circuit, an approximate solution may be obtained by considering the earth as equivalent to the " images " of the overhead wires in the plane of the earth's surface, i.e., considering the return circuit as consisting of the same number of wires as there are overhead, these fictitious return wires being the same distance below the earth as the actual wires are above it. The value of the inductances as thus calculated can never be greater than the actual inductances but will usually be slightly less than the actual values.

The *external* self-inductance of a rail is practically the same as that of a round wire, taking for r the perimeter of the rail divided by 2π; see eq. (4). The *internal* self-inductance depends upon the permeability μ and the frequency of the current. The internal inductance, however, is small compared with the external inductance and for approximate calculations may be neglected. See Electric Railways, Section 17.

EFFECT OF FREQUENCY ON INDUCTANCE. See article on Skin Effect.

† By multiple layer conductors is meant conductors with two or more layers of aluminum over the steel core.

* By single layer conductors is meant conductors with one layer of aluminum over the steel core.

‡ The inductance values of the table are based upon actual tests on various sizes of cable at various current densities at one foot spacing. The inductances at other spacings were calculated from those at one foot spacing by means of the fundamental inductance formula.

The inductance L' for any spacing D' not given in the table is equal to the inductance L at the next smaller spacing D given in the table plus the quantity $0.74113 \log_{10} D'/D$. Thus $L' = L + 0.74113 \log_{10} D'/D$. Or the inductance in millihenries to be added to that at the next smaller spacing may be taken from table below.

D'/D	1.05	1.10	1.15	1.20	1.25	1.30	1.35	1.40	1.45	1.50
$L+$	.016	.031	.045	.059	.072	.084	.097	.108	.120	.131
D'/D	1.55	1.60	1.65	1.70	1.75	1.80	1.85	1.90	1.95	2.00
$L+$	.141	.151	.161	.171	.180	.189	.198	.207	.215	.223

§ For any three-phase arrangement of conductors $D = \sqrt[3]{ABC}$, where A, B and C are the conductor spacings.

60-Cycle Reactance ‡ per Mile of Single Conductor Aluminum, Steel Core Cable

† By multiple layer conductors is meant conductors with two or more layers of aluminum over the steel core.

* By single layer conductors is meant conductors with one layer of aluminum over the steel core.

‡ The table values were derived from the equation $x = 2\pi fL$, in which x is the reactance in ohms, L is the inductance in henries per mile of single conductor and f is the frequency. The reactance at any other frequency than 60 cycles is $f/60$ times the table values.

The reactance x' at any spacing D' not given in the table is equal to the reactance x at the next smaller spacing D given in the table plus the quantity $0.2794 \log_{10} D'/D$.

Thus $x' = x + 0.2794 \log_{10} D'/D$. Or the reactance in ohms, to be added to that at the next smaller spacing may be taken from table below.

D'/D	1.05	1.10	1.15	1.20	1.25	1.30	1.35	1.40	1.45	1.50

§ For any three-phase arrangement of conductors $D = \sqrt[3]{ABC}$, where A, B and C are the conductor spacings.

POLE AND TOWER LINES

By Howard Enos

(Some of the original material by R. A. Philip and C. M. Spofford has been used.)

24. MECHANICAL DESIGN

In designing a pole or tower line the following factors, in addition to the purely electrical characteristics, must be considered: (1) character of the route, (2) clearances, (3) grade of construction, (4) type of supporting structures, (5) type of insulators, (6) conductors, (7) mechanical loading, (8) joint use by other utilities, (9) right-of-way. The requirements imposed by these several conditions are noted below, together with tables, formulas, and curves useful in making the necessary calculations.

Character of the Route

Usually the lower-voltage lines are run along streets and highways, wherever possible, in order to reach customers more easily and to make the lines accessible for maintenance. The higher-voltage transmission lines are more often run across country on private right-of-way in order to obtain the most direct route, as well as to avoid buildings and low-voltage lines, and to obtain adequate space for towers. Lines which are run along streets and highways must be designed to give proper clearances from buildings, other lines, railroad tracks, and trees. Poles must be so located as not to obstruct the public use of streets and driveways or to be subject to damage from traffic.

Urban Distribution Lines usually require close spacing of poles on account of the necessity of keeping the span length of service wires from pole to house as short as possible. Poles are usually set on property lines to avoid obstructing the front of each lot and to avoid overhanging, with the service wires, property adjacent to the building served. Normal span lengths for urban distribution lines vary from about 100 to about 175 ft, the average length being about 125 ft. Poles are usually set from 6 in. to 1 ft inside the curb when along streets, but in alleys it is often necessary to set the poles within the traveled space.

The restrictions mentioned above do not exist, for the most part, in respect to **rural distribution lines.** Much longer spans are possible, and the length of span is determined largely by economic considerations. Spans of 200 to 300 ft are common, and many lines are built with spans as long as 600 ft. Rural customers are relatively far apart. In the eastern part of the United States the average spacing is about 4 customers to the mile. In parts of the country where large farms are the rule, customers may be spaced from 1 to 2 miles apart. Poles from which services are taken to farm buildings, as for urban lines, must be set close to the building served. Rural lines, on account of long-span construction, require nearly as much engineering design from the mechanical standpoint as higher-voltage transmission lines. Owing to the wide spacing of customers, rural lines, for the greater portion of their length, consist of primary circuits only. On account of the relatively small electrical loads small conductors are used. With small conductors mechanical loading of the lines is low, in spite of the long spans. This results in the possibility of using small poles, especially when bare, high-strength conductors are used. Wood poles are used almost exclusively for rural distribution lines.

Higher-voltage transmission lines on private right-of-way are usually built with long spans, and the type of terrain covered by the line largely determines the type of construction to be used. In fairly level country the height of towers is determined mainly by the length of span, the ground clearances required, and economic considerations. In mountainous territory the valleys may often be crossed by single spans of more than a mile in length using fairly low towers. Under such conditions the towers must be specially designed for wide spacings of conductors and for heavy transverse and longitudinal stresses. Lines on private right-of-way often require special consideration of side-hill construction.

Clearances

The following clearances for conductors must be considered: to ground, tracks, buildings, trees, conductors and structures of another line, other conductors on the same structure, the structure itself, guy wires and other equipment on the structure, and the edge of the right-of-way.

Space does not permit the tabulation here of clearances for all the above conditions for all voltages used for overhead lines. The National Electrical Safety Code gives clearances which are considered good practice. For higher-voltage transmission lines on private right-of-way the clearance to ground should be 20 ft or more, depending on the voltage. The clearance to any grounded portion of the structure, to trees, or other structures, or to the edge of the right-of-way should exceed by a safe margin the arcing distance across the insulator string when the string is deflected the maximum amount by wind pressure. Consideration should also be given to the behavior of lightning flashovers as affected by the presence of grading shields or rings.

Horizontal separations between conductors for high-voltage transmission lines depend on the conductor size and material, the span length, the voltage, and whether pin-type or suspension insulators are used. Opinions of engineers vary as to exact values of spacing to be used for a given set of conditions. The following spacings represent average practice. For 33-kv lines on pin-type insulators: 4 to 6 ft for spans of 150 to 500 ft, respectively. For 33-kv lines on suspension insulators: 6 to 10 ft for spans of 300 to 1000 ft, respectively. For 132-kv lines: 10 to 17 ft for spans from 500 to 1500 ft, respectively. For 220-kv lines: 20 to 26 ft for spans from 800 to 1500 ft, respectively.

Mr. P. H. Thomas gives the following formula for computing the minimum horizontal spacing for conductors (*A.I.E.E. Trans.*, 1928):

$$S = Cd\frac{D}{w} + A + \frac{L}{2} \tag{1}$$

where S = horizontal spacing in feet; C = a constant depending on conductor material ($C = 4$ for copper and $C = 3.5$ for A.C.S.R. usually) and character of terrain; d = per cent sag; D = diameter of conductor in inches; w = horizontal loading lb per foot; A = the arcing distance of the line voltage in feet; L = the length of suspension insulator string in feet.

Vertical separations should be about the same as stated for horizontal separations, but consideration should be given to unequal sags due to unequal ice loading. Also the conductors of a vertical configuration should be offset away from the vertical planes through the other two conductors from 1 to 3 ft, depending upon the span length and the voltage. Horizontal separations between conductors of different circuits should be somewhat greater than between conductors of the same circuit to avoid involving both circuits in the same case of flashover. Horizontal spacings for conductors on steel towers determined by the required clearances to the tower are usually adequate.

TELEPHONE CIRCUITS FOR POWER LINES. When the line voltage does not exceed 66,000 volts, the telephone circuits are usually carried on the same poles or towers as the power circuits, being placed below the power conductors. A separate line of wooden poles on the same right-of-way is occasionally employed when the voltage is higher than 66,000.

Where the telephone wires are on the same supporting structure as the power wires, sufficient clearance between the power and telephone circuits must be allowed to make the telephone line accessible for repairs and also to prevent the two circuits touching under abnormal conditions. On wood pole lines of short span (100 to 125 ft) the vertical clearance at the poles or towers ranges from 4 ft for 22,000 volts to 6 ft for 66,000 volts. On long-span lines greater spacing is necessary to allow for safe clearance in the middle of the longest span due to the change in the sag of the power and telephone wires under all conditions of unequal ice loading and all variations of side deflection due to wind.

Telephone wires are ordinarily of copper, though copper-clad steel or A.C.S.R. is sometimes used for long spans. For spans up to 125 ft No. 10 B. & S. copper may be used (though No. 8 is preferable); for longer spans larger sizes (usually No. 8 or No. 6 or even No. 4) are necessary to allow for sleet load. A spacing of 12 in. between wires may be used for 125-ft spans, but a wider spacing is necessary for longer spans. Where inadequate spacing is used the telephone lines will frequently become crossed by the wind, unless they are strung with little sag, in which case they are overloaded and broken by sleet. With wide spacing and large sag higher poles must be used.

Carrier Current Communication. It is impracticable to carry telephone circuits on the structures of long-span high-voltage transmission lines, and it is very expensive to provide separate wood pole telephone lines. As a result, many power companies now use the power circuit conductors themselves as the telephone circuit. This is accomplished by modulating a high-frequency voltage by the voice current and impressing the modulated carrier voltage upon the transmission circuit by capacity coupling. At the receiving end the transmission line is capacity coupled to the receiving apparatus which demodulates the carrier voltage, and the resultant is a reproduction of the original voice current, which operates an ordinary telephone receiver or a loud speaker. The apparatus is quite similar to ordinary radio transmitting and receiving equipment, and provision can be made for either one-way or two-way conversations.

For additional data on this subject see the volume on Communication Engineering.

GROUND WIRES. Grounded cables or wires are placed above the transmission line circuits to protect the latter from lightning discharges (see Lightning Protection). They are usually grounded at each supporting structure except where short spans are used. The same care must be exercised to obtain clearances between conductors and ground cables or wires, as outlined above under telephone circuits. For tower lines having flexible towers and single-circuit towers having conductors arranged in a horizontal plane, two ground cables are preferable, but for double-circuit tower lines either one or two may be used. As a general rule a line drawn through the ground cable and any conductor should not make an angle of more than 45 deg with the vertical. See chapter on Grounding, Art. 96.

Grade of Construction

The criterion for the strength requirements of a line is known as the "grade of construction." In the National Electrical Safety Code the grades are designated by the letters, A, B, C, D, E, and N, grade A being the highest and requiring the greatest strength. The grade to be used depends upon the type of circuit, the voltage, and the surroundings of the line. For example, a power line of any voltage crossing over a main track of a steam railroad requires grade A construction, but under certain other conditions may require as low as grade N. Regulatory bodies of various states have set up similar requirements.

Type of Supporting Structures

Wood poles are used to support lines of any voltage. Steel structures of various types are used to a limited extent to support low-voltage lines but are largely used for higher-voltage transmission lines. Reinforced-concrete poles are also used to a limited extent where good appearance is a factor and where the expense can be justified.

Wood poles have the advantage of increasing the insulation value of a line against lightning and therefore are coming into greater use for high-voltage transmission lines as an economical means of minimizing flashovers. Wood poles are used with pin-type insulator construction for low-voltage distribution lines and low-voltage transmission lines. Single wood poles are used with suspension-type insulator construction up to

about 66 kv. Single-circuit lines of higher voltage are common using two-pole H-frame construction. Such construction has been used even for extremely long spans. With wood pole structures the stresses which cannot be sustained by the poles themselves are sustained by proper guying. (See Article 25 on Wood Poles.)

Steel structures are used in various forms such as: tubular poles, square latticed poles, and wide-base towers. Tubular steel poles are used primarily for low-voltage distribution lines and as trolley supports where good appearance is a factor, although they are being largely superseded by smoothly finished wood poles. Square latticed steel poles are used to some extent for medium-voltage transmission lines on narrow right-of-way and where high lateral strength is required which cannot be obtained by the use of wood poles without guying.

Wide-base steel towers are used for long-span lines on private right-of-way where considerable height is necessary to provide ground clearance for the conductors. Such towers usually have square or rectangular bases, although triangular-base towers have been used to some extent for single-circuit medium-voltage transmission lines. Wide-base towers are usually classified as suspension towers, angle towers, and strain or dead-end towers. Suspension towers are used in the straight sections of a line and are designed mainly to withstand stresses in a transverse direction resulting from wind pressure on ice-coated conductors and the tower itself. In a longitudinal direction they are designed to carry a certain amount of unbalanced stress due to broken conductors and wind loading. Certain torsional stresses due to unequal conductor loadings must also be taken into account. Angle towers are designed to withstand both the balanced stresses due to the angle in the line and also any unbalanced stresses due to wind pressures and unequal conductor loading as well as possible broken conductors. Strain towers are used at dead-end points in the line and must be designed for full lateral stresses the same as suspension towers, also for the full longitudinal stresses of all the loaded conductors and for torsional stresses due to broken conductors. Semi-strain towers are sometimes used for situations where the longitudinal stresses are intermediate between those of suspension and strain towers.

The great majority of towers for lines up to 154 kv are double circuit for economic reasons. Even though the second circuit may not be added until later, the additional cost for double-circuit towers above that for single-circuit towers is so small as usually to be justified. Such towers commonly have each circuit arranged in a vertical configuration on opposite sides of the tower. For lines of 220 kv or higher, single-circuit towers are nearly always used, although the use of double-circuit towers may be economically desirable under certain conditions. The cost of double-circuit towers for such voltages is not far different from the cost of separate lines. Single-circuit towers for the extreme high voltages invariably have the conductors arranged in a horizontal configuration.

After all the mechanical and electrical features of the line have been considered, the final choice of the type of structure to be used is determined by the overall economics of the problem. The selection should be made on the basis of minimum annual cost, modified by the other factors involved. (See article 26 on Steel Towers.)

Type of Insulators

Pin-type insulators are used almost exclusively for straight line work for voltages up to 15 kv and quite generally for that purpose up to 22 or 33 kv. Suspension or disk-type insulators are used for dead-ending lines of any voltage, although small conductors of low-voltage lines are often dead-ended on double arm construction using pin-type insulators. Suspension insulators are used for tangent and angle construction for practically all lines above 33 kv and sometimes for 22- and 33-kv lines. Pin-type insulators are unsatisfactory and expensive for the higher voltages. (See also article on Insulators.)

Conductors

Conductor materials for overhead lines include: copper, bronze, aluminum, steel, copper-clad steel, and steel-reinforced aluminum. All-aluminum and all-steel conductors have a limited application in modern overhead construction owing to the low strength of aluminum and the tendency of steel to corrode. High strength for long-span construction is obtained by the use of bronze, hard-drawn copper, copper-clad steel, or steel-reinforced aluminum. Conductors are practically always stranded in sizes larger than No. 2 A. W. G. Tubular copper conductors have been used on high-voltage lines. Steel-reinforced aluminum conductors are always stranded. The steel reinforcement forms the core and may be either solid or stranded. The aluminum wires are concentrically stranded around the steel core. Where large-diameter conductors are required to raise the corona

limit of the line, they may be obtained by the use of annular conductors or aluminum cables with steel-core reinforcement. The mechanical characteristics of conductor materials are given in Table I below. (See chapter on Conductors.)

Table I. Mechanical Characteristics of Conductor Materials

Item	H. D. Copper	Aluminum	Steel
Ultimate strength, in lb per sq in..	60,000–65,000	25,000–50,000	60,000–80,000

Coefficient of linear expansion per deg fahr......................	9.6×10^{-6}	12.8×10^{-6}	6.6×10^{-6}
Weight in pounds of a 1-ft length having a cross-section of 1,000,000 cir mils (stranded).............	3.09	0.92	2.67

See also chapter on Bare Wires and Cables.

The maximum stress in conductors should not exceed the yield point (usually called "elastic limit"). The elastic limit and modulus of elasticity of a conductor are not, however, fixed under all conditions. They are reduced by fluctuating stresses. Probably the working limit for fluctuating stress should not be over 50 to 70 per cent of the ultimate strength for uniformly increased stress, depending upon the material.

If a sample of wire is stretched in a testing machine with a maximum stress exceeding any previous stress on the wire, but within the working limit, and the stress is then gradually removed, a new stress-strain curve is obtained which is a straight line practically parallel to the tangent to the original stress-strain curve at the origin, but displaced along the axis of elongation. If the stress is again increased the stress-strain values will lie on the curve obtained under the previous reduction of stress, and, if the previous maximum stress is not exceeded, upon reduction of stress the stress-strain values will lie on the same straight line. Under such conditions the conductor will have a constant value of modulus of elasticity. The practical application of these principles may be carried out by two methods. One of these is to prestretch the conductor to the maximum stress which it may be expected to sustain in operation. If this method is used (which is often impracticable), sag-tension calculations are based on stress-strain diagrams for different temperatures obtained by stressing the conductor to the expected maximum stress and then reducing the stress to zero, and stress-length curves with different loadings together with length-sag curves. Conductors are then strung to the required sag, which sag they will always have under the same temperature condition. A more usual method is to calculate the stringing sags on the basis of the stress-strain diagram under initial stress application. These sags will be less than those which will exist for the same temperature after the conductor has been mechanically loaded. Therefore, for checking ground clearances the final sags should be calculated from the stress-strain diagram obtained by stretching to maximum allowable stress. It is not necessary to go to such refinements for lines having short spans and small sags. For further discussion of this subject see an article by Theodore Varney, entitled A.C.S.R. graphic method for sag-tension calculations, published by the Aluminum Co. of America. In the case of composite conductors such as A.C.S.R. the virtual modulus of elasticity and virtual coefficient of expansion are not the same as the values for either of the component materials. For example, for the composite cable of A.C.S.R. the virtual modulus of elasticity is:

$$M_{as} = M_a R_a + M_s R_s \tag{2}$$

and the virtual coefficient of expansion is:

$$A_{as} = \frac{A_a M_a R_a}{M_{as}} + \frac{A_s M_s R_s}{M_{as}} \tag{3}$$

where M is modulus of elasticity, A is coefficient of expansion, R is fraction of total cross-section, represented by each material; and subscripts a and s indicate aluminum and steel, respectively.

In a composite cable the stress may be transferred entirely to one material at extremely high temperatures and to the other material at extremely low temperatures. At high temperatures the material having the lower coefficient of expansion takes the stress, and at low temperatures it is taken by the material having the higher coefficient of expansion. This transfer of stress is not abrupt because of mechanical stretching of the material which tends to take more than its share of the stress. However, when the combined

rate of stretching and expansion of one material exceeds the combined rate of the other the transfer becomes complete. Data for checking this condition should be obtained from stress-strain diagrams of the individual materials. Further information on this subject may be obtained from the chapter on Wires and Cables and also from the article by Theodore Varney mentioned above. Fig. 1 shows typical stress-strain diagrams for composite cables and homogeneous cables. Curve 1 is the initial stress curve for A.C.S.R.; curve 2 is the final stress curve for the composite cable (on reduction of stress); curve 3 is the initial stress curve for the steel portion; curve 4 is the final stress curve for the steel portion; curve 5 is the initial stress curve for the aluminum portion; and curve 6 is the final stress curve for the aluminum portion. Curve 7 is the initial curve for a homogeneous

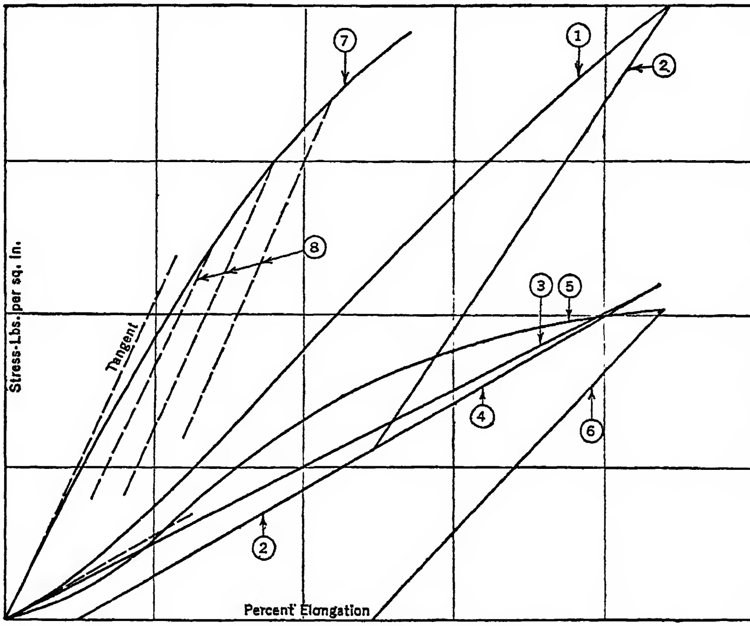

FIG. 1. Typical Stress-strain Curves

cable, and curves 8 are final stress curves obtained by reduction of stress after reaching the several maxima.

Mechanical Loading

The term mechanical loading refers to the external conditions which produce mechanical stresses in the line conductors and supports. It also includes the weight of the conductors and structures themselves. The external conditions referred to include: the temperature range to be expected, the collection of ice on the conductors and structures, and the variations in wind pressure on conductors and structures. The map shown on Fig. 2 is usually taken as a basis for determining the heaviest loading conditions for a line in a certain locality. The loadings corresponding to the terms heavy, medium, and light are as follows:

Heavy: $^1/_2$ in. ice, 8 lb wind pressure per sq ft, 0 deg fahr.
Medium: $^1/_4$ in. ice, 8 lb wind pressure per sq ft, 15 deg fahr.
Light: no ice, 12 lb wind pressure per sq ft, 30 deg fahr.

When local conditions are known to vary from the above, such variations should be taken into account.

TEMPERATURE RANGE. The maximum and minimum air temperatures which have been observed in any locality for a period of years can be obtained from the records of the U.S. Weather Bureau, or from similar records for other countries. The minimum air temperature recorded (which may be as low as −40 deg fahr in some of the northern states) will be the minimum temperature which the conductor may be expected to reach.

However, since the conductors are exposed to the direct rays of the sun, they will reach a maximum temperature in the summer considerably in excess of the Weather Bureau records, which give the temperatures in the shade.

Another important temperature which should be determined is that of the wire when coated with ice. As noted below, a sleet storm is usually followed by a fall in temperature, and although the ice forms at 32 deg fahr, the wire may reach a much lower temperature while the ice is on it.

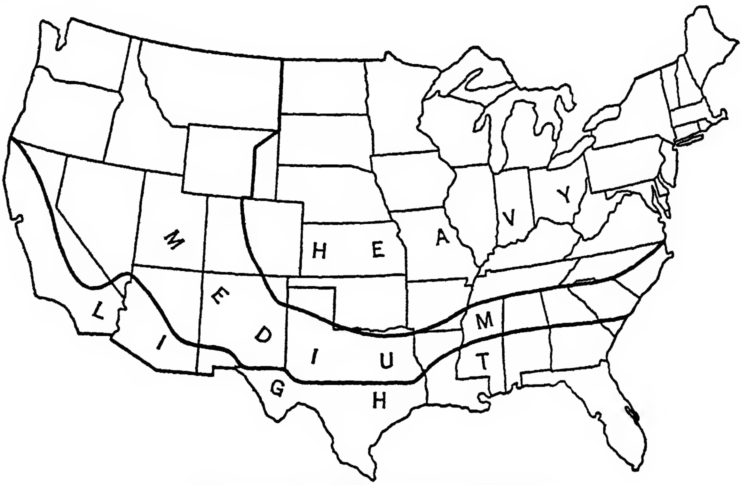

Fig. 2. Loading Map for Overhead Lines

The following temperature ranges have been used in the design of certain lines:

	Maximum	Minimum
Eastern Canada	+120 deg fahr	−40 deg fahr
Mississippi Valley	+120 deg fahr	−20 deg fahr
Southern California	+140 deg fahr	+10 deg fahr

COLLECTION OF ICE ON WIRES. Investigation of the records of the Weather Bureau leads to the conclusion that sleet and ice storms are generally followed by falling temperatures and high winds, and transmission lines should be designed to meet these conditions. Records indicate that under favorable conditions ice and sleet will collect on wires and cables to the same amount in any climate where freezing temperatures are obtained. Mild, moderate, and cold climates differ in the frequency with which conditions are favorable. In general, sleet storms are most frequent in the moderate climates, since precipitation takes place more often at freezing temperatures. Destructive sleet storms occur in the eastern part of the United States at least as far south as Atlanta. One-half inch thickness of solid ice on wires and cables is generally assumed in designing transmission lines, but thicknesses of one-quarter and three-quarters inch are also assumed in the more favorable and unfavorable localities, respectively.

Ice and sleet generally collect quite uniformly on wires throughout their length. The collection is sometimes in the form of icicles but more often is egg-shaped in cross-section, with the wire in the small end of the section. It frequently falls off non-uniformly in sections.

Clear solid ice weighs 57 lb per cu ft or 0.033 lb per cu in, but sleet or frozen snow such as often collects on wires weighs much less, sometimes as little as 8 lb per cu ft.

WIND PRESSURE. Wind pressure is a subject upon which little exact information exists, although many experiments have been made and much study has been given to the subject by engineers and scientists. Among the unsettled questions are:

(*a*) The relation between pressure and velocity.
(*b*) The variation of pressure with size and shape of exposed plane surfaces.
(*c*) The direction and intensity of pressure upon non-vertical surfaces.
(*d*) The intensity of pressure upon non-planar surfaces.

(*e*) The total pressure upon a number of parallel bars or other members placed side by side.

(*f*) The decrease of pressure upon leeward surfaces.

(*g*) The lifting power of the wind.

Relation between Indicated (U. S. Weather Bureau) Wind Velocity and Actual Velocity. The indications of the anemometers used by the U. S. Weather Bureau do not give the *actual* wind velocity, but give values considerably higher than the actual velocities, as shown in Table II:

Table II. Relation between Indicated and Actual Wind Velocity

Indicated Velocity, mi per hr	Actual Velocity, mi per hr	Indicated Velocity, mi per hr	Actual Velocity, mi per hr
10	9.6	60	48.0
20	17.8	70	55.2
30	25.7	80	62.2
40	33.3	90	69.2
50	40.8	100	76.2

In the U. S. Weather Bureau reports the indicated and not the actual wind velocities are given. However, as the anemometers used give the *average* velocity for several minutes, the instantaneous velocities due to sudden gusts may be considerably greater than the indicated velocities; the indicated velocity probably more nearly represents the " gust " velocity than the actual average velocity. In all calculations of maximum wind pressure it is therefore recommended that the *indicated* velocity be used.

The Weather Bureau records give no indication of the " gust " velocities which may occur during the 5-min periods, and which may greatly exceed the average velocity. Tests with a Dines pressure tube anemometer have shown that the extreme maximum is about 50 per cent greater than the average for short periods.

The extreme maximum wind velocity observed in Chicago in the whole 36-year period from 1873 to 1910 was 84 miles per hour (uncorrected) in February, 1894. A velocity of 76 miles per hour (uncorrected) was observed once in November, 1898, and a velocity of 72 miles per hour (uncorrected) was observed seven times. During the 10-year period from 1894 to 1903 the maximum wind velocity in a few other representative localities was as follows, all velocities being the observed or uncorrected velocities: Bismarck, N.D., 72; Eastport, Me., 78; Buffalo, N. Y., 90; New York City, N. Y., 78; Galveston, Tex., 84; Savannah, Ga., 76; Salt Lake City, Utah, 60. All the maxima range between 60 miles and 90 miles per hour. (See N.E.L.A. Overhead Systems Reference Book for more complete data.)

Relation between Pressure and Velocity. The pressure varies about as the square of the velocity, the results given by different experimenters for the pressure due to a *normal wind on a plane surface* ranging from

$$P = 0.004V^2 \quad \text{to} \quad P = 0.0032V^2 \tag{4}$$

where P = pressure in pounds per square foot.
V = actual wind velocity in miles per hour.

The former of these values is for small flat surfaces; the latter represents the results of unusually careful experiments by Stanton (see *Minutes of Proc. Inst. Civil Engineers*, Vols. 156 and 171) upon the intensity of pressure on plates varying in size from 25 to 100 sq ft and is probably more nearly correct than the higher value. In the Stanton formula the values are reduced to correspond to a temperature of 60 deg fahr and an atmospheric pressure of 14.7 lb per sq in., i.e., barometric pressure of 30 in.

The influence of size and shape of exposed surface is an important question and is not well understood, although it is known that the resultant pressure on a large surface may be taken as less per square foot than that on a small surface, since the maximum intensity of the wind is due to gusts of comparatively small cross-section.

Formulas for Pressure on Plane Surfaces When Wind is Not Normal. The pressure upon vertical plane surfaces may be taken as normal to the surface and equal in intensity to the assumed wind pressure. Upon surfaces which are not vertical, the pressure is usually considered to be normal to the surface but lower in intensity than upon vertical surfaces. The variation in pressure with respect to the slope is not well understood, and a number of empirical formulas are in use, among which are the Duchemin formula

$$P_n = P\frac{2\sin i}{1+\sin^2 i} \tag{5}$$

and the Hutton formula

$$P_n = P\,(\sin i)^{(1.84 \cos i - 1)} \tag{6}$$

where P = intensity of normal pressure upon the vertical surface.
P_n = intensity of normal pressure upon the given surface.
i = angle made by surface with the horizontal.

The following theoretical formula results from the assumption that the wind always blows in horizontal lines, and that if the pressure be resolved into normal and tangential components, the tangential component may be neglected:

$$P_n = P \sin^2 i \tag{7}$$

This formula gives lower values than the empirical formulas and probably gives too low results since it makes no allowance for the reduction in pressure on the leeward side which is known to occur, and which may in part be attributed to the influence of the tangential component. It should also be noted that the wind does not blow uniformly in horizontal lines but may deviate considerably from the horizontal.

The values given by these three formulas are tabulated for comparison, using an assumed value of 30 lb per sq ft for P. In the absence of further experience upon this phase of wind pressure it would seem wise to use one of the empirical formulas instead of the theoretical one. The Hutton formula is used quite generally by structural engineers in England and the United States.

Pressure on Non-Planar Surfaces. The pressure upon non-planar surfaces is important in the case of chimneys, standpipes, and other similar objects.

Upon the same assumptions as made in the preceding paragraph it may be demonstrated that theoretically the pressure on a cylinder is two-thirds of the total pressure on a plane diametrical section. This value is quite generally used. The pressures thus obtained lack experimental proof but are probably more nearly correct than the pressure obtained by the same method upon plane surfaces.

Effect of Reduction of Pressure on Leeward Side. The pressure upon the windward side of an exposed surface is a function of the density and velocity of the air currents. The pressure on the leeward side is also a function of the shape of the surface, and has been shown by numerous experiments to be less than the static pressure of the air current. The resultant total pressure upon a surface is in consequence a function not only of the direct pressure on the windward side, but also of the pressure on the leeward side, which in turn is a function of the form of the surface. No algebraic formula can be given which will indicate the pressure on surfaces of varying shape with any considerable degree of precision.

Wind Pressure on Wires. H. W. Buck (*Trans. Int. Elec. Cong., St. Louis*, 1904, Vol. 2, p. 318) gives the following formula for the pressure due to a normal wind on a stranded wire:

$$P = 0.0025V^2 \tag{8}$$

Table III. Wind Pressure in Pounds per Square Foot

P = 30 lb per sq ft

Angle i, degrees	Theoretical	Duchemin	Hutton
	$P \sin^2 i$	$P \frac{2 \sin i}{1 + \sin^2 i}$	$P\,(\sin i)^{(1.84 \cos i - 1)}$

85	29.7		
90	30.0		

where P is the pressure in pounds per square foot of projected area of wire and sleet, if any (length times diameter), and V is the velocity in miles per hour. This formula is based upon tests made on a 950-ft span at Niagara Falls; the wind velocities were measured by a U. S. Weather Bureau anemometer corrected to give actual average velocities.

Practical Rules for Wind Pressure Allowance. The many uncertainties connected with wind pressure make worthless the attempts to specify with precision its magnitude and direction. In the lack of additional information and further theoretical studies there seems to be no reason for deviating from the common rules which have been used for many years with satisfactory results.

For wind pressure on roofs and buildings it is common practice to allow 30 lb per sq ft acting horizontally upon the sides and ends of buildings, or on the vertical projection of roofs. It is also very important to figure the wind stresses on the steel frame considering it as an independent structure without walls, floors, or partitions, since failures often occur in erection.

Steel Towers. The National Electrical Safety Code requires the stated wind pressure for a given loading area to be increased 60 per cent for flat surfaces. In the case of latticed structures the wind pressure is taken on 150 per cent of the actual exposed area of one lateral face to allow for pressure on the opposite face. For grade A, B, and C construction the wind pressure is taken as 3 times the specified wind pressure for the loading area in computing the strength of the tower without conductors.

Vibration of Conductors. Under certain critical conditions of temperature and tension in conductors light intermittent winds across the line may start vertical vibration of the conductors. If conditions are exactly right the initially small vibrations are increased in amplitude by resonance until they have in some cases reached sufficient magnitude to break conductors or wreck structures. Probably some vibration occurs in all overhead conductors under the critical conditions. In short spans they do not, as a rule, reach dangerous amplitudes. It was not until long-span construction became common that these effects were noticed or correctly diagnosed. The vibrations tend to fatigue conductors at the point of support due to the rapid bending in opposite directions. The rigidity of clamping of the conductor at the support contributes to the fatigue of the conductor material. Mechanical damping devices attached to the conductors near the supports are often used to prevent the resonant condition as well as to reduce the rigidity of the support.

VERTICAL AND TRANSVERSE FORCES ON A SUSPENDED WIRE. The resultant force acting on one foot of a suspended wire is in general made up of three components, viz.:

c = weight of the conductor (including insulation, if any) per foot length, in pounds.
i = weight of the ice coating per foot length of the conductor, in pounds.
h = wind pressure per foot length of the conductor, in pounds.

The weight of the conductor per foot length may be taken directly from the tables in the articles on Bare Wires and Cables. Let d be the diameter in inches, and let t be the thickness of the ice coating; then the weight of the ice coating per foot length of the conductor is

$$i = 1.24\,t(d + t) \tag{9}$$

Let p be the wind pressure per square foot of projected area; then the wind pressure per foot length of the conductor, i.e., the horizontal component of the resultant force, is

$$h = \frac{p(d + 2t)}{12} \tag{10}$$

The vertical component of the resultant force per foot length of conductor, which is equal to the resultant force for no wind, is

$$v = c + i \tag{11}$$

Values of v and h for various ice thicknesses and various sizes of wires are given in Table II. v and h being known, the resultant force w for any combination of wind and ice loads is readily determined by the formula

$$w = \sqrt{v^2 + h^2} \tag{12}$$

Calculation of Sag and Tension

A wire or cable suspended between towers takes the form of a catenary curve. In transmission-line practice the maximum deflection or sag is always small compared to the span; that is, the curve is very flat. The shape of such a flat catenary curve does not differ appreciably from a parabola and, as the approximate parabolic formulas are much simpler than the more exact catenary formulas, they are used instead. The flatness

of the curve allows of some further simplifications even in the parabolic formulas, viz., (1) the tension is considered uniform throughout the span, the slight excess of tension at the ends over that at middle being neglected; (2) the change of length of the wire due

to elastic stretch or temperature expansion is taken as equal to the change of length of a wire equal in length to the horizontal distance between the points of support.

Notation Used in Sag-tension Formulas. The following notation, listed alphabetically, will be used throughout the discussion of sag and tension.

A = cross-section of the conductor (actual metal cross-section) in square inches = circular mils ÷ 1,273,000.

a = coefficient of linear expansion of the conductor per degree fahrenheit; see Table I above.

D = deflection, in feet, of the lowest point of the conductor from the line through supports when suspended from two points of support at the same elevation and at a distance L apart. (D is measured in the direction of the resultant transverse force.)

e = difference in elevation of the two points of support, in feet.

F = longitudinal horizontal component of the stress in the conductor, in pounds. (The resultant stress in the wire at the insulator is equal to $\sqrt{F^2 + H^2 + V^2}$, where V is the weight of the conductor and ice from the insulator to the lowest point of the span, and H is the total wind pressure on half the length of span; H and V in this expression are usually negligible compared with F.)

h = wind pressure in pounds per foot length of conductor assumed perpendicular to the vertical plane through the two points of support; see eq. (10) and Table IV above.

L = length of span in feet, i.e., the horizontal distance between the two points of support in feet.

l = length in feet of the arc of the curve in which the conductor hangs, i.e., the length of stretched conductor between the two points of support.

M = modulus of elasticity of the conductor in pound-inch units; see Table I above.

$S = \dfrac{vD}{w}$ = sag of the lowest point of the conductor below the horizontal line through the points of support; for no wind $S = D$.

T_0 = maximum allowable tension in the conductor in pounds per square inch of its cross section; T_0 is usually taken as one-half the ultimate strength of the conductor; see Table I.

v = vertical force in pounds on a one-foot length of the conductor, including the weight of conductor and the weight of the ice, if any, on it; see eq. (11) and Table IV above.

$w = \sqrt{v^2 + h^2}$ = resultant load in pounds on a 1-ft length of the conductor.

$Z = \dfrac{hD}{w}$ = side swing, in feet, of the middle point of the conductor, measured perpendicularly to the vertical plane through the two points of support.

The various symbols with the subscript "0" will be used to designate the values of the various quantities under the conditions of maximum assumed loading; see paragraph above on Maximum Loading.

FUNDAMENTAL EQUATIONS OF A WIRE SPAN. As noted above, a perfectly flexible wire suspended between two points of support hangs in a catenary. The assumption that the wire hangs in a parabola instead of in a catenary is sufficiently accurate for all practical calculations of wire spans, the error in the sag calculated on this assumption being less than 2 per cent of its true value when this sag is less than 0.06 times the length of the span (e.g., less than 60 ft in a 1000-ft span), and the error in the length of the wire calculated on this assumption being less than 0.002 per cent of its true value for the same limiting conditions. The formulas given below are all based on the assumption of a parabola.

Deflection, Sag and Side Swing. For a given length of span L, loading w, and stress F, the deflection D for the points of support at the same elevation is given by the relation

$$D = \frac{wL^2}{8F} \tag{13}$$

When there is no wind this is also equal to the vertical sag, that is $S = D$. When there is wind, w is greater than the vertical loading v, and the vertical sag for the points of support at the same elevation is

$$S = \frac{vD}{w} = \frac{vL^2}{8F} \tag{14}$$

D in eq. (14) has the value given by eq. (13). When one point of support is at an elevation

e above the other, then the vertical sag of the lowest point of the conductor below the lower point of support is

$$S' = S\left(1 - \frac{e}{4S}\right)^2 \tag{15}$$

where S is given by eq. (14). The horizontal distance of the lowest point of the conductor from the lower point of support is

$$L' = \frac{L}{2}\left(1 - \frac{e}{4S}\right) \tag{16}$$

The side swing Z of the middle point of the conductor, which is the point which is deflected the maximum distance from the vertical plane through the two points of support, is

$$Z = \frac{hD}{w} = \frac{hL^2}{8F} \tag{17}$$

D in eq. (17) has the value given by eq. (13).

Length of Stretched Conductor. The length of conductor between the two points of support for a given length of span L, loading w, stress F, and difference of elevation e, is

$$l = L + \frac{8}{3}\frac{D^2}{L} + \frac{e^2}{2L} \tag{18}$$

where D has the value given by eq. (13), that is, D is the deflection for the same length of span, loading, and tension, but for the points of support at the same elevation.

Effect of Changes in Loading and Temperature. When the loading or the temperature changes, the stress in the conductor will change to some new value, F_0 say, and the deflection will change to some new value, say D_0. Let the new loading be w_0 and the new temperature t_0, the initial temperature being t; also let a be the coefficient of linear expansion, M the modulus of elasticity, and A the cross-section of the conductor in square inches. Then, when the points of support remain fixed, the following relation must hold

$$\frac{8}{3L^2}(D^2 - D_0^2) = a(t - t_0) + \frac{1}{MA}(F - F_0) \tag{19}$$

The D's in this equation are the same as given by eq. (13) for a loading of w and w_0 respectively and stresses of F and F_0, respectively. Note that eq. (19) is independent of the difference in elevation of the two points of support; also that the two sets of symbols, with and without the subscripts, refer to *any* two sets of conditions.

STRESS-TEMPERATURE AND STRESS-DEFLECTION CHARTS. In order to apply the above equations to the calculation of deflections and stresses under various temperature and loading conditions, eqs. (13) and (19) may be written as follows:

$$D = \frac{wL^2}{8F} \tag{20}$$

$$D^3 = D\left[\frac{L^2 a}{2.66}(t - t_0) + D_0^2 - \frac{F_0 L^2}{2.66\,MA}\right] + \frac{3\,wL^4}{64\,MA} \tag{21}$$

From solutions of these equations under various conditions, curves showing the relation between deflection and temperature and between stress and temperature may be plotted. Such curves provide stringing charts and show maximum and minimum sags from which clearance templates may be constructed.

For an individual span the process of plotting sag curves for various temperatures is quite simple. The first step is to decide upon the maximum allowable tension (F_0), the temperature (t_0) at maximum tension, and the maximum expected mechanical loading, i.e., thickness of ice coating and wind pressure. Using eqs. (9) to (12), inclusive, or Table IV, the resultant force on the conductor (w_0) may be determined. Inserting these values in eq. (20), the deflection (D_0) for maximum tension at temperature (t_0) may be computed. The second step is to apply the above values to eq. (21). Six to eight temperatures should be selected, ranging from the lowest to the highest temperatures to which the line may be exposed. It should be remembered that the temperature of a conductor carrying current and exposed to the sun may rise as much as 30 deg fahr above the ambient air temperature. Eq. (21) should be solved for each of the selected temperatures to obtain the corresponding values of deflection (D). These values of (D) may then be plotted against the corresponding values of temperature, giving a stringing curve and also values of maximum and minimum sags. By the use of eq. (20), the tensions (F) may be determined for each value of deflection and temperature. Plotting the values of (F) thus determined against temperature provides a stringing tension curve.

For any temperature the corresponding stresses and deflections may be taken from the curves. Conductors strung in accordance with these values will not have the maxi-

mum allowable stress or sag exceeded if the maximum loading or temperature selected are not exceeded.

The stresses computed are independent of any difference of elevation of supports. If there is a difference of elevation of supports the sags below the lower support may be determined by the use of eq. (15), and the horizontal distance of the lowest point of the conductor may be obtained by using eq. (16).

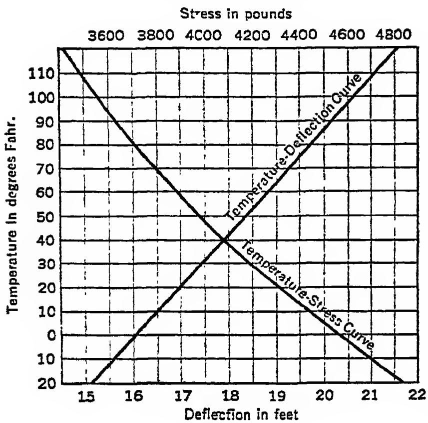

FIG. 3

Fig. 3 shows an example of stress-temperature and deflection-temperature curves for a 300,000-cir-mil 19-strand copper conductor on an 800-ft span, with the maximum allowable tension (T_0) at 30,000 lb per sq in., and maximum loading (w_0) equal to 1.807 lb per ft, due to 1/2-in. ice thickness and 6 lb per sq ft wind pressure, at 0 deg fahr.

For example, if the cable is strung at 70 deg fahr, then it should be given a deflection (vertical sag) of 19.25 ft, provided the points of support are at the same elevation, or at a stress of 3800 lb, this stress being independent of the difference of elevation of the two points of support. If there is a difference of elevation of 30 ft, say, between the two points of support, then from eq. (15), the cable should be drawn up until the sag of the lowest point below the lower point of support is

$$S' = 19.25\left(1 - \frac{30}{4 \times 19.25}\right)^2 = 7.17 \text{ ft}$$

and the stress will then be 3800 lb.

DIRECT CALCULATION OF CHANGE IN DEFLECTION AND STRESS WITH LOADING AND TEMPERATURE.* When for F in eq (19) is substituted its value from eq. (20) there results a cubic equation in D, eq. (21). This cubic equation can be solved directly by means of Tables V(*a*) and V(*b*) given herewith (H. Pender, *Elec. World*, Vol. 66, p. 344, 1915). The procedure is as follows: using the same notation as above, calculate

$$b_1 = \frac{1000\,F_0}{MA}$$

$$b_2 = \left(\frac{w_0 L}{0.155\,F_0}\right)^2$$

$$b_3 = 1000\,a(t - t_0)$$

$$b = \frac{1000\,wL}{MA}$$

$$B = \text{numerical value of } [b_1 - (b_2 + b_3)]$$

$$x = \frac{b}{B\sqrt{B}}$$

Take y from table. Then the deflection is

$$D = yL\sqrt{B} \tag{22}$$

and the stress is

$$F = \frac{wL^2}{8D} \tag{23}$$

Note that b_1 may be greater or less than $(b_2 + b_3)$; in either case B is to be taken *positive* and equal to the numerical value of $b_1 - (b_2 + b_3)$. Also note that:

b_1 is the elongation, in feet per 1000 ft, of a straight wire when subjected to a stress of F_0 pounds.

b_2 is the number of feet per 1000 ft of wire, by which the length of the wire at t_0 degrees and loading w_0 exceeds the horizontal distance between the points of support (when these are at the same elevation).

* From lecture notes by Dr. H. Pender.

b_3 is the elongation, in feet per 1000 ft of wire, due solely to a change in temperature from t_0 to t degrees.

b is the elongation, in feet per 1000 ft of wire, due to a stress equal to wL(= its own weight plus the total ice and wind, if any, at the temperature t).

Example. To find the sag at which a No. 0 B. & S. stranded copper wire must be strung at 60 deg fahr on a 400-ft span so that the wire will have a factor of safety of 2 at 0 deg fahr when loaded with ice 0.5 in. thick all around the wire and with a wind pressure of 8 lb per sq ft of projected area. The breaking strength of the wire is 4980 lb, cross-section 0.083 sq in., modulus of elasticity 16×10^6, and coefficient of expansion 9.6×10^{-6}.

The data and calculations are then as follows:

$$F_0 = 2490 \qquad M = 16 \times 10^6$$
$$w = 0.323 \qquad L = 400$$
$$w_0 = 1.26 \qquad t - t_0 = 60$$
$$A = 0.083 \qquad a = 9.6 \times 10^{-6}$$

Then

$$b_1 = \frac{1000 \times 2490}{16 \times 10^6 \times 0.083} = 1.878$$

$$b_2 = \left(\frac{1.26 \times 400}{0.155 \times 2490}\right)^2 = 1.705$$

$$b_3 = 1000 \times 9.6 \times 10^{-6} \times 60 = 0.576$$

$$b = \frac{1000 \times 0.323 \times 400}{16 \times 10^6 \times 0.083} = 0.0975$$

Noting that b_1 is less than $(b_2 + b_3)$,

$$B = 1.705 + 0.576 - 1.878 = 0.403$$

$$x = \frac{0.0975}{0.403\sqrt{0.403}} = 0.382$$

and, from Table V(b), $y = 0.0308$. Whence

$$D = 0.0308 \times 400\sqrt{0.403} = 7.82 \text{ ft}$$

This is the sag at 60 deg fahr with no ice or wind.

The sag at 0 deg fahr with no ice or wind is found in exactly the same way, noting that for these conditions $b_3 = 0$, and b_1 is greater than $(b_2 + b_3)$, giving for B the value

$$1.878 - 1.705 = 0.173$$

and for x the value

$$\frac{0.0975}{0.173\sqrt{0.173}} = 1.355$$

and y from Table V(a) is then 0.0367, and

$$D = 0.0367 \times 400\sqrt{0.173} = 6.10 \text{ ft}$$

A fairly quick slide-rule method of solving the cubic equation in D is given here. Though not as accurate as the method outlined above, it may serve a useful purpose for many calculations. The combination of eqs. (20) and (21) may be put in the following form:

$$D^3 = D\frac{Q}{K} + \frac{wL^2}{8K} \tag{24}$$

where

$$\frac{Q}{K} = D_0^2 + \frac{L^2 a}{2.66}(t - t_0) - \frac{F_0}{K} \tag{25}$$

$$K = \frac{2.66\,MA}{L^2} \tag{26}$$

and are constant for a given set of conditions.

Having calculated $\frac{Q}{K}$ and $\frac{wL^2}{8K}$, set the index of scale C to a tentative value of D on the D scale of the slide rule. Calculate D^3 using the A and B scales, and $D\frac{Q}{K}$ using the C and D scales. Usually this can be done without changing the setting. Mental addition of the right-hand side of the equation will determine how closely the equation balances. Two or three trial values for D will result in a very close approximation. One or two more trials with accurate addition will determine a value of D which is accurate enough for many purposes.

Many graphical methods for sag and tension calculation have been developed. The Thomas method and the Pender and Thompson charts are covered in detail in the N.E.L.A. Overhead Systems Reference book, and the method developed by Theodore Varney for A.C.S.R. is given in an article published by the Aluminum Co. of America. A convenient set of tables for sag calculations based upon the catenary was presented by Mr. J. S. Martin

before the Engineers Society of Western Pennsylvania in 1922. These tables have been recently republished by the Copperweld Steel Co.

STRESS AND DEFLECTION IN SPANS OF UNEQUAL LENGTH. By stringing cables according to the stress determined for each particular length of span, the maximum allowable tension will be reached in all spans under maximum loading conditions. Under other loading conditions the tension will be unequal where span lengths are not the same. This is shown in Fig. 4, which is plotted for the same conditions as stated in the discussion of Fig. 3, but for spans of 600 to 900 ft in length. Fig. 5 shows the corresponding deflections.

The unequal stresses on the two sides of the insulator will tend to bend the tower or insulator pin, but any motion of the point of support will tend to equalize the stresses. When suspension insulators are used, the stresses are practically equalized, since the

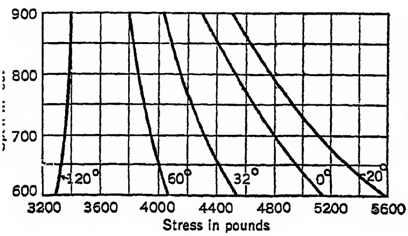

FIG. 4

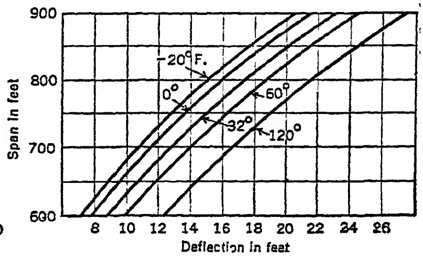

FIG. 5

insulator is free to move. It should be noted that the motion of the insulator necessary to equalize the stresses is small. When suspension insulators are used the cable is therefore strung at a tension corresponding to the ruling span. The ruling span is usually taken as the average span plus two-thirds of the difference between the average span and the maximum span.

To plot stringing curves for unequal spans under the ruling-span method it is necessary first to plot a temperature-stress curve for the ruling span by the method outlined above in the paragraph on Stress-Deflection-Temperature Charts. By the use of eq. (12), deflections corresponding to several span lengths at several stringing temperatures are computed, using stresses (tensions) taken from the stress-temperature chart for each temperature considered. From these values it is possible to plot a span-deflection curve for each temperature, which may be used as a stringing chart.

When the cable is thus strung the tension under minimum temperature and maximum loading will usually exceed the assumed tension in the shorter spans and be less than the assumed tension in the longer spans. Similarly, under maximum temperature conditions, the longer spans will have a sag in excess of the value calculated on the assumption of the maximum allowable tension being reached with maximum loading, and the shorter spans will have a sag less than the calculated value. The actual stresses and deflections can be calculated by the method given in the following paragraph.

CALCULATION OF STRESSES IN UNEQUALLY LOADED SPANS.* When suspension insulators are used, any tendency of the stresses in two adjacent spans to become unequal will produce such a deflection of the insulator, in the direction of the span with greater stress, as will establish equilibrium in the line. This state of affairs will occur (1) when adjacent spans carry unequal ice loads, (2) when the wire on one side of the insulator breaks, and (3) to a slight extent with changes in temperature when the adjacent spans are unequal in length, as noted above. The following method of calculating the "equilibrium" stresses in the wires and corresponding sags is applicable to all cases of initially unbalanced stresses, irrespective of their cause. The method may also be used to calculate the stress and sag in spans supported on pin insulators, provided the moment of bending of the pin and of the pole or tower is known or can be calculated.

Change of Stress Due to Change in Length of Span. When the length L of the span (i.e., distance between points of support) increases by λ inches, due to a horizontal displacement of the insulators (without slipping of the wire), the stress in the wire is increased by the same amount as would be produced by a fall in temperature of

$$t - t' = \frac{\lambda}{12\,aL} \quad \text{or} \quad t' = t - \frac{\lambda}{12\,aL} \tag{27}$$

* From lecture notes by Dr. H. Pender.

degrees fahrenheit, where t is the actual temperature and t' may be called the "equivalent" temperature corresponding to the change in length λ. In this equation λ is the actual increase in the distance between the points of support in inches, a the temperature coefficient of linear expansion per degree fahrenheit, and L the original length of the span in feet. For example, in an 800-ft span of copper wire an increase of 1 in. in L corresponds to a drop of temperature of $1 \div (12 \times 9.6 \times 10^{-6} \times 800) = 10.85$ deg, and an increase in length of λ inches corresponds to a drop of temperature of $t - t' = 10.85\,\lambda$ deg.

Hence the stress-temperature chart for any given length of span, see Fig. 3, may be used directly to determine the stress in the wire after any change in the length of the span, due to the deflection of the insulator. For example, consider an 800-ft span of 300,000-cir-mil bare copper conductor, at 32 deg fahr, without ice or wind, initially stressed to 4170 lb and let the length of the span be increased 4 in. as the result of the deflection of the insulators by this amount. This increase in length of span will then give the same stress in the wire as would be produced if the temperature fell from 32 deg to $t' = 32 - 4 \times 10.85 = -11.4$ deg. The point on the stress-temperature curve (Fig. 3) corresponding to a temperature of -11.4 deg gives the new stress, viz., 4700 lb.

Horizontal Pull of Insulator. Referring to Fig. 6, let m = the horizontal distance in inches (measured along the span) which any insulator is deflected from the vertical, taken positive when to the right, say, and negative when to the left. Let x = the length of the insulator string in inches, i.e., distance from point of attachment to tower to point of attachment to wire; V = total weight of wire and ice between the lowest point of the wire in the span to the left of the insulator and the lowest point of the wire in the span to the right of the insulator plus one-half the weight of the insulator; H = total wind pressure on the length of wire between the middle points of the two adjacent spans, plus half the wind pressure on the insulator; and put $W = \sqrt{V^2 + H^2}$. Then the horizontal component of the pull of the insulator toward the left along the line of the span is *

$$P = \frac{m}{\sqrt{x^2 - m^2}} \cdot W \tag{28}$$

For example, consider two adjacent spans of 300,000-cir-mil copper, each 800 ft long and with points of support at the same elevation. Let the span to the left be free of ice and let the one to the right have a 1/4-in. ice coating; assume the insulator to be 60 in. long and to weigh 100 lb. Then for no wind $H = 0$, $V = 1.19 \times 400 + 0.915 \times 400 + 100/2 = 892$ lb. Whence for deflections of the insulator of less than 12 in. the horizontal pull of the insulator is $P = (892 \times m) \div 60 = 14.9m$, or 14.9 lb per in. deflection.

STRESSES IN A SERIES OF SPANS WHEN POINTS OF SUPPORT ARE NOT FIXED. Referring to Fig. 6, let the left-hand end of span 1 be anchored, and assume the insulator at the right-hand end to be deflected a horizontal distance of m_1 inches, due, for example, to a change in the loading on the succeeding spans (or to a change in temperature when the spans are of unequal length). From eq. (27) calculate the "equivalent" temperature t'_1 corresponding to this change in length, and from a stress-temperature curve, corresponding to the assumed loading w_1 of this span find the stress on this curve corresponding to a temperature of t'_1 degrees; call this stress F'_1.

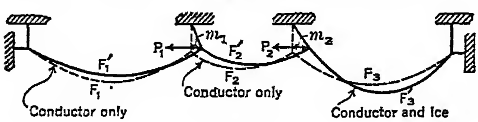

FIG. 6

Next calculate the transverse and vertical loads on the insulator, viz., H_1 and V_1, and the resultant load $W_1 = \sqrt{V_1^2 + H_1^2}$, as explained above. Then from eq. (28) or (29) calculate the horizontal pull P_1 of the insulator. The stress in the second span, assuming the value of m_1 chosen at the start is correct, must then be

$$F'_2 = F'_1 + P_1 \tag{30}$$

t'_2 is then determined from F'_2 on the stress-temperature curve. From eq. (27) the corresponding increase in the length of span 2 must then be

$$\lambda_2 = 12\,aL_2(t - t'_2) \tag{31}$$

where L_2 is the length of the second span. The corresponding deflection of the insulator at the right-hand end of span 2 must then be

$$m_2 = m_1 + \lambda_2 \tag{32}$$

always taking the insulator deflection positive when to the right, say.

* When m is less than 20 percent of x this may be written, with an error of less than 2 percent,

$$P = \frac{m}{x} W \tag{29}$$

Using the values of λ_2 and m_2 thus found, calculate the λ_3 and m_3 in exactly the same manner as λ_2 and m_2 were calculated, and similarly for the succeeding spans until the next anchor tower is reached. For the anchor tower at the right-hand end of the nth span, say, the deflection of the insulator must be zero, viz.,

$$m_n = 0 \tag{33}$$

If m_n as calculated comes out greater than zero, then the assumed value of m_1 is too great; if m_n comes out less than zero the assumed value of m_1 is too small. By calculating m_n for two or three assumed values of m_1, and plotting m_n as ordinates against m_1 as abscissas, the correct value of m_1 will be where this curve crosses the axis of abscissas. Using this correct value of m_1, the stresses and deflections in each span may then be accurately calculated by the process just given. The complete process is best shown by an example.

Example. Consider three spans between anchor towers (Fig. 6), all of the same length, 800 ft, and all supports at the same elevation, 300,000-cir-mil copper being used for the conductor. Let the temperature be 32 deg fahr, and let the middle span have a $^1/_4$-in. ice coating but the other two spans have no ice on them; also assume no wind. The stress-temperature chart given in Fig. 3 then applies directly, provided the wires are strung in accordance therewith. Assume that each insulator weighs 100 lb and has a length of 60 in. Then for an increase of λ inches in the length of any span, the "equivalent" temperature is, from eq. (27),

$$t' = 32 - 10.85\lambda$$

or if the equivalent temperature rise t' is known

$$\lambda = 0.092(32 - t')$$

The horizontal pull of any insulator for a deflection of m inches (small compared with the length of the insulator) is, from eq. (29),

$$P = 14.9\,m$$

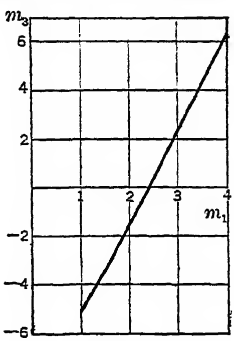

Fig. 7

In the following table are given the calculations for assumed values of m_1 of 1, 2, 3, and 4 in., and in Fig. 7 are plotted the corresponding calculated values of m_3 against m_1. It is seen that the relation between m_3 and m_1 is practically a straight line cutting the horizontal axis at $m_1 = 2.4$, which is therefore the correct value of m_1. The calculations for $m_1 = 2.4$ in. are given in the last column of the table. Hence the stresses and deflections in the two end spans (without ice) are $F'_1 = F'_3 = 4460$ lb and $D'_1 = D'_3 = 16.3$ ft respectively, and the stress and deflection in the middle span loaded with $^1/_4$ in. of ice are $F'_2 = 4496$ lb and $D'_2 = 21.1$ ft respectively.

These calculations will be facilitated, if many are to be made, by plotting stress-temperature curves for each loading assumed. The equivalent temperatures corresponding to calculated stresses are then taken directly from the curves. If only a few calculations are necessary eqs. (20) and (21) may be employed.

m_1	= assumed	1	2	3	4	2.4

Location of Towers and Determination of Clearances

The height of towers is determined so as to give some specified minimum clearance from conductor to ground for some length of span chosen as a nominal standard on the basis of level ground. In practice the ground is rarely level, and the towers are actually located to conform to the irregularities of the ground. In locating towers of a given

height the spans are made as long as possible consistent with maintaining the ground clearance. The irregularities of the ground are ordinarily advantageous and permit of slightly longer spans on the average than could be obtained with the same height of towers on level ground.

Profile and Plan of Right-of-way. In order to locate towers properly it is necessary to have a profile of the right-of-way. Profiles are conveniently plotted on standard ruled profile section paper to a vertical scale of 20 ft to the inch and a horizontal scale of 200 ft to the inch. Three profiles are desirable, one along the center of the tower line and one

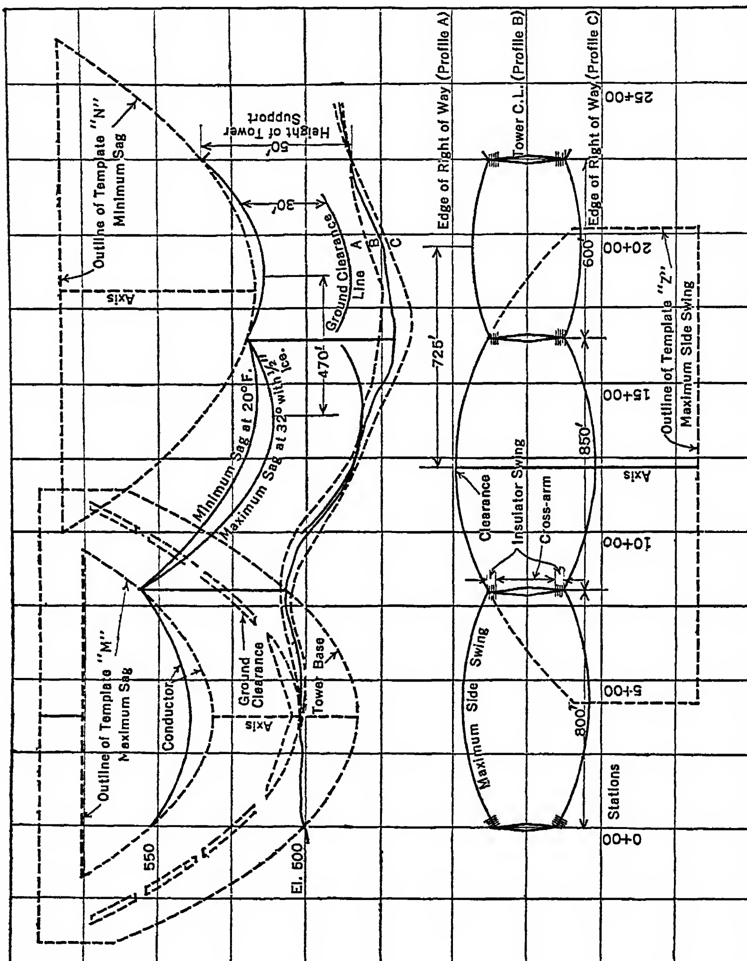

Fig. 8

on each side, say at each edge of right-of-way, as shown on Fig. 8 at *A*, *B*, and *C*. The two side profiles indicate the amount and direction of the slope of the ground across the line which must be allowed for in determining ground clearance and foundation or tower extensions.

A plan of the right-of-way is of course also necessary for determining the construction at angles in the line, and the clearances from the conductor to the edge of the right-of-way when the conductor is deflected horizontally by the wind. Such a plan is shown at the bottom of Fig. 8.

TEMPLATES FOR LOCATING TOWERS. Three templates are required, one for ground clearance with maximum sag, marked M in Fig. 8, one for uplift at times of minimum sag, marked N, and one for maximum side swing, marked Z. These are cut from thin celluloid and are to the same horizontal and vertical scales as used for the profile and plan of the right-of-way.

Since the curvature of the catenary or parabola in which the wire hangs depends only on the tension and loading and not on the length of the span or on the difference in elevation of the points of support, all spans having the same tension and loading can be drawn (for any one predetermined scale) from a single template, irrespective of their lengths or of the differences in elevation of the points of support. However, when the elevations of the points of support are not the same, the lowest point of the curve is shifted from the middle of the span toward the lower support, but the axis of the curve remains vertical.

Construction of Maximum Sag Template M. The maximum sag is found from the deflection-temperature curve, Fig. 3, and may be the deflection corresponding to the maximum temperature, and conductor only, e.g., 21.4 ft in Fig. 3, or may be the deflection corresponding to 32 deg fahr and the maximum ice loading. Wind will increase this deflection but will not increase the *vertical sag*. Call S_m this maximum sag. Then the equation of the maximum sag template, or template M, is

$$y = \left(\frac{4\,S_m}{L^2}\right) x^2 \tag{34}$$

where L is the length of the particular span for which the maximum sag is S_m, and the origin of the curve is its lowest point and the axis of y is vertical; all dimensions are in feet. Three parabolic curves are given by this template; the top curve represents the position of the cable and is drawn on the basis of the average span under the maximum load; the middle curve is a similar parabola below the upper curve a distance equal to the minimum allowable clearance to ground; the bottom curve is another similar parabola below the upper curve by a distance equal to the height of cable above ground at the support.

Instead of solving eqs. (34), (35), and (36), use may be made of the multipliers in Table VI which gives the percentage of the sag at the center of the span for various percentages of the span. Level supports are assumed. If supports are not level, use a value for span length equal to twice the horizontal distance from the upper support to the point of maximum sag.

Table VI

Percentage of Span Length	Percentage of Sag at Center of Span	Percentage of Span Length	Percentage of Sag at Center of Span
5 or 95	19.5	30 or 70	84.4
10 — 90	36.5	35 — 65	91.3
15 — 85	51.0	40 — 60	96.0
20 — 80	64.0	45 — 55	98.9
25 — 75	75.0	50 — 50	100.0

Construction of Minimum Sag Template N. The minimum sag is also found from the temperature-deflection chart, and is usually the deflection corresponding to the minimum temperature and conductor only, e.g., 15.1 ft in Fig. 3. Call this sag S_n; then the equation of the minimum sag template, or template N, is

$$y = \left(\frac{4\,S_n}{L^2}\right) x^2 \tag{35}$$

Construction of Maximum Side-swing Template Z. The maximum side swing occurs at time of maximum wind pressure and may be at maximum temperature or may be at 32 deg fahr when covered with ice. In the latter case the side swing depends on the shape (circular or elliptical) of the ice covering and its specific gravity. For a circular covering of solid ice one particular thickness (usually but not necessarily the maximum thickness) gives the greatest side swing. Calling the maximum side swing Z_m, then the equation of the side swing template, or template Z, is

$$y = \left(\frac{4\,Z_m}{L^2}\right) x^2 \tag{36}$$

LOCATING TOWERS BY MEANS OF TEMPLATE M. Choose a starting point, as shown for example in Fig. 8, at station 0 + 00, elevation 500.0 ft for the first tower location. The template M is then placed over the profile and shifted until its axis is vertical and the lower curve is at station 0 + 00, elevation 500.0 ft, and the middle curve is tangent to the ground profile as shown. The proper location for the second tower is at the point where the lower curve again intersects the ground profile, or at station 8 + 00, eleva-

tion 506.0 ft, in the example. The operation is then repeated for the next tower. Adjustments in length of span are usually necessary to meet local conditions, in order to avoid locating towers in roads or swamps and to bring towers at angle points. Adjustments which increase the ground clearance are of course allowable.

The position of the conductors with maximum sag may be drawn on the profile from the top curve of the template.

UPLIFT ON INSULATOR; USE OF TEMPLATE *N*. An insulator sustains the weight of the lengths of conductor from the insulator to the lowest point of the span on each side. If the conductor leaves the insulator horizontally on one side, the lowest point of that span is at the insulator, which then sustains no weight due to that span. If the conductor has an upward inclination where it leaves an insulator, it is exerting an uplift equal to the weight of a length of conductor extending from the insulator along the span produced in the reverse direction to the lowest point of the parabola. Where the conductor has a downward inclination on one side and upward on the other side of the insulator, there will be a weight or uplift on the insulator equal to the difference between the weight of conductor on one side and uplift on the other.

Suspension insulators when used hanging downward to sustain weight are incapable of resisting uplift. Where uplift occurs the conductor may be dead ended or may be be tied down or weighted down.

The method used for locating towers ordinarily precludes uplift under the loading which gives maximum sag, but uplift may occur when the loading is less. To determine this the minimum sag is drawn on the profile with template *N*. The minimum sag curve is drawn between points of support, keeping the axis of the parabola vertical as before.

SIDE SWING OF SUSPENSION INSULATORS. Let l_1 = the length of conductor between the lowest point in the span to the left of the insulator and the lowest point in the span to the right of the insulator, and let l_2 = the distance between the middle points of these two spans, both in feet. Also let v = the weight of the conductor and ice per foot length, and h = the wind pressure per foot length (see Table IV). Then the vertical pull on the insulator is vl_1 and the transverse horizontal force is hl_2. Also let v_1 = the weight of the insulator and h_1 = the total wind pressure on it. Then the insulator is deflected sidewise from the vertical by approximately the angle

$$\theta = \tan^{-1}\left[\frac{hl_2 + 0.5\,h_1}{vl_1 + 0.5\,v_1}\right] \tag{37}$$

Usually the weight of the insulator and the wind pressure on it are negligible compared with the weight and wind pressure on the conductor, in which case

$$\theta = \tan^{-1}\left(\frac{hl_2}{vl_1}\right) \tag{37a}$$

When the points of support are at the same elevation $l_1 = l_2$ and

$$\theta = \tan^{-1}\frac{h}{v} \tag{37b}$$

Calling X the length of the insulator in feet, then the transverse horizontal deflection of the insulator is $X \sin\theta$ ft.

For example, consider the side swing of the third insulator (from the left) in Fig. 8. Then $l_1 = 470$, $l_2 = 850/2 + 600/2 = 725$, $v = 1.61$ (for 300,000-cir-mil conductor with $^1/_2$ in. of ice), and $h = 0.82$ (for wind pressure of 6 lb per sq ft). Whence, neglecting the weight of the insulator and the wind pressure on it,

$$\theta = \tan^{-1}\frac{0.82 \times 725}{1.61 \times 470} = 38°$$

If the insulator is 5 ft long, the transverse horizontal deflection is then $5 \sin 38° = 3.1$ ft.

If the angle of swing as thus determined is excessive the cables and insulators will be lifted up into the cross arms at times of low temperatures and high winds. The remedy is the same as in case of direct uplift.

SIDE CLEARANCE; USE OF TEMPLATE *Z*. Where a right-of-way of definite width is obtained it is necessary to determine whether the conductor will swing beyond the edge of the right-of-way. Therefore after the towers have been located by the use of the profile they should be marked on the plan and the side swing marked in from template *Z*, as shown in Fig. 8. In determining side swing, the swing of the insulator (if suspension type) must be allowed for, as well as the side swing of the conductor. Adequate margin should be allowed between the extreme position of conductor and the edge of the right-of-way, so that a safe clearance will be preserved from any structures

erected adjacent thereto. Where extraordinarily long spans must be used, an adequate extra width of right-of-way should be obtained in the first place.

LOSS OF CLEARANCE BETWEEN CONDUCTORS DUE TO UNEQUAL ICE LOADING. Where one span is loaded with ice and the one immediately below it is not, the clearance is reduced. This condition may sometimes arise due to the ice falling off the lower wire before it falls off the upper wire. Where the wires are directly over each other the normal clearance must be great enough to prevent the crossing of wires under these conditions. For ice loading without wind, clearance under unequal loading is most easily obtained by offsetting the wires horizontally for the required clearance instead of increasing the vertical clearance. However, to prevent crossing of the unequally loaded wires when deflected by wind pressure, this horizontal offset must be considerable, as the clearance must then be obtained between the wires in their inclined positions.

If the conductors to which Fig. 3 refer are normally 10 ft apart vertically on an 800-ft span, the sag would be 17.5 ft without ice at 32 deg fahr, 19.0 ft with $1/4$ in. ice, and 20.9 ft with $1/2$ in. ice at 32 deg fahr. Consequently, if two cables are used one above the other, and ice should form on the upper but not on the lower, then, assuming fixed points of support (pin insulators), the clearance would be reduced by 3.4 ft for $1/2$ in. ice, and 1.5 ft for $1/4$ in. ice, making the clearances 6.6 ft and 8.5 ft respectively, instead of 10 ft.

Where suspension insulators are used the reduction of clearance from unequal ice loading is greater. If one span is loaded with ice and the adjacent spans of the same wire are not loaded, the sag of the loaded span will be increased because the insulators will swing toward that span. Similarly if one span is unloaded and adjacent spans are loaded, the sag will be decreased. The minimum clearance occurs where only one span of the upper wire is loaded and is immediately over the only unloaded span of the lower wire. The actual reduction is readily calculated by the method given above in the paragraph on Calculation of Stresses in Unequally Loaded Spans. The amount of reduction depends on the number of spans between anchor towers, and the distance from the anchor towers at which the unbalanced loading occurs. For a 300,000-cir-mil copper cable on 800-ft spans at 32 deg fahr with unequal loadings on sections of one, two, three, and five spans (see Fig. 9) the assumed conditions of unequal loading and the loss of clearance are as follows:

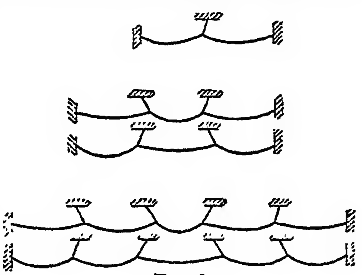

Fig. 9

Number of Spans between Anchor Towers	1	2	3	5
Upper conductor; $1/4$ in. ice on spans Nos.:*	1	1	2	3
Lower conductor; $1/4$ in. ice on spans Nos.:*	....	2	1, 3	1, 2, 4, 5
Sag of middle span of upper conductor, feet	19.0	20.5	21.1	21.6
Sag of middle span of lower conductor, feet	17.5	15.9	15.5	15.2
Loss of clearance in middle span, feet	1.5	4.6	5.6	6.4

* The other spans assumed to have no ice load.

STRESSES AND DEFLECTIONS DUE TO BROKEN CONDUCTORS. When a conductor breaks in a span supported by suspension insulators, the insulators adjacent to the broken span swing up into line with the cable, throwing increased slack into the unbroken part of the cable equal to the length of the insulator. This slack divides between the unbroken spans, increasing the deflection of each. The stresses and deflections of the unbroken spans may be determined by the method given above for Calculation of Stresses in Unequally Loaded Spans, calling the span in which the break occurs span 1.

Joint Use of Poles with Other Utilities

When supporting structures of power lines are used jointly by other utilities, such as telephone or other communication systems, additional factors are introduced into the problem of line design beside those needing consideration in the case of power lines alone. Often a higher grade of construction is necessary, and attention must be given to the required separations between the conductors and equipment of the two utilities. When the poles are used jointly by power and communication utilities the separations required are generally greater than necessary between attachments of the same or different

power utilities. Usually contracts are entered into between the joint-use parties which set forth in detail the construction specifications to be followed.

Right-of-way

The right-of-way should be as short and straight as practicable. Its width will depend largely on the type of line to be constructed. A width of 50 ft is generally considered adequate for a single pole line with moderately short spans. For a double circuit tower line even with fairly long spans a width of 100 ft is generally adequate. With exceptionally long spans and extremely high voltages widths of as much as 200 ft may be necessary. In the case where two parallel pole or tower lines are to be constructed on the same right-of-way the distance between the center lines of the two lines should be added to the width of right-of-way required for a single line. The towers for the two lines should be placed directly opposite each other in order to reduce the width of right-of-way required.

The direction of the line will often need to be shifted to avoid buildings or other obstructions. In such a case consideration should be given to the maximum side swing of the conductors in the wind, and adequate clearance should be provided between the conductors and such obstructions under the worst condition of side swing. In computing the side swing, allowance should be made for swing of suspension insulators.

When it is necessary that the right-of-way cross railroads, roads, or other lines the length of crossing should be reduced to a minimum by making the crossing at as near right angles as practicable. Rights-of-way through swamps often require expensive road building and expensive tower foundations, though small swamps (up to about 1000 ft across) can often be crosssed in a single span. Steep side hills require extra expense for foundations and tower extensions, and introduce a hazard of injury to tower from sliding earth, rocks, trees, or snow. A right-of-way through forests requires expensive clearing.

It is usually advantageous to own and fence the right-of-way. However, when the right-of-way passes through farm lands, it is sometimes advantageous not to fence it in, but to have it cultivated and kept free from brush. Instead of purchasing a right-of-way, it is often sufficient to obtain easements covering the location of towers and suspension of wires. Easements and right-of-way agreements should include the right to remove and trim trees under and adjacent to the line. The right-of-way should be passable (or at least accessible) for patrolling as well as for construction.

The first step in selecting a route for a line is to lay out the possible routes on accurate maps. Topographic maps are of considerable assistance in this work. Rough reconnaissance surveys are made to determine the most suitable route. Aerial photographic surveys are very valuable especially in mountainous country. The next step is to obtain the right-of-way either by outright purchase or by obtaining easements. This is followed by sending out a party to make an accurate survey, including plans and profiles showing buildings, obstructions, natural features and property lines. (See Location of Towers.)

25. WOOD POLES FOR OVERHEAD LINES

Basis for Selection of Poles

The length of pole required for a particular location is determined by the following factors:

1. Amount of vertical space required for wires and equipment.
2. Clearance required above ground or obstructions for wires and equipment.
3. Sag of conductors.
4. Depth pole is to be set in the ground.

The size (class) of pole is determined by the strength required to sustain the mechanical loading imposed upon it. The strength of an unguyed pole is usually determined by its circumference at the ground line. This dimension determines the resisting moment of the pole when bending as a cantilever. For a guyed pole the resisting moment at the point of guy attachment must be sufficient to withstand the bending stresses imposed at that point. The top of the pole must also be of adequate diameter to permit the attachment of cross-arms without unduly weakening the pole near the top. Four and one-half inches is about the minimum top diameter suitable for cross-arm construction.

The basis for the selection of kind and quality of pole timber is principally economic. Long life is very desirable provided that it can be obtained at a low annual cost and provided that the line is expected to be more or less permanent. Long life for poles is obtained by the use of durable wood species and usually by preservative treatment methods applied to both durable or non-durable species. In order to obtain the quality of pole timber desired purchase specifications are required, and the specifications should be enforced by careful inspection of the poles before, during, and after the preservative treatment.

Methods of Specifying Pole Dimensions

A wood pole is usually specified by its total or "nominal" length and by its class. The word class refers to the dimensional classifications set up by the specifications of the American Standards Association. In those specifications classes numbered from 1 to 10 inclusive are provided for poles of the wood species principally used. Classes 1 to 7 inclusive specify the minimum top circumference for each class and the minimum circumference at 6 ft from the butt end for each nominal length in each class. Class 1 provides the largest ground line circumference, and Class 7 the smallest. Classes 8 to 10 inclusive specify minimum top circumferences only. Table VII shows dimensions for three wood species.

The dimensions specified for each class of Classes 1 to 7 inclusive are so selected that for any one wood species, any pole of a certain class, regardless of the length, will support the same conductors located in the same manner relative to the top of the pole (including wind and ice loading on conductors and pole) with the same fiber stress (within close limits) in the pole. This permits the same class pole to be used throughout a line if the size and arrangement of the conductors do not change, but a different class may be necessary on account of changes in grade of construction, angles, etc. Poles of different species but of the same class will support the same mechanical loading. The following tables are the A.S.A. standards for classes of poles.

Taper of Poles. The taper of various kinds of poles, specified as the difference, measured in inches, between two circumferences 10 feet apart, is given as follows in *Forest Service Bull.* 84: chestnut (Maryland), 3.8 to 4.0; northern white cedar (Michigan), 5.2; western yellow pine (California), 4.0; lodgepole pine (Montana), 3.0; loblolly pine (Texas), 2.4; western red cedar (Washington), 3.5. Trees grown upon a high elevation have a greater taper in the trunk than trees grown lower down.

Timber, to be desirable for use as poles, should have the following qualities: straightness, small taper, low weight, few knots, good resistance to decay, lack of serious defects, high strength, and softness enough to permit the spikes of a climber to enter readily. No pole timber is perfectly resistant to decay, but any timber can have its life greatly prolonged by preservative treatment. Treatment methods are discussed later in this article.

UNCERTAINTIES IN NAMES OF TIMBER TREES. The terms cedar, pine, etc., used in describing poles and cross-arms, and even the apparently more exact terms, such as white cedar, yellow pine, etc., each cover several kinds of trees and have different meanings in different localities.

At least eight pines (of the thirty-five native ones) are in the market, some of which so closely resemble each other in their minute structure that they can hardly be told apart; and yet they differ in quality and should be used separately, although they are often mixed or confounded in the trade.

Forestry Bulletin 10 states: "'Yellow pine,' is applied in the trade to all the southern lumber pines; in the Northeast it is also applied to the pitch pine; in the West it refers mostly to bull pine. 'Yellow longleaf pine,' 'Georgia pine,' chiefly used in advertisement, refers to longleaf pine."

Timbers Ordinarily Used for Poles and Cross-arms

The principal timber trees used for poles and cross-arms are briefly described below in accordance with the names used in the trade.

Chestnut grows throughout the Appalachian Mountain region. A blight in recent years has reduced the supply of satisfactory chestnut timber to an almost negligible amount. The sapwood is very thin, usually from about $1/8$ to $3/8$ in. in thickness. It is not so straight as cedar and is likely to be knotty. It is slightly stronger and heavier than cedar. At the present time it is mostly used for poles in the locality where it is cut.

Northern White Cedar has its principal source of supply in the region of the Great Lakes. It is used mainly in the northeast quarter of the United States for small poles. Its large taper and spreading butts make it undesirable for long poles. The sapwood varies from $1/2$ to 1 in. in thickness and is usually thicker at the top than at the butt. Frequently, the butts are decayed at the center. It is very slow in growth, requiring about 190 years for a 30-ft pole.

Southern White Cedar grows mainly in the southern swamps and is somewhat less durable than the northern cedar. It is used very little for poles as its sapwood decays very quickly.

Red Cedar is a small to medium-sized tree scattered through the forests, or, in the West, sparsely covering extensive areas (cedar brakes). The red cedar is the most widely distributed conifer of the United States, occurring from the Atlantic to the Pacific and

from Florida to Minnesota, but attains a suitable size for lumber only in the southern and more especially in the Gulf States and is seldom used for poles.

The term juniper is commonly used by telephone men for southern white cedar; the term also is applied to red cedar. Juniper poles come from Virginia, the Carolinas, and other South Atlantic States.

Western Red Cedar is light, straight, and durable, and is one of the principal pole timbers used at present. The main sources of supply are in northern Idaho, western Washington, and British Columbia. Its durability is greatly increased by treating the butts to a point about 1 ft above the ground line with creosote. (See Preservative Treatments.) It does not have as great strength as southern pine, and it does not stand impact very well. The sapwood is somewhat subject to dry rot in certain localities.

Cypress is a large deciduous tree, occupying much of the swamp and overflow land along the coast and rivers of the southern states. Cypress is usually considered a durable wood, and the heartwood is, in fact, one of the most durable of our native species. The sapwood, however, decays quickly, and this seriously weakens the pole. The width of the sapwood on pole-size trees is from 3/4 to 1 1/4 in. Cypress frequently is too large for use as a pole and has greater value for lumber. Even when its general diameter is small enough the butt will often be so big that it adds too much weight.

Southern Yellow Pine is a trade term covering the longleaf, shortleaf, loblolly, slash, and pond pines. These species are strong, straight, and symmetrical, but are subject to quick decay in the form of poles unless treated with preservative throughout their length. There is a plentiful supply of these pines, and they easily reproduce, with rapid growth.

Longleaf Pine is a large tree which forms extensive forests and furnishes the hardest and strongest pine lumber in the market. Coast region from North Carolina to Texas. The longleaf pine is strikingly heavy, hard, and resinous, and usually very regular and narrow ringed, showing little sapwood, and differing in this respect from the shortleaf pine and loblolly pine, which usually have wider rings and more sapwood, the latter excelling in that respect.

Shortleaf Pine resembles loblolly pine; often approaches in its wood the Norway pine. The common lumber pine of Missouri and Arkansas, North Carolina to Texas and Missouri.

Loblolly Pine is a large tree; it forms extensive forests; wider-ringed, coarser, lighter, softer, with more sapwood than the longleaf pine, but the two often confounded. This is the common lumber pine from Virginia to South Carolina and is found extensively in the southern states, from Virginia to Texas.

Norway Pine is a large tree; it never forms forests; usually scattered or in small groves, together with white pine; largely sapwood and hence not durable. Minnesota to Michigan; also in New England to Pennsylvania. The Norway pine, which may be confounded with the shortleaf pine, can be distinguished by being much lighter and softer. It may also, but more rarely, be confounded with heavier white pine, but for the sharper definition of the annual ring, weight, and hardness.

Western Yellow Pine is used for poles to a limited extent in certain parts of the Southwest, where the high cost of more durable pole timbers makes it necessary to find a cheaper substitute. The life of this timber, untreated, is very short. In the upper part of the San Joaquin Valley of California, where a study of this species was made, untreated pine

poles last only two or three years; but since the wood when not exposed to the soil is fairly durable, it is believed that a butt treatment with a good wood preservative will result in a pole that will give good service. A butt-treated pine pole costs considerably less than an untreated cedar pole in this locality.

Lodgepole Pine is cut to a limited extent for poles. It grows at high altitudes in the Rocky Mountains. It decays quickly in contact with the soil, but is durable when not so exposed. The tree grows tall and straight, with very little taper, and makes a well-shaped pole. In certain parts of the West, where there are large bodies of fire-killed lodgepole that remain standing for many years, sound and thoroughly seasoned, conditions for effective treatment are excellent. If given a butt treatment, this dead timber makes a durable pole, and in many localities the cost of the pine pole plus the cost of the treatment is less than that of the Idaho cedar untreated. The sapwood of pole-sized timber may be an inch or an inch and a quarter thick.

Douglas Fir is a conifer found largely in the North Pacific coast region and principally in Oregon. It is light, strong, and straight grained. It is very durable when not in contact with the soil and therefore particularly adapted for use as cross-arms.

Terms Describing Part of a Pole

Knots are the heartwood of branches extending transversely through the sapwood of the trunk outwardly from the central heartwood.

Annular Rings are the concentric rings added yearly under the bark as the tree grows. Each ring is composed of two rings called respectively spring wood and summer wood.

Spring Wood and Summer Wood are differentiated by their density and color. The spring wood is relatively porous and usually is light in color; the summer wood is denser and darker in color. In conifers the summer wood is a reddish yellow on account of its resin content. In most woods the summer wood is thinner than the spring wood.

Pith. The pith of a tree is the central core about which the annual rings are formed. It goes through the tree from top to bottom and branches into the limbs. The pith is quite thick, usually $^1/_8$ to $^1/_5$ in. in Norway pine and in the southern species, though much less so in white pine, and is very thin, $^1/_{15}$ to $^1/_{25}$ in., in cypress, cedar, and larch. The pith of the tree is the weakest part on account of the many knots which it invariably and necessarily contains.

Sapwood. The sapwood of a tree is a zone of wood next to the bark, 1 to 3 or more inches wide and containing 30 to 50 or more annular rings (in coniferous trees). It is of lighter color than the inner, darker part of the log which is the heartwood. Sapwood changes to heartwood as the tree grows.

The width of the sapwood is small for longleaf and white pine and great for loblolly and Norway pines. In old trees of longleaf pine the sapwood forms about 40 per cent of the merchantable log, in the loblolly and in all young (coniferous) trees the bulk of the wood is sapwood.

Sapwood, being the normal condition of the outer rings of a tree, is not a "defect" in poles, where the whole cross-section of the tree (except bark) is used. Being weaker and more liable to decay it is considered a "defect" in pins and cross-arms, which are better if made from the heartwood only.

Defects in Wood Used for Poles and Cross-arms

The following are the defects in timber which are frequently referred to in specifications for poles and cross-arms.

Cup-shakes. These are cracks extending circumferentially at one or more places, caused by the separation of the annual rings.

Dote. This is a speckled stain found in beech, American oak, and other timber, due to incipient decay. It is produced by imperfect seasoning or by exposure for a long period to a stagnant atmosphere.

Heart-shakes. These are splits or clefts occurring in the center of the tree. They are common in nearly every variety of timber and are very serious when they twist in the length, as they interfere with the conversion of the tree into boards or scantlings. They sometimes divide the log in two for a few feet from the end.

Star-shakes. When several heart-shakes occur in one tree they are called star-shakes from the appearance produced by their radiation from the center.

Wind Cracks. Shakes or splits on the sides of a balk (a log which has been squared off) of timber, caused by shrinkage of the exterior surface, are called wind cracks.

Dry Rot. Dry rot is a special form of decay in timber caused by the growth of a fungus which spreads over the surface like a close network of threads, white, yellow, or brown, and causes the inside to perish and crumble. Causes which render timber favorable to the

growth of this fungus are: large proportion of sapwood; felled at wrong season when full of sap; cutting down in the spring or fall of the year instead of in midwinter or midsummer, when the sap is at rest; stacked for seasoning without sufficient air spaces being left; fixed before thoroughly seasoned; painted or varnished while containing moisture. (Six preceding definitions from Carpentry and Joinery, by Paul N. Hasluck.)

Sound Knot. A sound knot is one which is solid across its face and as hard as the wood surrounding it; it may be either red or black, and is so fixed by growth or position that it will retain its place in the piece.

Loose Knot. A loose knot is one not firmly held in place by growth or position.

Pith Knot. A pith knot is a sound knot with a pith hole not more than $^1/_4$ in. in diameter at the center.

Encased Knot. An encased knot is one which is surrounded wholly or in part by bark or pitch. Where the encasement is less than $^1/_8$ in. in width on both sides, not exceeding one-half the circumference of the knot, it shall be considered a sound knot.

Rotten Knot. A rotten knot is one not as hard as the wood it is in.

Pin Knot. A pin knot is a sound knot not over 2 in. in diameter.

Spike Knot. A spike knot is one sawn in a lengthwise direction. The mean or average width shall be considered in measuring these knots.

Pitch Pocket. A pitch pocket is an opening between the grain of the wood containing more or less pitch or bark.

Pitch Streak. A pitch streak is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well defined streak, or where the fiber between grains—that is, the coarse-grained fiber, usually termed " spring wood "—is not saturated with pitch, it shall not be considered a defect.

Wane. Wane is bark, or lack of wood from any cause, on edges of timber.

Shakes. Shakes are splits in timber which usually cause a separation of the wood between annual rings.

Checks. Checks are splits in timber which usually cause a separation of the wood across annual rings. (Last twelve definitions are those used in the timber-test work of the Forest Service in describing defects. *Forest Service Circular 88*, Revised.)

Wind-shake. A crack or incoherence in timber produced by violent winds while the timber was growing.

Wind. A turn or bend. A piece of timber is out of wind when it is perfectly straight or flat.

Warped. Twisted out of shape by seasoning.

Cat-faces. Old wounds, partially overgrown, leaving a long, narrow, dead surface exposed.

Insect Damage is caused by the boring of various insects and is indicated by small holes or bumps on the pole surface.

Crook is an offset in the axis of the pole. The axis above the crook may be parallel to, coincident with, the axis below the crook, or it may be curved.

Sweep is produced by a curving axis. It may be in one plane and one direction, or in two planes (double sweep), or in two directions in one plane (reverse sweep).

Volume and Weight of Poles

A quick way to find the approximate volume of a pole is to multiply the area of the circle at the center of gravity by the length of the pole. The formula for the volume, considering a pole as a frustum of a cone, is

$$v = \frac{\pi}{1728}(d_1^2 + d_1d_2 + d_2^2)h \tag{38}$$

where v = volume in cubic feet; d_1 = diameter at butt in inches; d_2 = diameter at top in inches; h = length of pole in feet.

The weight of a pole may be found by multiplying its volume in cubic feet by its weight per cubic foot. Table VIII gives the weight per cubic foot.

Seasoning

Poles of chestnut and cedar should be seasoned because it increases their resistance to decay, increases their strength, and decreases their weight. The strength of partially seasoned timber, other things being equal, increases as the amount of moisture it contains decreases. Thoroughly seasoned timber of small sizes is sometimes three or even four times as strong as the same timber when green.

Seasoning of poles reduces their weight, commonly from 16 to 30 per cent, and even more for some species, with a corresponding decrease in the cost of transportation. Thor-

Table VIII. Weight per Cubic Foot of Poles

Kind of Pole	When Cut		When Seasoned	
	Weight,* pounds per cubic foot	Moisture, per cent of dry weight	Weight,* pounds per cubic foot	Moisture, per cent of dry weight
Southern white cedar	38.9	88	25.0	21
Chestnut (N. C.)	56.5	101	43.2	54
Chestnut (N. J.)	51.8	85	42.2	50
Chestnut (Pa.)	54.0	92	40.7	45
Chestnut (Md.)	56.4	86	44.9	48
Northern white cedar	34.2	90	22.9	27
Western red cedar	42.4	133	23.5	29
Western yellow pine	66.6	154	30.3	16

* Including contained moisture.

ough seasoning is essential if the poles are to be treated with preservatives. The percentage of moisture in a pole when cut varies with the season when cut as shown in Table IX.

In general, poles cut during the spring and summer lose weight most rapidly. Poles cut during autumn and winter lose weight less rapidly, but more regularly. Too rapid seasoning may be detrimental to the timber by causing excessive checking. Shrinkage of poles during seasoning is very slight and does not exceed 1 per cent on the circumference.

Table IX. Moisture Content When Cut, Percentage of Dry Weight

Kind of Pole	Spring	Summer	Autumn	Winter
Southern white cedar (N. C.)	68	77	87	88
Chestnut (N. C.)	97	91	95	101
Chestnut (N. J.)	81	83	81	85
Chestnut (Pa.)	89	92	88	88
Chestnut (Md.)	83	84	85	86
Northern white cedar (Mich.)	77	82	79	90
Western red cedar (Cal.)	...	133	...	...
Western yellow pine (Cal.)	149	147	145	154
Southern yellow pine	...	52	...	...

The time in months required for poles cut at different periods of the year to season to approximately air-dry weight is given in Table X.

Table X. Time Required for Seasoning

Kind of Pole	Spring	Summer	Autumn	Winter	Moisture Content * Seasoned
	Months	Months	Months	Months	Per cent
Chestnut (Md.)	5	4	8	7	55
Southern white cedar (N. C.)	3	3	8	5	26
Northern white cedar (Mich.)	12	9	7	6	37
Western red cedar (Cal.)	..	..	..	..	43
Western yellow pine (Cal.)	5	3	9	6	25

* The average amount of moisture remaining in the poles after seasoning as above in percentage of the weight of the dry wood.

Roofing

If the top of the pole is left flat, rainwater will more easily penetrate the top of the pole, following the grain, causing early decay of the pole top. Poles are accordingly "roofed" by cutting the top to form an inclined surface. Either a single cut is made at an angle of 15 to 30 deg, or two such planes at an angle of 30 to 45 deg are cut to meet in a horizontal ridge. Roofs are sometimes painted, or coated with a bituminous substance, or covered with zinc, lead, or copper caps.

Preservative Treatments

Practically all wood species when used as poles are subject to decay either where in contact with the earth or throughout the length of the pole. Untreated cypress, pine, and juniper poles last only from 5 to 10 years; untreated cedar and chestnut poles last from 15 to 20 years under favorable conditions. Very few reliable data are available to

show the full value of preservative treatments in prolonging the life of poles. Pole service records available do show, however, that increases in life of at least 10 years, on the average, may be expected as a result of the best preservative treatments. From an economic standpoint such treatments are justifiable since they result in:

1. Increase of pole life.
2. Possibility of using smaller poles, as less allowance need be made for decay.
3. Possibility of using wood species not naturally durable.

Cedar and chestnut poles decay mainly in contact with soil, and therefore the butt trearment method is principally used for those species. The pines are subject to decay throughout their length, and therefore must be full length treated. Poles should not be painted with oil paints as these prevent evaporation of moisture and promote decay.

Cause of the Decay of Timber. Decay of wood is due to low forms of plant life called fungi. The germs of decay are not inherent in the wood. The wood-destroying fungi start from the outside, either from adjacent rotten wood or by spores, which correspond to seeds, being carried by the wind and deposited on the surface. While the fungi from these spores begin at the " surface " of the wood, this surface must be understood to include all holes or cracks which the spores may enter.

Fungi require for their growth and development air, heat, moisture, and food. Warmth, preferably between 60 and 100 deg fahr, favors decay. Cold retards it, and temperatures above 150 deg fahr prevent it. Under water or deep under the surface of the ground where the air is excluded, decay does not take place. Ordinarily wood which is seasoned until it is air-dry does not contain sufficient moisture to support the growth of fungi.

Preservatives. The best method of checking the growth of fungi is to poison their food, which is the wood itself. Such poisonous substances are called preservatives and are injected into the wood by various methods. Only two preservatives are extensively employed in the United States at the present time. These are creosote and zinc chloride. The latter is mainly used for preserving lumber, seldom for poles or cross-arms. Carbolineum, coal-tar solution, and crude petroleum have a limited application. Solutions of various arsenic salts have also been used, but their value has not been fully determined.

Creosote Oil is a distillation by-product of coal tar and is produced in the manufacture of coke and illuminating gas. It is sometimes known as dead oil of coal tar. The American Wood-Preservers' Association has specifications for three grades of creosote oil. That known as Grade 1 is mainly used in the preservation of poles. Creosote is a mixture of chemical compounds and consists principally of liquid and solid aromatic hydrocarbons, tar acids, and tar bases. It has a specific gravity of not less than 1.03, and it has a continuous boiling range from 200 to 325 deg cent. In Grade 1 creosote oil the amount of residue at several distillation temperatures is strictly limited. It is believed that oils boiling below 200 deg cent will not remain in the wood to preserve it, but that the fractions above 200 deg cent are admirably suited to the purpose.

Zinc Chloride is the zinc salt of hydrochloric acid. Wood preservative treatment with this salt is accomplished by either the pressure-tank process or by soaking the wood. Either method uses a water solution of the salt, the solution generally being not above 5 per cent in concentration. Since the salt is water-soluble it is subject to leaching if the wood becomes wet. Such leaching, of course, quickly reduces the preservative effect. Therefore, wood treated with zinc chloride should be used only in dry locations such as building interiors. For some preservative purposes zinc chloride is mixed with creosote or gas tar distillate or solution.

Carbolineum, like creosote, is derived from the distillation of coal tar but at higher distillation temperatures. It has good preservative properties but is somewhat more expensive than creosote.

Water-gas Tar is a by-product in the manufacture of water-gas and is somewhat similar to the tar obtained in the manufacture of coal gas. The oil obtained by the distillation of water-gas is known as **water-gas tar distillate** and is quite similar to creosote oil, although its toxic properties are not considered as great as those of creosote. A mixture of 60 per cent of the distillate with 40 per cent of refined or filtered water-gas tar is known as **water-gas tar solution.**

METHODS OF TREATMENT. The methods of applying the preservatives to the pole are the brush treatment, open-tank treatment, and pressure-tank treatment.

The brush treatment is applied to a part of the butt at the ground line, the open-tank treatment to the whole butt, and the pressure-tank treatment to the whole pole.

The brush treatment is least expensive and gives the least protection and the pressure tank is most expensive and gives the most protection.

Open-tank Treatment is used for poles which are durable except where in contact with the soil. It is used mainly for cedar and chestnut poles. In order to promote the penetration of the preservative the section of the pole to be treated is usually incised.

The wood is punctured by machines in a definite pattern of short, narrow incisions to a depth of $^3/_8$ to $^1/_2$ in. The butts of the poles are immersed in creosote oil at a temperature of about 230 deg fahr for not less than 6 hours. The depth of immersion is at least 1 ft more than the height of the ground line above the butt end. After the hot bath the butts are immersed in a cold creosote bath to the same depth. The temperature of the cold bath is not allowed to exceed 150 deg fahr. The length of time in the cold bath must not be less than 2 hours. All the outer bark and practically all the inner bark must be removed before the treatment.

Pressure Treatment is used for all poles, such as pine, which decay quickly even in the above-ground section. It is a full-length treatment, in which small cars are loaded with poles and run into horizontal cylinders which may be made pressure-tight. Pressure treatments are classified as full-cell and empty-cell processes. In the full-cell process the wood cells are left practically full of preservative at the end of the treatment. In the empty-cell process the wood cells are practically emptied of preservative before the completion of the treatment.

In the full-cell process the poles are subjected first to a vacuum to draw out as much moisture as is practicable, then without breaking the vacuum the preservative is introduced into the tank at a temperature between 165 and 200 deg fahr. The pressure is then raised to 100 lb per sq in. or more and maintained until the maximum penetration and injection which are practicable has been obtained. Lastly the tank is quickly drained of preservative and a quick high vacuum applied to remove the preservative from the surface of the poles. The net final retention of preservative is usually specified at from 10 to 20 lb per cu ft of pole volume. To insure long life of the pole, the entire sapwood content should be penetrated by preservative.

In the Reuping empty-cell process, air pressure is applied of sufficient amount to assist properly in the final emptying of the wood cells. Following the application of the air pressure, and without reducing it, the preservative is introduced into the tank at a temperature between 165 and 200 deg fahr and under sufficient pressure to obtain the desired penetration. After the pressure application is completed the cylinder is quickly drained and a vacuum is applied and maintained until the net retention of preservative is reduced to the specified amount. In the Lowry empty-cell process the application of initial air pressure is omitted, thus permitting lower pressures while the preservative is in the cylinder; however, higher vacuum is needed at the end to remove the excess preservative. The net final retention of preservative is usually specified as from 6 to 10 lb per cu ft of pole volume. Complete penetration of the sapwood is also desirable in this process. It should be noted that in all these pressure processes excessive temperatures, pressures, and vacuums tend to injure the timber.

Specifications for Poles

The American Standards Association has prepared specifications covering dimensions and quality of timber for pole use. These specifications are widely used, although individual purchasers often prepare their own. Space does not permit the incorporation of these specifications here.

Forces Acting on a Pole

A pole is subject to the following forces:

1. Vertical forces due to weight of pole, wires, sleet, etc., and to downward pull of guys.
2. Lateral horizontal forces due to wind across line on pole, wire, sleet, etc.
3. Longitudinal horizontal forces due to unbalanced pull of wires.
4. Torsional forces due to unbalanced pull of wires.

A pole is strong as regards the vertical forces but weak for horizontal forces, and the cross-arms are weak for the torsional forces. The theory of good line work is, therefore, first to reduce the horizontal and torsional forces as much as possible by balancing the stresses, and second to convert remaining unbalanced horizontal stresses into vertical stresses on the pole by the use of guys.

In practice the lateral horizontal force of the wind is one which cannot ordinarily be provided for by guys. Calculations for strength of poles, when made, are ordinarily limited to the effect of side wind.

BREAKING OF POLE BY CROSS WIND. The principal forces tending to break a pole are wind pressures on pole and conductors when the wind blows transversely. These tend to break it by cross bending.

Let M_1 = moment of the wind on the pole.
M_2 = moment of the wind on the wires.
M = moment of resistance of the pole.

Then the condition that the pole shall not break is that

$$M_1 + M_2 < M \tag{39}$$

The calculation of M_1, M_2, and M is given below.

Moment of Wind on Pole (M_1). Moment at ground level due to wind pressure on pole is

$$M_1 = \frac{P_1 H_1^2(D_1 + 2D_2)}{72} \tag{40}$$

M_1 = moment at the ground in pound-feet.
P_1 = wind pressure in pounds per square foot of projected area of pole.
H_1 = height of pole in feet.
D_1 = diameter of pole at ground in inches.
D_2 = diameter of pole at top in inches.

The maximum bending moment due to horizontal forces at the top of the pole is ordinarily assumed to be at the ground level; it is really a little below ground level and opposite the center of pressure of resistance furnished by the ground.

Moment of Wind on Wires (M_2). Moment at ground level due to wind pressure on the wires is

$$M_2 = \frac{P_2 H_2 nd(S_1 + S_2)}{24} \tag{41}$$

M_2 = moment at the ground in pound-feet.
P_2 = wind pressure in pounds per square foot of projected area of wires.
H_2 = height of wires above ground in feet.
n = number of wires.
d = diameter of wires (including ice) in inches.
S_1 and S_2 = lengths of adjacent spans in feet.

Where wires are of different diameters or at different levels the formula is to be applied to each size and each level separately and moments summed.

¶ American Standards Association.

Moment of Resistance (M). The moment of resistance or strength of a circular pole for bending as a cantilever is

$$M = 0.000264 fC^3 \tag{42}$$

M = maximum allowable moment of resistance at the ground line, in pound-feet.
f = maximum allowable fiber stress, in pounds per square inch.
C = circumference of the pole at the ground line, in inches.

Fiber Stress (f) and Actual Tests of Strength. Table XI gives the value of the fiber stress for various kinds of timber and the actual breaking load from tests of a number of poles.

Weakest Point of a Pole. A pole is approximately a truncated cone in shape. For a bending force applied at one end such a cone is weakest at the point where the diameter is $^3/_2$ the diameter at the point (near the small end) where the force is applied. A pole with 8-in. diameter at the cross-arm is, therefore, weakest where it is 12 in. in diameter and may be expected to break at this point provided this point is above the place where maximum bending occurs. If it is less than 12 in. in diameter at the point of maximum bending then the break may be expected here. This rule must be considered approximate as it neglects the fact that the pole is not homogeneous, i.e., outer annual rings are sapwood and inner are heartwood, and also neglects effect of knots, etc. In practical working calculations the weakest section is taken at the ground line, since that point tends to become weaker than any point above ground as a result of its greater moisture content and because of its greater tendency to decay.

STRESS DUE TO ANGLE IN LINE. If there is an angle in the line an additional stress is imposed upon the supporting structure at the angle point due to the tensions in the conductors. If the conductors in the adjacent spans have equal tensions (t) and the angle of departure of the line is (a), the resultant force on the structure will be:

$$F = 2\,t \sin \frac{a}{2} \text{ pounds} \tag{43}$$

and the angle between the direction of the resultant and the direction of either span will be: 90 deg $- \frac{a}{2}$. If the tensions in the adjacent spans are not equal the resultant force will be:

$$F = \sqrt{t_1^2 + t_2^2 - 2\,t_1 t_2 \cos a} \tag{44}$$

and the angle (b) between the resultant and the span in which the tension is (t) is obtained from:

$$\cos b = \frac{F^2 + t_1^2 - t_2^2}{2\,Ft_1} \tag{45}$$

Attachment of Cross-arms to Poles

Wooden cross-arms are attached to wooden poles:

1. By gaining the pole, see below.
2. By one or two bolts.
3. By one or two cross-arm braces.

The forces at the point of attachment which these fastenings must resist are:

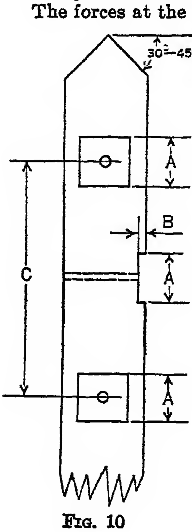

FIG. 10

1. A force vertically downward, equal to weight of cross-arm, pins, insulators, and wire (including sleet).
2. A horizontal force parallel to axis of arm, equal to pressure of wind blowing across line on wires.
3. A horizontal force at right angles to axis of arm: (a) toward pole or (b) away from pole and equal to difference in pull of wires on two sides of arm.
4. A couple in a vertical plane parallel to arm, equal to difference in moments of weight on the two ends of arm.
5. A couple in a horizontal plane parallel to arm, equal to difference in moments of wire pull on the two ends of arm.
6. A couple in a vertical plane at right angles to arm, equal to difference in moments of wire pull (caused by pin leverage) in the two directions.

GAINING. A gain is a notch cut in the side of a pole to receive a cross-arm. The width (vertical dimension) of the gain should be just large enough for the cross-arm. The depth of gain varies from $^1/_2$ to 1 in. With gains shallower than $^1/_2$ in. the cross-arm has insufficient support below and the flat bearing surface at the back is inadequate unless the pole is of larger diameter than usual. Deep gains greatly weaken the top of the pole especially when double arms are used. Poles which require full-length preservative treatment should be drilled, gained, and roofed completely before treatment.

Cross-arm Construction

On ordinary straight-line construction single cross-arms are generally used. If conductors are carried at more than one level a single arm is used at each level and all cross-arms are placed on the same side of the pole. If the pole has any sweep the arms are placed on the concave side to leave the convex side clear for climbing. At four-way corners single arms are used with alternate arms at right angles to each other. At two-way corners, dead-ends, angles, and where the line stresses are not balanced longitudinally, double arms are used. In alleys and at other places to avoid obstructions, alley arms are often used.

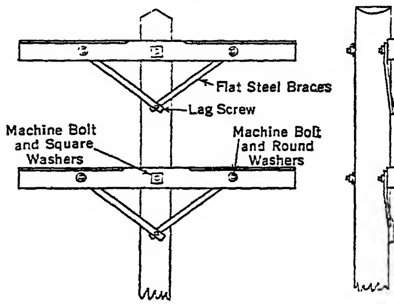

Fig. 11

The size of cross-arms depends on the size of conductors carried and upon the voltage of the circuits. The spacing of arms depends upon the voltage of the circuits carried and upon the length of spans.

The accompanying figures show various types of wood pole construction. Fig. 11 shows single-arm construction for low- and medium-voltage lines. Fig. 12 is an example of double-arm construction at a dead-end in the line. Fig. 13 shows typical construction for a four-way corner. Fig. 14 is an example of alley-arm construction. Fig. 15 shows a typical medium-voltage transmission line pole for straight line construction using suspension insulators. Fig. 16 is the type of construction sometimes employed for corners on single-circuit transmission lines. Two poles of this type are sometimes used for corners in double-circuit lines of vertical configuration. Fig. 17 is an example of construction largely used with single circuit wood pole transmission lines of high voltage.

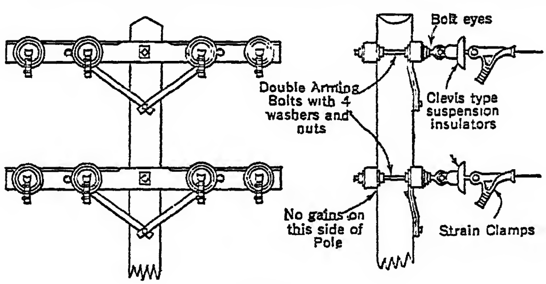

Fig. 12

Hardware

Hardware for wood pole lines is usually of steel which is hot-dip galvanized. The N.E.L.A. has prepared specifications, covering material, dimensions, and galvanizing, for the commonest items of hardware. Specifications of the A.S.T.M. also cover material and galvanizing. Hardware items include: machine bolts, double-arming bolts, lag screws, square and round washers, eye bolts, clevises, guy plates, hooks and shims, hub plates, pole steps, and cross-arm braces. Most items are manufactured in a wide range of sizes to cover the varied conditions to be met in wood pole construction. Wood braces with steel connectors are often used on transmission lines to minimize phase-to-phase flashovers.

Setting Poles

Table XII gives the average depth of setting recommended by the National Electrical Safety Code. In soft or swampy soil, poles should be braced by cribs or swamp braces and guyed if necessary. Unguyed poles at angles in the line should be set from 6 in. to a ft deeper.

In ordinary firm soil pole holes are dug by hand, using digging bars and long-handled, spoon-shaped shovels, or by hole-digging machines. Such digging machines are earth

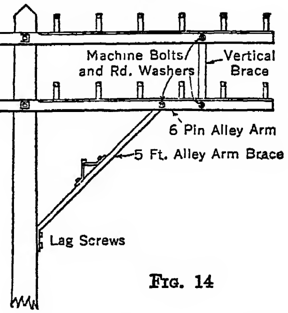

FIG. 14

50	7.0	4.5	..	...	...

augers driven by gasoline engines and mounted on trucks, trailers, or tractors. The motive power of the truck or tractor is generally used to drive the auger. Caterpillar tractors are especially suitable for this work in rural territory as they are able to travel over uneven or soft ground without difficulty. Pole holes should be the same diameter at the top as at the bottom and should be only enough larger than the pole butt to allow the use of tamping bars to tamp the backfill thoroughly around the pole.

In swampy soil or quicksand a barrel or split caisson is required to prevent the sides of the hole from caving in. As the hole is dug, the barrel or caisson is gradually pushed down; the barrel may be left in the hole after the pole is set, but the caisson may be withdrawn to be used again. Another successful method employs a high-pressure water jet. In this method the hole is started with shovels and the pole is set up in position and held by hand lines. A hose with a long pipe nozzle is laid alongside the pole, and the water under high pressure is started. The jet loosens the soil and brings it to the surface in suspension. By reason of its weight the pole drops slowly into the hole. Eighty-foot poles have been set 40 ft deep by this method in extremely deep marshes.

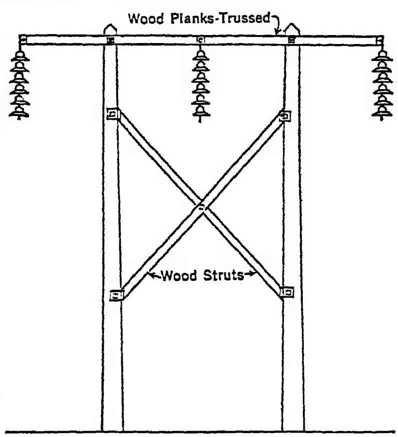

Fig. 17

Explosives are often used for setting poles in soft or sandy soils, or in rock. In soft soils a charge of dynamite is laid at the bottom of a small pipe driven to the required depth of hole. The pipe is then withdrawn and the pole is set on the surface directly over the charge and held upright by hand lines. When the charge is exploded the pole drops into the hole and the soil drops back around the pole. When the pole is to be set in rock a small hole is drilled to the required depth and the charge laid at the bottom. The small hole is backfilled and tamped. Firing the charge opens a hole to take the pole. Experience in such work is necessary to determine the size of charge and the proper depth to open a hole no larger than necessary for the pole.

A pole may be raised and set in the hole by a hoisting rig such as a gin pole or a derrick mounted on a truck or tractor. Poles may be set by three to five men using pike poles. After the pole is set in the hole it is supported in proper position by pike poles while the backfill is made and tamped.

Guying of Poles

Whenever a pole is not strong enough to withstand the bending stresses imposed on it by unbalanced forces it should be guyed. Guys should be strong enough to take the entire stress in the direction in which they act, the pole acting only as a strut. Guys consist usually of stranded steel wires, together with means of attaching to poles and anchors, and also include strain insulators where they are required.

STRESSES IN GUYS AND ANCHORS. To compute the tension in a guy wire use the formula:

$$T = \frac{M}{H \sin a} \text{ pounds tension} \tag{46}$$

where M is the bending moment applied to the pole in the plane containing the pole and

the guy, in pound-feet; H is the height above ground of the point of attachment of the guy to the pole in feet; a is the angle which the guy makes with the vertical.

GUY WIRE. Stranded steel wires used for guys are usually heavily galvanized, but in locations where corrosion is excessive stranded copper-clad steel wires are often used. Mild steel is common for lightly loaded lines, but Siemens-Martin or high-strength steel is used for many important or heavily loaded lines. Table XIII gives the characteristics of various types of guy wires.

Table XIII. Mechanical Characteristics of Stranded Steel Cables

Nominal Size, in.	Diameter, in.	Area, sq in.	Breaking Load, lb		
			Ordinary	Siemens-Martin	High-strength
5/8	0.625	0.2356	12,720	15,900	26,500

ATTACHMENT TO POLES AND ANCHORS. Guys are attached to poles by wrapping the end of the wire twice or more around the pole and clamping the free end to the main part of the guy by means of one or more guy clamps. Steel shims or plates are placed between the wrappings of the guy wire and the pole. Steel hooks are also used to prevent the guy from slipping down the pole. Hooks, shims, and plates are attached to the pole by nails or lag screws. An alternative method is to attach the guy wire to an eye-bolt or patented attaching device which is bolted through the pole. Anchors sunk in the ground are provided with long anchor rods extending slightly above the ground surface and terminating in an eye. The free end of the guy is passed through the eye of the anchor rod, bent back parallel to the main portion of the guy, and clamped to it. The loop is protected by a guy thimble where it bears on the anchor rod eye.

STRAIN INSULATORS. Strain insulators are placed in guys to prevent the lower part of the guy from becoming electrically energized by contact of the upper part of the guy with conductors or by leakage. Two strain insulators are used whenever a single insulator would not effectively prevent a hazard to the public or to linemen. No guy insulator should be located less than 8 ft from the ground. Insulators are not necessary where no part of the guy is within 8 ft from the ground or where the guy is permanently and effectively grounded.

Two types of strain insulators are used. One type is made of porcelain and the other is of wood with steel connecting parts. Porcelain insulators are usually designed so that the porcelain is in compression with the guy wire interlinked. In this type the porcelain may fail and allow the guy wire loops to come together, making the insulation ineffective without a mechanical failure of the guy. Such insulators are used only in connection with low- and medium-voltage lines. The National Electrical Safety Code requires guy insulators to have a mechanical strength equal to that of the guy in which they are installed, a dry flashover value of twice the line voltage, and a wet flashover not less than the line voltage. Wood insulators are now used extensively with high-voltage wood pole transmission lines. They are made of treated wood with steel connecting parts at each end and are provided with arcing horns to prevent flashovers from burning the wood. Generally the wood portion is long compared with its cross-sectional dimensions, and usually the cross-section is rectangular. The wood is used in tension, and of course a failure of the insulator causes a mechanical failure of the guy.

GUY ANCHORS AND STUBS. Guys may be anchored to the earth, to other poles, and occasionally to trees or buildings. When guys are anchored to the earth it is necessary to bury in the earth some object to which the guy is to be connected. Such an object, known as an anchor, must be so designed as to press against a sufficient volume and weight of earth to resist completely the force due to the tension in the guy. A common form of anchor is the so-called " dead-man " or log anchor. It usually consists of a log or section of a pole buried in a trench. An anchor rod is inserted through a diametrical hole bored through the middle of the log and is held in place by a plate and by nuts on the end of the rod. A transverse trench is provided running from the surface of the ground, at the proper angle with the ground surface, down to the bottom of the trench dug for the log. After the anchor is in the proper position the trenches are, of course, backfilled and tamped.

A large volume of undisturbed earth is provided for the anchorage by this method, and it is therefore useful for anchoring heavy guys.

Many forms of patented anchors are available. These are usually made of steel or malleable iron. Some are designed to screw into the earth, and some are placed or driven into small holes and afterwards expanded to increase the bearing area. Such patented anchors are made in a wide range of sizes to be used with small or large guy wires and light or heavy loads.

Guy stubs are short poles to the tops of which guys from line poles are attached when the guy is required to clear the ground by a considerable distance. An anchor guy is usually run from the top of the guy stub to the ground, in which case the stub is raked a sufficient amount so that it will act only as a strut. Sometimes guy stubs are made self-supporting by giving them considerable rake and by burying a log just below the surface of the ground and another log at the bottom of the stub on the opposite side for the stub to bear against. Fig. 18 shows a self-supporting guy stub and a common form of log anchor.

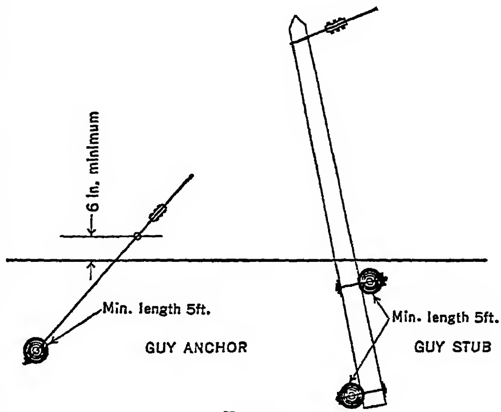

FIG. 18

Repairing Decayed Poles

If poles have been weakened at the ground line by decay the strength may be restored by cutting off the decayed butt and resetting the pole, thus reducing its height by 6 to 8 ft. If reduction of height is not permissible, the pole may be stubbed by setting along side of it a short pole or stub extending a few feet above ground to which the old pole or the undecayed part above ground is bolted or otherwise fastened. This does not look well and is unsuitable for city distribution lines but has been used for transmission lines. Another method is to reinforce the decayed pole by a sleeve of concrete (usually reinforced) extending above and below the decayed portion.

Several patented devices are also available. Some of these act as sockets for the upper portion of the pole which has been cut off at or above the ground line. Another method leaves the pole intact but T-shaped steel bars are driven into the ground close beside the pole and are clamped tightly to the pole by curved steel rods.

26. STEEL TOWERS AND POLES

Steel structures are often used instead of wood poles for supporting electrical circuits. They have the advantages over wood structures that they can be made as large as necessary and that they may be made self-supporting without the use of guys. They have the disadvantage of not having an inherent insulating value, and, therefore, when steel structures are used the line insulators must be selected with that fact in mind. They do, however, have the advantage of being less susceptible to damage by grass, brush, or forest fires.

General Features of Design

Towers are composed of two parts, the tower proper and the foundation. Towers are usually built of standard structural-steel shapes. Angles are used for most members. Channels are used for the larger members of some towers, usually the cross-arms, or for posts of flexible towers. Flat pieces are sometimes used for the minimum-sized bracing of light towers. Round rods are used for tension members in some types. The principal members of a tower are the corner posts or legs, which are vertical or approximately vertical, and are usually the heaviest members of the tower proper, and the horizontal and diagonal web members which connect the posts together in vertical planes which constitute the sides or faces of the tower.

The spread of a tower at the base is generally between one-fourth and one-fifth of the height. The greatest economy in cost of tower plus foundation usually requires a little wider base than that which gives the least cost for the tower taken alone.

Towers are usually designed for either one or two three-wire circuits, usually with one or two ground wires above and sometimes with a telephone circuit below. Where two circuits are on one tower they are generally located on opposite sides to reduce the hazard of repairing the line. (See Fig. 19.) The three wires of a circuit are occasionally arranged to form an equilateral triangular prism, but frequently lie in a single plane which is usually horizontal for single-circuit towers, and vertical for two-circuit towers. (See Figs. 20 and 21.)

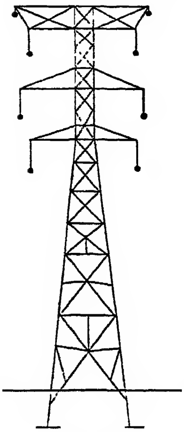

FIG. 19

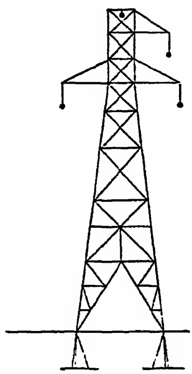

FIG. 20

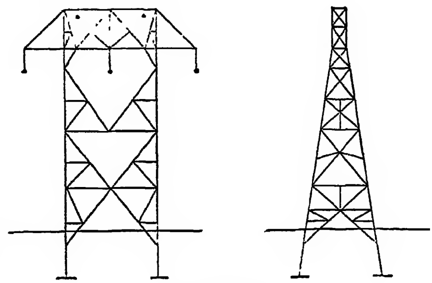

FIG. 21

Steel poles are commonly of the tubular type or of the square latticed type. Tubular poles serve mainly to support trolley conductors and feeders on city streets but latticed poles are used to support distribution lines and low- or medium-voltage transmission lines. Latticed steel poles have narrow bases; that is, the taper of the pole is small. The vertical members are usually angles and the lacing on each face is either flat steel bars or small angles with one leg turned inward. They may be designed for one or more low-voltage circuits arranged in horizontal or triangular configuration. Single-circuit high-voltage lines may be arranged in triangular configuration, but double-circuit high-voltage lines are always arranged in vertical configuration with one circuit on each side of the pole.

TYPES OF TOWERS. Two general types of towers have been used; the flexible and the rigid. Flexible towers are more or less obsolete at the present time. The general form of such a tower is a flat A-frame having good lateral strength but none in the direction of the line. Strength in that direction is usually attained by attaching a ground wire rigidly to the top of each A-frame. Such structures are not adequate for important or high-voltage lines, and they have been largely superseded by wood pole structures.

Rigid Towers are usually triangular, square, or rectangular. The square tower is probably the most common. Square towers usually have the four faces framed with the same size members (even though the stresses in the longitudinal and lateral faces rarely figure the same), because of the economy of manufacture and erection which results from the simplicity. This feature has an advantage in design in that the torsional stresses are more simply determined. Rectangular (including square) towers have the disadvantage that the unequal settlement of the foundations may produce high internal stresses not allowed for in the design. Triangular towers avoid internal stresses from unequal foundation settlement, but present difficulties in the joining of standard structural shapes, and stresses in them are difficult to calculate. (See Fig. 22.)

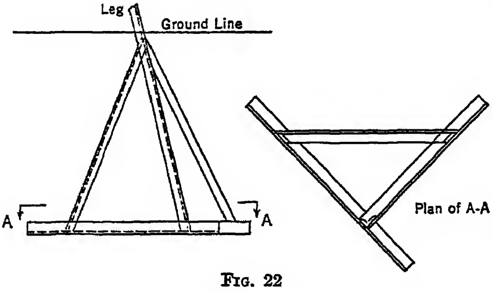

FIG. 22

CONNECTIONS OF MEMBERS. The members of a tower are usually connected by bolts. By using no rivets the members may be fabricated in quantities, compactly

bundled, easily handled even in rough country, and erected by less skillful labor; also the galvanizing can be done after all shop work is completed. All the bolts of a tower should be of one diameter ($^5/_8$ in. is suitable for the members generally used) and of as few different lengths as possible. Bolt holes should be slightly larger than the bolts ($^1/_{16}$ in. is a usual amount). By designing bolted connections so that friction between the surfaces develops the full compressive strength of members, the play in the bolt holes with changing compression and tension in the members is eliminated.

If the unit shearing stress is made two-thirds of the unit tensile stress in the members connected, and the unit bearing stress is made twice the unit shearing stress, a bolted connection will be not less than 10 per cent stronger than the members connected.

CLEARANCE BETWEEN CONDUCTORS AND TOWER. Clearance from conductor to tower is usually based on that existing at maximum sideswing of the insulator string, toward the tower members, due to wind pressure on the conductors. The sideswing is usually taken at 60 deg, but sometimes, under favorable conditions, at only 45 deg from the vertical. The sideswing should be calculated for maximum wind pressure both with and without ice. Reduced clearance of the conductor itself from the corners of the tower should also be considered. The angle of swing will be greater for small or light-weight conductors than for large or heavy ones. Clearance from the cross-arm should be considered as well as from the vertical portion of the tower. If arcing rings or arc-suppressing devices are used on insulator strings, clearances from their live parts should be determined. Flashovers ordinarily are due to lightning potentials impressed on the conductors; therefore, arcing distances should be selected on the basis of the characteristics of impulse flashovers. The flashover distance to the tower, through air, should be at least 10 per cent greater than that over the insulator string, with its protective equipment, if any.

FOUNDATIONS FOR TOWERS. Structural steel, mass (unreinforced) concrete, reinforced concrete, or piles may be used for tower foundations. Rock footings are also used in special locations.

Structural-steel Foundations are cheap and easily transported. They usually consist consist of grillages of structural-steel I-beams with tie members consisting of I-beams or channels. (See Fig. 23.) These grillages are either buried at a proper depth in the earth

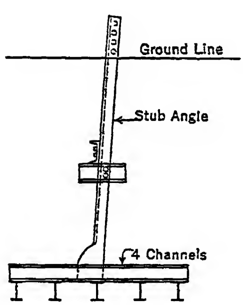

FIG. 23

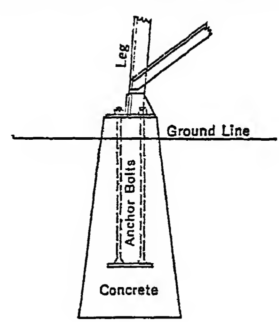

FIG. 24

or surrounded by a mass of concrete. They should have sufficient horizontal area so that they will have adequate bearing surface to withstand downward pressures and carry sufficient of earth to withstand possible uplift forces. The corner leg members are usually carried down to the grillage and connected to it in a proper manner to transmit the vertical and horizontal stresses involved.

Concrete Foundations have an advantage over structural steel in that they can more easily be varied in depth, spread, etc., to accommodate themselves to local conditions of soil. This is especially advantageous where boulders or irregular ledges interfere with the use of a standard-sized foundation. (See Fig. 24.)

Mass-concrete foundations are advantageous in those cases where it is necessary or desirable to have a foundation of such weight as to withstand much uplift with little reliance on the holding power of the earth. The towers may be conveniently attached to anchor bolts imbedded in the foundation, or the leg member may extend down to the bottom of the concrete. To avoid tension in the concrete the bolts must extend to the bottom, with proper plates for distributing the stress. The anchor bolts and plates then become a crude system of reinforcement.

Reinforced concrete foundations are durable and require less material than mass concrete, thereby facilitating transportation.

Piles are used under or for foundations in very marshy ground where the holding power of other foundations is unreliable.

Rock Footings for towers standing on ledges may consist of anchor bolts grouted into holes drilled in rock and extending through level bearing plates grouted to the rough rock surface at the proper elevation.

Forces Acting on Towers

The stresses in towers are caused by: (1) the weight of tower, insulators, clamps, cables (conductors, ground wires, telephone wires) and ice loads on them; (2) the wind pressure on above;* (3) the unbalanced tension in cables when dead ended or broken on one side; (4) the unbalanced resultant due to cable tension at angles in the line; (5) the loads imposed when erecting towers, stringing wire, or repairing line.

A careful study should be made of all the combinations of these loads which are possible or probable. Often no single combination can be found which will produce the maximum stress in all tower members, and therefore several combinations must be used to determine the design.

In a square anchor tower carrying six wires, three on each side, the maximum stress may be expected in the corner posts when all six wires are pulling in the same direction; the maximum stress in the web members will probably be produced by three wires pulling on one side in one direction and the three on the other side in the opposite direction. In the first case the tower is subject to a bending stress and in the second to a torsional stress. In each case the stresses due to weight and wind are to be superimposed. The wind may act as a force along the line or across the line, but generally its longitudinal effect is negligible while its lateral effect is important.

STRESSES IN TOWER MEMBERS.—The stresses in the several members of a tower are usually determined graphically from the assumed loadings by means of stress diagrams; see section on Trusses in Kent's Handbook for Mechanical Engineers. In most designs the distribution of stress is not fully determinate.

Fundamental Assumptions. Certain assumptions are, however, commonly made which give a determinate distribution for the purposes of design. Among these assumptions are:

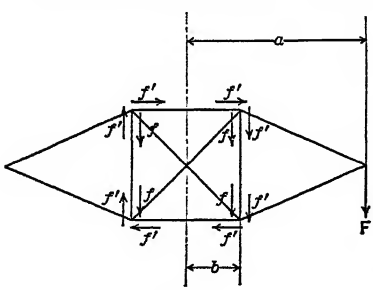

FIG. 25

1. An unbalanced stress on the tower (say a broken wire pulling on one side) can be resolved into an equal stress at the axis of the tower and a torsional moment.
2. The equivalent stress at the axis of a rectangular tower can be considered as balanced between the two faces parallel with it, each face taking one-half the stress.
3. The torsional moment can be considered as divided between all four faces of a rectangular tower.
4. If the tower is square each face takes one-fourth of the torsion.

The above relations may be expressed as follows (see Fig. 25):

Let F = unbalanced force in pounds applied at end of cross-arm.

a = distance, in feet, from *end of cross-arm* to axis of tower.

b = distance, in feet, from *side of tower body* to axis of tower.

Then

$f = \frac{F}{4}$ = balanced force in pounds applied at each corner post equivalent to F in bending effect on body of tower. (47)

$f' = \frac{Fa}{8b}$ = torsional force in pounds applied at each corner post equivalent to F in twisting effect on body of tower. (48)

* The wind pressure on a tower is assumed to be uniformly distributed per square foot of surface against which the wind blows, one-half of it consequently being on the windward side of the windward face and the other half on the windward side (inside) of the leeward face. For simplicity in calculation this uniformly distributed force is replaced by a series of concentrated forces, one at each panel point equivalent to the total distributed force extending over a half panel above and a half panel below the panel point. By panel point is meant a point of intersection of principal members, for example, of horizontal members with vertical members; and by panel is meant the section of a side between panel points, a panel usually being bounded by two vertical and two horizontal members.

5. In a tower framed with a double system (i.e., diagonals in duplicate and suitable for compression as well as tension) each system may be considered as taking one-half of the stress as far as possible.

Approximations Made in Calculating Tower Stresses. The stress diagrams are usually simplified by employing certain approximations:

(*a*) Faces of towers are usually battered so that they deviate slightly from a true vertical plane, but the stress diagrams usually neglect this inclination and are based on the vertical projection of the face.

(*b*) Where the face of a tower does not lie in one plane (i.e., has a change of batter as occurs frequently at bottom cross-arm where a prismatic cage joins a pyramidal base) the change of inclination is neglected and the diagrams are based on a single vertical projection as before.

Subject to the limitations of the assumptions and approximations given above, the four faces of the tower can be regarded as four cantilevers, supported at the base and loaded at the top, which are independent except that the four corner posts are each common to two faces and must contain the resultant of both stresses.

Where a face of a tower or any part of a face has any considerable inclination the above approximations may not be used without danger of serious error.

Unstressed Members. A tower usually contains members no stress in which is shown by the stress diagram, viz.:

1. Diagonal members in a horizontal plane do not usually appear in the stress diagram when located below the lowest cross-arm. These members play an important part in the distribution of torsion among the faces. In a rectangular tower the torsion will usually redistribute between the four faces at each level where there are horizontal diagonals; therefore the failure of the stress diagram to show stresses in them may be taken to indicate that the assumed distribution of torsion is not quite correct rather than a true absence of stress.

2. Redundant members are braces which carry no determinate stress but perform the important function of supporting the compression members which do carry stress. The unit stress allowable in a compression member diminishes as the unsupported length increases. The weight of compression members is therefore diminished by dividing their unsupported length by braces applied at one or more intermediate points.

Unit Stresses in Towers. Towers are designed for certain combinations of loads. If the tower were designed to withstand all possible combinations of loads with each load at its maximum possible value, the tower would be uneconomical as its overload capacity under conditions which would occur on the average would be out of reason. Therefore, towers are designed for average loading conditions, and unit stresses are used which will take care of a reasonable overload. The term "factor of safety" is no longer used in reference to tower design since it is misleading; the term "possible overload" is used in its place.

For ordinary transmission towers the following unit stresses in pounds per square inch are generally used:

Axial tension on net section	20,000
Axial compression on gross section (not over 15,500, $\frac{L}{R}$ not over 150)	$20{,}000 - 85\frac{L}{R}$
Axial compression on gross section $\left(\frac{L}{R}\text{ exceeding }150\right)$	$15{,}500 - 55\frac{L}{R}$
Shear on bolts or rivets	13,500
Bearing on bolts or rivets	27,000
L = unsupported length (inches)	
R = least radius of gyration (inches)	

For river crossing or other important structures the following unit stresses are generally used:

Axial tension on net section	18,000
Axial compression on gross section (not over 14,000, $\frac{L}{R}$ not over 150)	$18{,}000 - 80\frac{L}{R}$
Axial compression on gross section $\left(\frac{L}{R}\text{ over }150\right)$	$13{,}500 - 50\frac{L}{R}$
Shear on bolts or rivets	12,000
Bearing on bolts or rivets	24,000

The use of the above stresses results in a possible overload capacity of 90 to 96 per cent for ordinary transmission towers and about 120 per cent for river crossing towers.

Eccentricity in Stresses at Joints. As tower members are ordinarily connected together the stresses in them are slightly eccentric, thereby preventing the full strength of the members being developed. The eccentricity should be eliminated or reduced as much as possible by having the center of gravity of the several members at each connection meet at one point as exactly as possible.

Forces Acting on Tower Foundations

Foundation stresses are of two classes: first, the foundations resist the tendency of the tower to slide and overturn due to the external forces on it considering the tower as a self-contained structure; second, the foundations resist certain stresses which would be internal tower stresses were the tower framed as a complete self-contained structure, but which become external stresses because the ground is depended on for the function of certain omitted members. The weight of the tower can evidently be reduced by thus substituting the ground for certain members, but the size of foundation is thereby increased. The amount of these latter stresses depends on the outline and framing of the tower, and their effect should not be overlooked in determining loadings on foundations.

The magnitude and direction of the forces acting on the tower foundations may be illustrated by taking the case of a rectangular tower, and considering a transmission line which runs north and south.

Let a = width (feet) of base of tower (east and west).

b = length (feet) of base of tower (north and south).

W = total weight (pounds) of tower, insulators, fittings and one span of all the wires, including ice load, if any.

W' = total weight (pounds) of any unbalanced load, such as a wire c feet off center.

F = resultant force (pounds) of the wind on the tower and a complete span of all the wires (with ice coat, if any), acting at a distance of d feet above the foundation, wind assumed blowing across line from west to east.

P = pull (pounds) of any unbalanced force toward the south applied at a distance of e feet above the foundation and f feet to the west of axis of tower, as for example, a dead-ended wire or when a wire on the north side of the tower is broken.

Then, assuming that the forces divide equally among the four foundations and that the torsional forces are in a circumferential direction, the relations given in Table XIV hold. These assumptions are reasonably correct for a tower with the four legs joined at the bottom with a horizontal strut in each of the four faces and with horizontal ties across the diagonals, unless the framing which is usually provided in the other faces is inadequate. Probably few towers in use fully meet these requirements. Therefore, there are usually additional stresses of large magnitude due to the foundations performing the function of missing or inadequate members, as pointed out in the notes appended to Table XIV.

RESULTANT FORCES ON FOUNDATIONS. From the above relations the resultant force on each of the four foundations may be found. In general there will be on each foundation; (1) a downward pressure, (2) a direct uplift, and (3) a horizontal overturning force, producing a tendency to slide and an uplift on one side of the foundation and a downward pressure on the other side.

Downward Pressure. The downward pressure usually is of little importance in determining the size of the foundation as a foundation large enough for uplift and overturning is unnecessarily safe against downward pressure.

Direct Uplift. The uplift is very important, as the weight of tower and foundation is rarely sufficient to provide more than a small fraction of the holding-down power required. The excess uplift is usually resisted by the earth in which the foundation is buried. Not only is the weight of the earth directly over the foundation effective but there is an additional resistance due to friction or cohesion of the earth which may be several times greater. These forces are usually computed on the assumption that they are equivalent to the weight of the earth in a frustum of an inverted cone or pyramid covering the foundation and extending to the surface of the earth. The face of this cone is usually taken as making an angle of 30 deg with the vertical.

Horizontal Overturning Force, Sliding, and Indirect Uplift. The horizontal overturning force is also important. Its effect on the base may be resolved into two components, one a horizontal force tending to slide the foundation and the other a moment tending to rotate the base about a horizontal axis. The resistance of the earth to these forces is an obscure subject, especially if the foundation is of irregular shape. The following discussion which neglects several favorable elements may be considered as a conservative view of the earth resistance.

Table XIV. Forces on Tower Foundations

Magnitude of Force on Each of the Four Foundations	Direction at Each Foundation			
	N. E. corner	S. E. corner	S. W. corner	N. W. corner
$\frac{W}{4}$	Down	Down	Down	Down
$\frac{cW'}{a}$	Down	Down	Up	Up
$\frac{F}{4}$ (Note 1)	East	East	East	East
$\frac{dF}{a}$	Down	Down	Up	Up
$\frac{P}{4}$ (Note 2)	South	South	South	South
$\frac{eP}{b}$	Up	Down	Down	Up
$\frac{afP}{4(a^2+b^2)}$ (Note 3)	North	North	South	South
$\frac{bfP}{4(a^2+b^2)}$ (Note 3)	West	East	East	West

NOTES: Where there are no struts between the bottoms of the legs, and especially where the bottom panel is framed on the single system, both of which conditions are usual:

1. The force of the wind F will give a greater force than $F/4$ in an easterly direction on the two west foundations and a correspondingly less force on the other two, and will in addition produce four new forces tending to force the legs apart on the compression side and draw them together on the tension side.
2. Similarly the pull of the wire P will give a greater force than $P/4$ in a southerly direction on the two north foundations and a correspondingly less force on the other two, and will in addition produce a westerly force at the N. E. and S. W. corners and an easterly force at the S. E. and N. W. corners.
3. Similarly, the torsional forces due to P will increase in magnitude and change in direction, and the unbalanced pull P may develop new forces tending to raise two diagonally opposite legs and depress the other two.

The resistance to sliding may be considered as due to the friction of the bottom of the base on the earth, and it may further be assumed that any base large enough to resist uplift will also furnish sufficient friction to prevent sliding. The arm of the overturning force is then the same as the height of the foundation (bottom of base to top where tower is attached), and the overturning moment is equal to the horizontal force multiplied by this arm. The resisting moment may be considered as due entirely to the vertical reaction of the earth on the top and bottom of the foundation. These vertical pressures may be taken as varying uniformly from zero at a horizontal neutral axis through the middle of the base, to a maximum at the edges of the base most remote from the axis. The moment of resistance is calculated as for a beam subject to bending and having a cross-section identical with the area of the base. It may be assumed that any unit pressure allowable on the uplift edge will be amply safe on the opposite edge where the pressure is downward, so that calculations for uplift only are necessary. The maximum allowable unit stress on the uplift edge may be taken as equal to the average unit resistance to uplift of the whole foundation, determined as described above under Direct Uplift.

Limiting Conditions. Usually the most severe condition that a tower foundation is required to meet consists of a combination of uplift and overturning. For this condition the unit stress of uplift proper must be added to the maximum unit stress of uplift due to overturning and the sum must be within the allowable average unit resistance to uplift.

STRENGTH OF FOUNDATIONS. (See also Kent, on Strength and Elasticity.) A foundation is subject to stresses from the tower tending to move it and from the resistance of the earth preventing motion. The foundation should, of course, be strong enough not to break when subject to these opposing forces. As the points of application of the resistance of the earth and the magnitude of the unit stresses transmitted by the earth at any point are subject to great uncertainty, the foundation should be designed for strength for the distribution of earth resistance which is most severe, considering for example that, while the holding power is calculated on a uniformly distributed earth resistance, it may be developed in practice by concentrated pressure from stones or timber located near the outer edge of the base.

IMPORTANT POINTS REGARDING DESIGN OF FOUNDATIONS. The following are important conclusions which follow from the above discussion:

1. The inverted cone theory of resistance to uplift gives a calculated resistance which increases at a rapid rate with the depth (eventually increasing approximately as the cube of the depth). It would be unsafe, however, to apply the theory for foundations differing much from those of usual dimensions, say for depths much exceeding 6 ft and for foundations where the spread of base was much less than the depth to which it is buried.

2. The foot of the tower (top of foundation) should be brought as close to the surface of the ground as possible to reduce the overturning moment.

3. The tower diagonals of the bottom panel of the tower should intersect the corner posts as low as possible, because this is the actual point of application of the overturning force to the foundation, and if this intersection is above the foundation this extra length must be added to the arm of the overturning moment.

4. By inclining the axis of the foundation approximately in line with the inclined tower leg (i.e., to bring it as near as possible into line with the resultant of the horizontal overturning force and the vertical pressure or uplift) a more economical use of material may be made to resist the combined uplift and overturning.

Testing of Towers

Since towers are generally indeterminate structures, new designs are usually tested. Test loads proportional to the loads specified for the design are applied until the required factor of safety has been proved or failure occurs. Towers are usually mounted on a rigid base for testing. This gives the strength which the tower would develop on an "ideal" foundation. In practice the tower must be expected to develop somewhat less strength, as unequal movement of the foundations will ordinarily overstrain certain members. Test loads may be applied by means of weights suspended directly at proper points for vertical loads and applied by means of pulleys attached to a tower-testing structure ("test tower") for horizontal loads. This method of application makes the determination of the test loads easy, but it is inconvenient to have the weights fall any considerable distance if the tower is tested to failure.

TESTING OF FOUNDATIONS. Foundations are occasionally tested, but the test is usually for determining the holding power of the soil rather than the strength of the foundation. For the former purpose the test result will depend largely on the character of the soil and its condition (dry, wet, or frozen). Tests for holding power are necessary only for uplift and overturning forces. In testing it is important that the testing machine should not press down on the surface of the soil near the foundation. The machine should rest on the ground outside of the base of an inverted cone of angle of 45 deg from the vertical and enveloping the base of the foundation under test.

Specifications, Contracts, and Proposals

Different manufacturers of towers use different details of construction, so that specifications written for the purpose of obtaining proposals should contain only conditions and requirements. These should state the loadings, possible overload, and maximum allowable stresses, and should show outline dimensions of the tower as determined from clearances required.

The specifications should state whether towers are bolted or riveted, galvanized, or painted, shipped assembled or partly assembled, tested or not tested, etc., besides containing the usual structural-steel specifications; see Steel.

The proposals should show the arrangement and sizes of members and typical details of connections.

Contracts are oftentimes let on the basis of furnishing an approximate number of towers when the exact number required cannot be determined in advance, and a unit price per pound is included to cover extensions, special foundations, and modifications that may be required.

The galvanizing of towers and parts is usually specified to pass the A.S.T.M. specification for galvanized steel (see Galvanizing for Iron or Steel). All members of towers that are not too heavy, so that there is danger of their buckling in the process, may be specified to be galvanized by the hot-dip process.

Installation and Erection

Towers are generally shipped disassembled, with each piece marked to show the type of tower of which it is a part, also with a part number to show its location in the tower. Similar parts are usually bundled together with the proper number of each for an individual tower. A tower schedule should be drawn up, showing, for each tower number; the type of structure; shipping point; extensions, if any; adjacent spans; and angle in line, if any. A bill of material for each different kind of tower in the line should be provided. These schedules will aid materially in the distribution and checking of material.

The staking gang follows the right-of-way clearing gang, staking the tower locations

accurately according to the survey. Closely following the staking gang comes the material distribution crew, and after them the foundation gang.

PREPARATION OF FOUNDATIONS. Foundations should be set with their bases below the frost line. The hole should not be excavated deeper than necessary, so that the foundation may rest on undisturbed earth. If any of the several foundations of a tower rest on loose backfill, unequal settlement may be expected which may greatly weaken the tower. The hole should not be larger than necessary, as the backfill will be less effective than undisturbed earth in resisting uplift. The resistance of concrete foundations can sometimes be increased by digging a hole smaller in diameter than the base and undercutting it at the bottom; with structural-steel foundations large stones can sometimes be placed against the steel to increase its resistance to motion, either vertical or lateral. The backfill should be well tamped in place, and especial care should be used if it is probable that the foundation will be subject to heavy stress before the earth has had time to settle. On sloping ground, filling may be required on the low side to give the designed weight of earth against uplift. In water or mud the floating power of hydrostatic pressure beneath the foundation must be allowed for. Where towers are raised on extensions the increased foundation stresses due to increased moment must not be overlooked.

The several foundations of a tower should be set accurately by template both as regards spacing and elevation so that towers stand truly vertical and have no initial stresses due to distortion.

ERECTION OF SUPERSTRUCTURE. The method of erection depends largely upon the type of tower and its location. Short, light towers, under favorable conditions, may be completely assembled lying on the ground. Such a tower may be raised into position by the use of an A-frame or gin pole. A line is connected to the tower slightly above its center of gravity and run over the top of the gin pole or A-frame and through proper rigging to the source of power. Sufficient guys and hand lines should be provided to control the position of the tower while being raised.

Heavy towers must be assembled piece by piece, although panel sections may be assembled on the ground and raised into position by means of booms, floating gin poles, or other suitable rigging. Individual pieces are raised to position by hand lines or tackle attached to the leg members.

With bolted connections the nuts should be prevented from working loose by checking threads on bolts, riveting over the end of the bolt, or by lock-nut or washer.

Each tower member should have a number which should be shown on the erection drawings and marked on the corresponding member of each tower.

The members should be cut, bent, and punched to template so that the parts will be interchangeable and the assembled tower will fit the foundation prepared for it.

A clean-up gang should follow the wire stringing crew to inspect and tighten bolts, pick up left-over material, and make sure everything is in proper condition. This gang should work with the inspecting engineer who makes the final inspection.

Maintenance of Towers

All bolted connections on towers should be carefully watched and kept tight, and the galvanizing or paint should be inspected regularly and towers must be repainted before any deterioration from rusting occurs. Foundations are the most likely source of trouble in operation. These should be kept properly backfilled and should be watched for unequal settlement of legs.

Dimensions, Weights

Data on these items for a number of towers are given in Table XV.

Table XV. Data on Typical Steel Towers

Use	Conductors		Number of Ground wires	Voltage, kv	Height, feet		Base, feet		Normal Span	Maximum Angle, degrees	Weight, pounds
	Number	Size, circular mils			To Lower Cross-arm	Overall	Across Line	Along Line			
T	6	336,400 ACSR	1	132	64.0	95.0	18.6	18.6	1060	5	10,900
L	6	336,400 ACSR	1	132	64.0	96.6	22.0	22.0	1060	15	13,600

Steel	4	7	....	392
Steel	4	7	....	2675

27. CROSS-ARMS

Cross-arms are usually of wood though sometimes of steel. "Buck-arms" or "reverse arms" are cross-arms attached to a pole at right angles to the principal arms, and are used for taking off wires at right angles to the line, either at the junction of intersecting lines or at services. "Double arms" are pairs of cross-arms attached to opposite sides of a pole so as to act as one compound arm. Double arms are used to increase the strength of an arm and to permit the use of two pins and two insulators for supporting a single wire where additional strength is required.

Cross-arms are used principally for supporting pins, insulators, and wires, though lightning arresters, transformers, switches, and other miscellaneous appliances are often mounted on them, usually for the purpose of keeping the pole free of incumbrances so that it will be more easy to climb.

When city distribution lines are located in alleys it is common to locate poles next to the property line. Where it is not permissible to let arms overhang private property special arms may be used which extend on one side of the pole only. These must be well braced and should not be used for dead-ending wires. Another type of construction is obtained by locating two poles on opposite sides of the alley and putting special cross-arms across the alley between them.

Forces on and Stresses in Cross-arms

The forces which a cross-arm resists are:

(*a*) Vertical forces due to weight of pins, insulators, wires (with sleet), and accidental loads due to linemen standing on arms, etc.

(*b*) Transverse horizontal forces due to wind pressure on the wires (with sleet) at right angles to the line.

(*c*) Longitudinal horizontal forces due to the pull of the wires where the pull is unbalanced. Unbalanced pull is usually due to an angle in the line, the ending of the wire at the arm, a change in the size of wire at arm, and an unequal tension in the spans on the two sides of the arm.

The principal internal stresses produced in an arm from these forces are:

1. A bending force in a vertical plane due to vertical forces (*a*).
2. A bending force in a horizontal plane due to horizontal forces (*c*).
3. A twisting force about the longest axis of the arm due to the "pin leverage" of the horizontal forces (*c*). The pin leverage is the distance from the center of the wire to the axis of the arm.

Of these stresses the most destructive is probably the twisting stress which tends to split the arm in a vertical plane through the pinholes and along the grain of the wood. On this account the pin and insulator should be no taller than necessary, and the pin should extend completely through the arm to give the best distribution of bearing pressure.

The vertical and horizontal bending stresses are of some importance and may be computed by the usual beam formula. Data of tests on strength of cross-arms for these stresses are given below.

STRENGTH TESTS OF CROSS-ARMS. (Forest Service Cir. 204.) Tests made on 3 1/4 in. by 4 1/4 in. by 6 ft, 6-pin air-dried cross-arms with vertical load distributed equally at each pin hole gave the results in Table XVI.

The tests showed that for ordinary use the strength, for vertical loads of 6-pin arms, need not be considered in calculations of line construction, except in the rare case of abrupt change of the grade of the line.

Table XVI

Kind of Wood	Average Maximum Load, lb	Maximum Crushing Strength, lb per sq in.
Longleaf pine, 75 per cent heart	10,180	8950
Longleaf pine, 100 per cent heart	9,780	8940
Shortleaf pine	9,260	7300
Longleaf pine, 50 per cent heart	8,980	5425
Shortleaf pine, creosoted	7,650	5770
Douglas fir	7,590	7080
White cedar	5,200	4700

Cross-arm Classifications

Cross-arms are classified generally as (1) telephone arms, (2) power distribution arms, and (3) transmission arms. They are more specifically designated by stating the number of pin positions, overall length, cross-sectional dimensions, and whether standard arms, alley arms, or other special types.

Requirements for Cross-arms

The dimensions of cross-arms standardized by the N.E.L.A. are shown in Table XVII.

Table XVII

Use of Arms	Number of Pins	Width, in.	Depth, in.	Length, in.
Distribution—Std	2	3 1/4	4 1/4	36
Distribution—Std	4	3 1/2	4 1/2	67
Distribution—Std	6	3 1/2	4 1/2	96
Distribution—Std	8	3 3/4	4 3/4	120
Distribution—Alley	6	3 1/2	4 1/2	96
Transmission—Std	2	3 3/4	4 3/4	84
Transmission—Std	4	3 3/4	4 3/4	120

Transmission cross-arms suitable for use with suspension insulators are usually special and have cross-sectional dimensions 4 in. by 5 in. or 5 in. by 7 in., or larger if necessary.

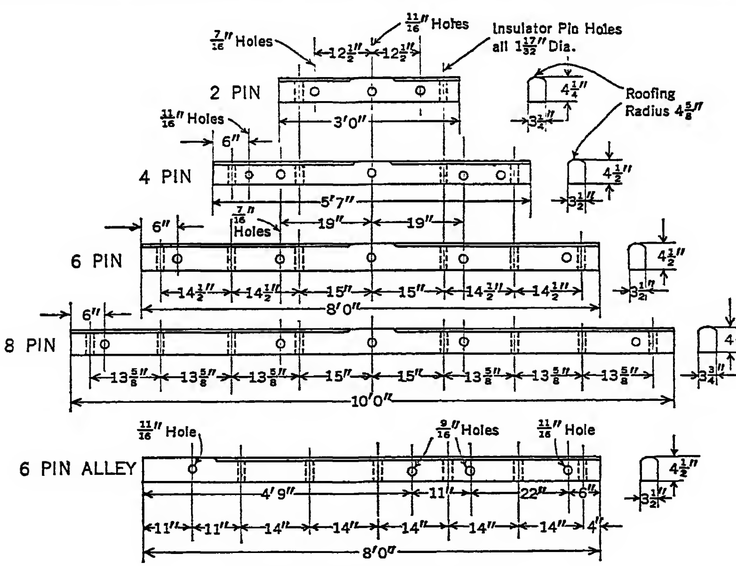

FIG. 26. Standard Cross-arms

Fig. 26 shows dimensions and drilling for N.E.L.A. standard cross-arms. The strength of double arms, with spacing bolts, in the direction of the line should not be considered as more than 30 per cent greater than that of a single arm.

DISTANCE BETWEEN POLE PINS. The requirements for climbing space determine this dimension. If telephone cross-arms are used on joint poles with power cross-arms above them, the pole-pin spacing must be the same as required for the power cross-arms. On power cross-arms the pole-pin spacing is required to be: 24 in. for voltages up to 300, 30 in. for voltages up to 7500, 36 in. for voltages from 7500 to 15,000, and more than 36 in. for voltages above 15,000.

DISTANCE BETWEEN OTHER PINS. For low-voltage power distribution cross-arms the pin spacing called for by the N.E.L.A. Standards is 14 $1/2$ in. The 4-pin medium-voltage transmission cross-arm standardized by the N.E.L.A. has a pin spacing of 36 in. On long-span construction even on low-voltage lines it may be necessary to have greater conductor spacings. This is often accomplished by using longer arms with more pin positions, but omitting intermediate pins. Pins not used should be left out of the arm.

DISTANCE FROM END PIN TO END OF ARM. This is 4 in. for low-voltage power arms and 5 in. for medium-voltage transmission arms. These distances are chosen to minimize splitting of the arm by pin leverage.

PINHOLES. Pinholes are specified to be of a diameter which will give a close fit for the pin. N.E.L.A. standard wood pins have a maximum diameter at the shank of 1 $1/2$ in. Pinholes for such pins are to have nominal diameters of 1 $17/32$ in. and are tested with a steel gage having plugs of 1 $1/2$ in. and 1 $9/16$ in. The hole must take the 1 $1/2$-in. plug without forcing, but not the 1 $9/16$-in. plug. Holes for steel pins must take a testing plug $1/16$ in. smaller than the diameter of the pin shank without forcing.

BOLT HOLES. For fastening the arm to the pole one $11/16$-in. hole is placed at the center of the arm for a $5/8$-in. machine bolt. For fastening flat cross-arm braces to the arm two $7/16$-in. holes are placed each side of the middle of the arm 38 in. apart. These holes are drilled to take $1/2$-in. machine bolts. Bolt holes are tested by steel gages and must take a test plug $1/16$ in. smaller than the bolt diameter without forcing.

SPECIFICATIONS. The points to be covered in specifications for cross-arms are as follows:

Material. Usually Douglas fir or creosoted yellow pine.

Quality of Material. Should be free from loose or unsound knots, loose heart, rot, shakes, wane, or wormholes. Checks should not exceed 12 in. in length, $3/4$ in. in depth, or $1/16$ in. in width. Grain should be parallel with the axis of the arm within 5 deg. Knots larger than $1/4$-in. diameter should be avoided. Large pitch pockets are not desirable. Sapwood should not be allowed in yellow pine arms nor sapwood in excess of 25 per cent in Douglas fir arms. Excessive warp should not be allowed.

Dimensions, Pinholes, etc., as noted in previous section.

Seasoning. Cross-arms should be thoroughly air-dried or kiln-dried before manufacture. When arms are dried after manufacture the pinholes become elliptical owing to shrinkage across the grain.

Preservative Treatment

Yellow pine cross-arms are usually pressure treated with creosote. Since the heartwood of yellow pine is difficult to penetrate with preservative, the treating process should be carried out so as to obtain the maximum penetration without injuring the timber. (See Preservative Treatment of Poles.)

Cross-arms should not be painted, especially with paints containing oil, although creosote stains may be used. Paint seals the pores of the wood and prevents evaporation of moisture. Retained moisture promotes fungus growth, and painted arms soon rot internally.

Use of Specifications

Where the maximum overall economy can be obtained by using the best quality of material standard specifications should be strictly adhered to, but local conditions may make it advisable to use cheaper material in some cases. Under such conditions the requirements may be relaxed somewhat, but consideration should be given to the probable life or failure of the material.

Storage

Cross-arms held in storage should be stacked on creosoted skids. Each layer should be placed at right angles to that below it. Plenty of air space should be left around each arm for ventilation. Each stack should be roofed to drain off rain, and it should be protected from the direct sun. Cross-arms should not be stored in heated buildings; open sheds are best.

28. INSULATORS FOR OVERHEAD LINES

Insulators for overhead lines may be classified as pin-type, suspension, and strain insulators. Pin-type insulators are used for low- and medium-voltage lines. Suspension insulators are used for all voltage lines. Strain insulators are used in guys and for dead-ending low-voltage lines. The general features of design common to all classes of line insulators will be first considered.

Design of Line Insulators

The insulating materials principally used for line insulators are: wet-process porcelain, dry-process porcelain, and glass. Wet-process porcelain is used for this purpose to a far greater extent than dry-process porcelain. Wet-process porcelain has greater resistance to impact and is practically impervious to moisture without glazing; dry-process porcelain is not. However, dry-process porcelain, if well made, has a somewhat higher crushing strength. Dry-process porcelain is therefore used only for the lowest-voltage lines, and even there to only a limited extent.

Prior to the development of high-grade wet-process porcelain, glass was used extensively for all lines up to about 44 kv. The glass available at that time was fragile and subject to breakage due to temperature changes combined with the effect of internal strains. Improved porcelain quickly eliminated glass from line use except for low-voltage signal lines. Recently, however, great advances have been made in the art of glass manufacture resulting in the development of glass insulators which are quite tough and which have low internal strains. The use of these insulators is therefore increasing for low- and medium-voltage lines.

An insulator must be designed to stand extreme and sudden temperature changes, sleet and rain, as well as smoke, dust, and often special conditions such as salt fogs, salt-water sprays, and chemical fumes, without deterioration from chemical action, breakage from mechanical stresses, or electrical failure. The design of high-tension insulators is a process of compromise between requirements often antagonistic in nature.

PROPERTIES OF PORCELAIN AND GLASS. Table XVIII gives some of the more important characteristics of porcelain, glass, and Pyrex.

Table XVIII

Property	Glass	Porcelain	Pyrex
Tensile strength, lb per sq in	7600–12,100	6000–8500	3000
Crushing strength, lb per sq in	12,100–50,000	44,000–60,000	120,000
Modulus of elasticity, lb per sq in	7–12 ($\times 10^6$)	10–15 ($\times 10^6$)	9×10^6
Coefficient of expansion per deg F	4.4–4.92 ($\times 10^{-6}$)	1.82–3.7 ($\times 10^{-6}$)	1.8×10^{-6}
Coefficient of expansion per deg C	7.9–8.83 ($\times 10^{-6}$)	3.3–6.6 ($\times 10^{-6}$)	3.2×10^{-6}
Weight, lb per cu in	0.09–0.125	0.08–0.085	0.0815
Puncture strength, kv per in	1800–3000	316–695	2800+
Dielectric constant	6.0–8.0	6.15	4.48

SHAPE. The insulating surfaces should conform to the flow lines of the electrostatic field; the surfaces of the rain sheds or petticoats should conform to equipotential surfaces. The leakage resistance per shell for multipart pin-type insulators should be about equal; the plane of mechanical rupture should not coincide with the plane of electrical stress, and the unit should have approximately equal capacitances per shell.

Thickness to Resist Puncture. The insulating material must be thick enough to resist puncture by the combined working voltage of the line and any probable transients whose time lag to spark over is great. If this thickness is greater than desirable from a manufacturing standpoint, two or more pieces are used to give the proper aggregate thickness. The thickness of a porcelain part must be so related to the distance around it that it will arc over before it will puncture. The ratio of puncture strength to arc-over voltage is the factor of safety of the part, or of the insulator, against puncture.

This ratio should be high to give sufficient margin to protect the insulator from puncture by the transients before mentioned.

LEAKAGE AND ARCING DISTANCES. The leakage and the dry and wet arcing distances are criteria of the effectiveness of insulators in their insulating function. These terms are defined in the following paragraphs and are illustrated in Fig. 27. Table XIX gives values for these factors for representative insulators.

Leakage distance is the shortest distance between conductor and pin, or between cap and pin, measured along the surface of the insulating material. This distance is roughly

proportional to the amount of voltage required to cause leakage current to flow over the surface of the insulator. It does not, however, take into account the varying width of leakage path nor the conductivity of the dirt or moisture film which may be deposited on the surface.

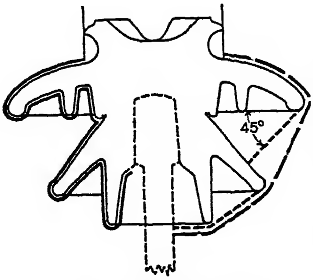

Fig. 27

Wet arcing distance is the shortest distance between conductor or cap, and pin, measured partly over the surface of the insulating material and partly through the air. Where, in any portion of the path to be measured, the striking distance through air between any two points is less than the length of path over the surface between those points, the air striking distance is measured for that portion of the wet arcing distance in place of the distance over the surface. The wet arcing distance is a fairly good measure of the voltage required to arc over the insulator when exposed to rain.

Dry arcing distance is the shortest distance between conductor or cap, and pin. It is measured entirely through the air, and is a fairly good measure of the voltage necessary to arc over the insulator when it is perfectly dry.

Table XIX. Characteristics of Typical Insulators

Type	Dry Flashover, kv	Leakage Distance, in.	Dry Arcing Distance, in.	Wet Arcing Distance, in.
Low-voltage pin-type	50	4.75	3.12	1.37
Low-voltage pin-type	70	9.00	4.50	2.25
Medium-voltage pin-type	95	12.12	6.25	4.00
Medium-voltage pin-type	170	35.50	14.37	9.50
Suspension 10 in. disc	80	12.00	8.00	4.12
Suspension 12 in. disc	95	12.50	9.20	4.30

FREE ARCING. The porcelain must extend beyond the charged conducting connections (i.e., tie wire or cap at the top and pin at the bottom) sufficiently so that the distance between the connections through the air around the porcelain is greater than the arcing distance of the maximum voltage to be carried. The arcing distance required for a given voltage may be determined roughly (but only very roughly) from the tables of arcing distances between needle points; see article on Spark Gap. The greater radius of curvature (compared with needle points) of such metal parts as the insulator pin decreases the potential gradient at the terminals. Also the porcelain has a much greater specific inductive capacity than the air, and its proximity to the arcing path disturbs the electrostatic field through the air. Surface charges on the porcelain because of surface leakage or corona also modify the field.

Free arcing is the property of arcing-over along a line which does not touch the porcelain body from the point where the arc leaves the metal cap to where it strikes the metal pin. Where the arc touches any part of the porcelain the great heat fractures the porcelain in a few seconds; hence the desirability of designing the insulator so that it is free arcing. A properly designed insulator will arc over as a whole before any individual part (i.e., shell or unit) arcs over. In many defective designs the insulator will fail by some parts arcing over, thereby increasing the voltage on others which then fail by puncture or arcing over.

SPREAD OF PETTICOATS OF PIN INSULATORS. In two concentric shells the two surfaces which lie opposite to each other are at different potentials except where they are cemented together. The difference in potential between two points on opposite surfaces is greater the further they are removed from the joint. Unless the shells diverge correspondingly so as to increase the distance between the shells as the potential increases the air will break down and part of the leakage surface will be short-circuited by a corona discharge. This divergence is shown in Fig. 32 where the top is a disk made slightly convex to shed water and the inner shells are cone shaped.

MINIMUM HEIGHT OF PIN. Pin insulators mounted on metal cross-arms should be provided with metal pins which have sufficient length above the cross-arm to insure that flashover will take place to the pin rather than the arm, otherwise the full flashover value of the insulator will not be obtained. The distance to the arm from the lowest skirt should never be less than the shortest distance from the skirt to the pin even with wood arms. On the other hand, the pin should not be longer than necessary on account of the increase in bending moment on the pin with increased height.

COLOR AND GLAZING. Brown, slate and white are the common colors used in glazing porcelain. Brown is the most common color since it is more of an aid in determining faults. Slate-colored glazing of the same color as galvanizing on towers makes insulators a less conspicuous target for malicious destruction.

Glaze is somewhat similar in composition to porcelain. The ingredients are mixed with water and held in suspension while the unfired insulator is dipped in the mixture. Upon firing, the glaze takes on a glass-like consistency which retards the collection of dirt and allows the dirt to be washed off easily by rain.

CEMENTING OF INSULATORS. Porcelain insulator parts are cemented together with neat Portland cement which is carefully selected for quality, strength, fineness, and absence of metallic particles. The insulators after cementing are placed in compartments or tanks and slowly cured under automatically controlled humidity and temperature conditions. The surfaces to be cemented are left unglazed and are either corrugated or sanded to obtain good bond.

PINHOLES. The pinholes in pin-type insulators are made in various forms to accommodate various forms of pins. Insulators for pins with full-size threads are made with the threads molded in the porcelain or have threaded sheet-metal thimbles cemented into unthreaded sockets. Some pins have malleable-iron thimbles, and insulators for use with these pins have the pin sockets unglazed, but with either plain or corrugated surfaces for cementing to the thimbles. Some insulators for this purpose have the sockets glazed but with sharp porcelain grains held to the surface by the glaze. Special flexible cements are often used for thermal relief.

FAULTS IN INSULATORS. The more common faults in porcelain are porosity, folds and flaws in molding, and the development of checks and hair cracks in process of drying, incomplete and non-uniform glazing, warping, air bubbles, conducting impurities, under- and over-firing, and chipping of edges. Only 50 to 75 per cent of molded shapes ordinarily pass final test, and even fewer of the more difficult shapes. Inspection and testing are essential to eliminate faults in both design and manufacture.

Distribution Line Insulators

Insulators for power lines from 115 to 17,000 volts are included in this classification. Both pin-type and suspension insulators are used for lines within this voltage range. For secondary lines carried on racks, spool insulators are used.

PIN-TYPE INSULATORS. The smallest insulator in this class is the side-groove rounded-top type. The side groove is $^3/_8$ in. in radius, the overall height is 3 $^9/_{16}$ in., and the skirt diameter is 3 $^1/_4$ in. The dry flashover voltage is about 50 kv, and the wet flashover voltage is about 20 kv. This insulator is suitable for voltages up to 5 kv, although it has some disadvantages in not being able to accommodate large wires and in not having a top groove.

All the other insulators in this class are provided with both top and side grooves. The most-used insulator of this class is suitable for lines up to 7500 volts. It has top and side

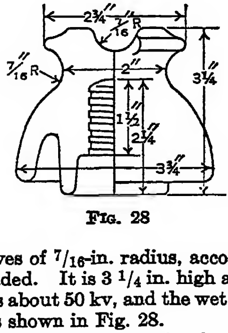

FIG. 28

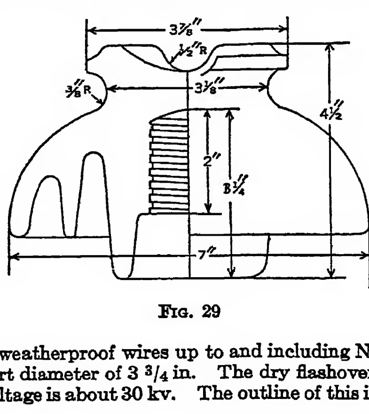

FIG. 29

grooves of $^7/_{16}$-in. radius, accommodating weatherproof wires up to and including No. 4/0 stranded. It is 3 $^1/_4$ in. high and has a skirt diameter of 3 $^3/_4$ in. The dry flashover voltage is about 50 kv, and the wet flashover voltage is about 30 kv. The outline of this insulator is shown in Fig. 28.

The larger pin-type insulators of this class are similar in form to the insulator described in the preceding paragraph. All dimensions are increased to provide the increased flashover values and leakage distances required for the higher voltages. An example of an insulator

suitable for 17-kv lines is shown in Fig. 29. This insulator has a dry flashover of 90 kv and a wet flashover of 50 kv.

All the pin-type insulators of this class are made for pins with 1-in. diameter tops, but the larger sizes are also made for 1 3/8-in. pins.

SUSPENSION INSULATORS. In this voltage class, suspension insulators are used mainly for dead-ending lines or for angle construction, although in a few cases lines of 15 to 17 kv have been built using suspension insulators throughout. The ones most used are of the cap and pin (or disk) type. The insulator disks have a diameter of 6 to 10 in. The caps are malleable iron or steel and are provided with clevis tops for connecting to the cross-arm. The pin takes the form of a hook, eye, or ball, depending upon the method of connection desired. Still other variations of cap and pin designs are available for special purposes.

The top of the insulator disk is provided with a hollow projection in the shape of a truncated cone. This projection is cemented into the hollow cap, and the pin is cemented into the hollow portion of the cone. Fig. 30 shows a typical suspension insulator for low-voltage lines. It has a dry flashover of 50 kv and a wet flashover of 30 kv and is suitable for use on lines up to 7500 volts.

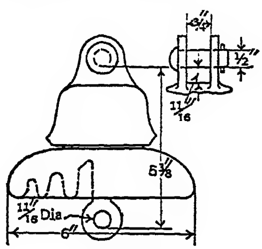

Fig. 30

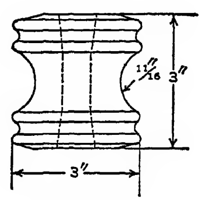

Fig. 31

SPOOL INSULATORS. Insulators to be used on secondary racks having vertical rods for insulator supports are of the spool type. These are available in two standard sizes, one for light racks and one for heavy racks. Fig. 31 shows a typical insulator for heavy racks. The smaller size spool is similar in shape with a height of 2 1/8 in. and a diameter of 2 1/4 in. The groove radius is 1/2 in.

Transmission Line Insulators

For transmission lines above 17 kv both suspension insulators and pin-type insulators are used although the pin-type insulators are now mainly confined to lines below 45 kv.

PIN-TYPE INSULATORS. Pin-type insulators for high-voltage transmission lines must necessarily be made up of two or more parts cemented together. This construction has often resulted in radio interference due to lack of a good bond between the cemented parts, and in early failure due to the effect of temperature changes. It is not now considered good practice to use pin-type insulators having more than two parts. Fig. 32 shows a pin-type insulator suitable for use on lines of 35 kv. The dry flashover of this insulator is about 125 kv, and the wet flashover is about 85 kv.

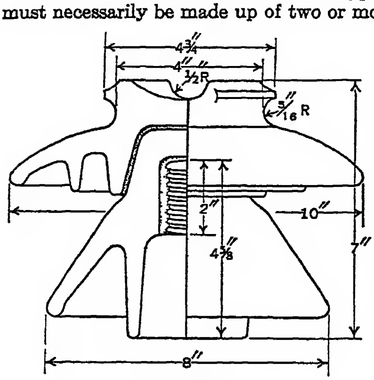

Fig. 32

SUSPENSION INSULATORS. Suspension insulator units are usually connected together in strings of two or more for high-voltage transmission lines to provide sufficient insulation. The construction of these units is similar to that described under the subject of Distribution Line Insulators. Ten-inch disks are used almost exclusively, although high-strength 12-in. disks have been used under special conditions. Suspension insulators are designed to give spacings between individual units of 4 3/4 in. to 7 in., to meet varying insulation requirements. For most purposes, however, the 5 3/4-in. spacing is satisfactory. Suspension insulators are made with different

mechanical strengths. It is therefore possible to select insulators to meet almost any conditions, including the economic requirements of a given line.

The suspension-type insulator is always used in tension, the connections at the two ends being made so that the insulator is free to swing in any direction; the insulator takes

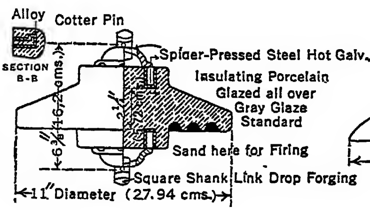

FIG. 33

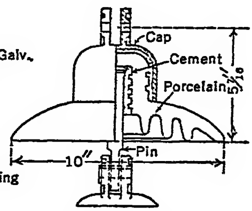

FIG. 34

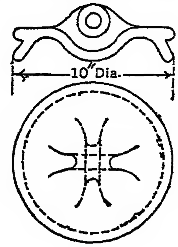

FIG. 35

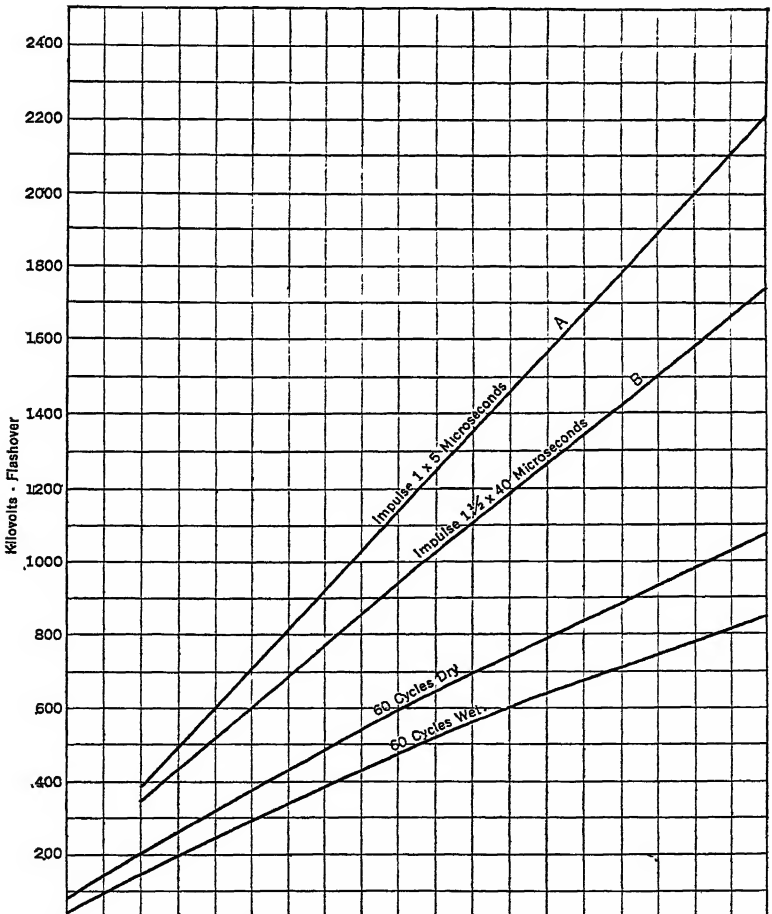

FIG. 36

such a position that its axis coincides with the direction of the mechanical stress. This type is used hanging below the cross-arm with axis vertical as a suspension insulator for sustaining the weight of cable at points where there is little horizontal force, and also with axis approximately horizontal as a " strain " or " dead-end " insulator at points where the horizontal force predominates.

Electrical Characteristics of Insulator Strings

The potential per unit required to flash over a suspension insulator string composed of units of the same design decreases with an increasing number of units as shown in Fig. 36. This is due to an unequal potential gradient. The potential gradient for various insulator strings is shown in Fig. 37. If grading shields or arcing rings are used in connection with

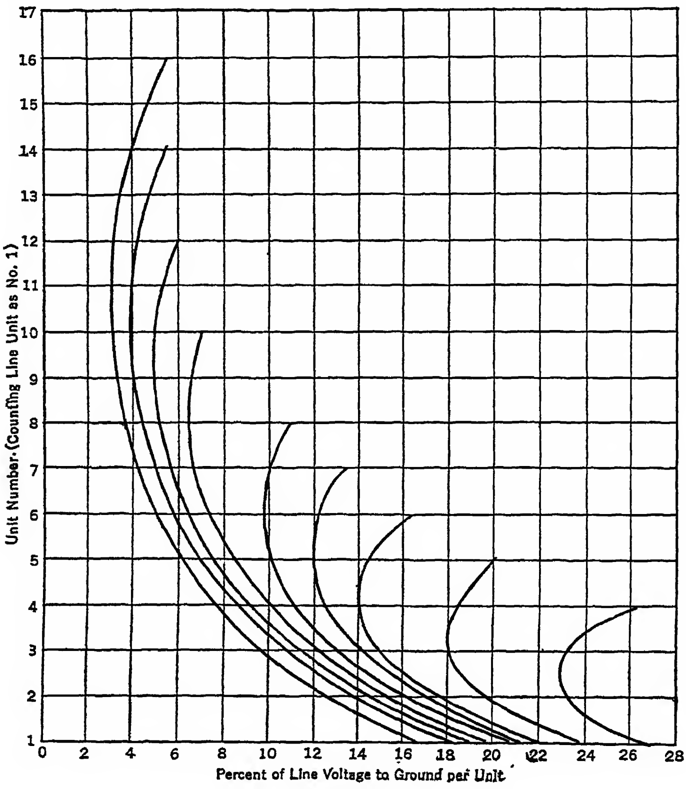

FIG. 37

an insulator string the voltage gradient is changed and made more uniform. A typical effect of adding grading rings is shown in Fig. 38.

The impulse flashover characteristics of typical insulator strings is shown in Fig. 36. Curve *A* gives the crest voltage for flashover of a positive wave of 1 × 5 microseconds (i.e., reaching crest value in 1 microsecond and dropping to $^1/_2$ crest value in 5 microseconds from the start of the wave). Curve *B* gives flashover values for a positive wave of 1 $^1/_2$×40 microseconds.

Insulation Coordination

It would be desirable, of course, to make a transmission line proof against all flashovers, if that were possible. It is doubtful whether it is possible so to insulate a line as to achieve this result. Lightning voltages are so great that any amount of insulation that is economically feasible would probably fail to eliminate flashovers. Increasing the insulation

of the transmission line itself only transfers the flashovers to the terminal equipment where they cause greater damage than they would on the line. Therefore, the insulation of terminal equipment should be greater and better protected than the line insulation. Lightning arresters, shielding, and other methods are feasible and economical at substations but not on the line. For line insulation, protection arcing and grading rings, ground wires

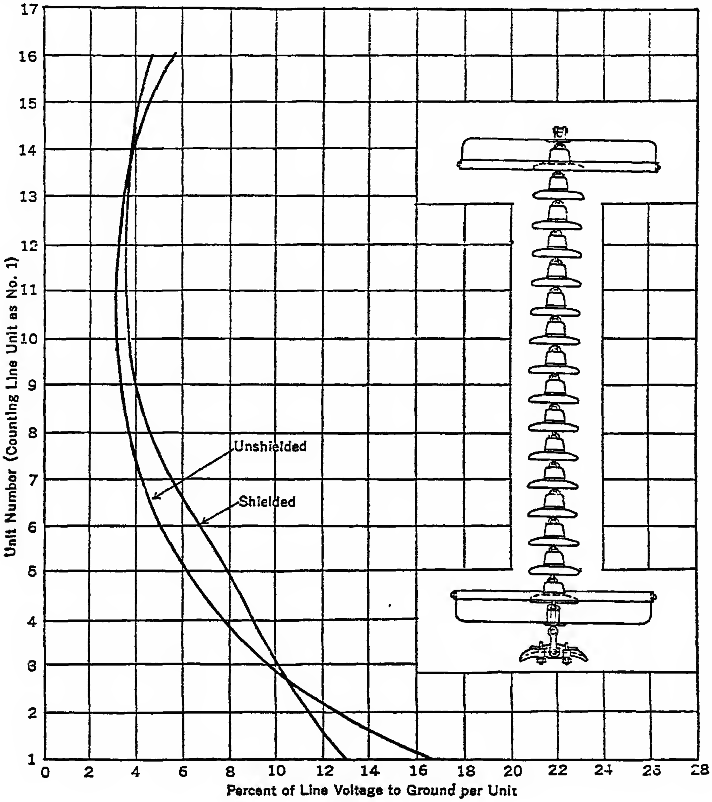

Fig. 38

and counterpoises, and expulsion protective gaps have been used with fairly good results. (See Bibliography.)

Strain Insulators

Insulators of this type are used primarily for insertion in guy wires. Most porcelain strain insulators are designed to place the porcelain under compression and are of cylindrical form with grooves for the loops of the guy wires. The design is such as to allow the loops of the two sections of guy wire to be interlaced with porcelain between them. Insulators for the higher voltages are provided with deep fluting or fins to provide additional leakage surface. This design prevents mechanical failure of the guy even if breakage of the porcelain takes place. Insulators of this type are also used for dead-ending circuits up to about 2500 volts. Several styles of metal clevises are available for attaching them to poles or cross-arms when used for dead-ending purposes. Fig. 39 shows a typical strain insulator.

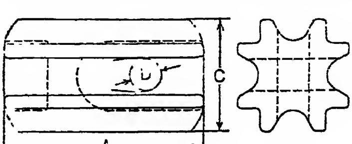

Fig. 39

Wood strain insulators are coming into greater use for guys on wood transmission line structures in order to increase the overall insulating value of the wood structure against

lightning voltages. The flashover value of insulation under lightning voltages depends primarily on its length between live parts and grounded parts. Wood provides a long flashover path at lower cost than any other material of the same mechanical strength. The wood is used in tension and is connected to the guy wires by metal end pieces specially designed to develop the full mechanical strength of the wood. Arcing horns are provided to make sure that any possible arc across the insulator will be kept away from the wood.

Tests of Insulators

Tests of insulators may be classified as: (1) design tests, made on a few insulators to determine the electrical and mechanical characteristics of each different design; and (2) routine tests, made on all or a certain percentage of each lot of insulators purchased, to detect defects of material or workmanship. Standard 41 of the A.I.E.E. gives complete test specifications for porcelain insulators, which are generally accepted. These specifications, slightly modified, may also be used for glass insulators. Space does not permit the incorporation of these specifications here. They are reprinted in several manufacturers' catalogs.

DESIGN TESTS include: wet and dry flashover, corona, and puncture tests. For suspension insulators a combined mechanical and electrical test is required.

ROUTINE TESTS include: (1) Continuous dry flashover for 3 minutes for pin-type insulators, both on individual parts and on the assembled insulator. For suspension insulators the flashover is continued for 5 minutes. (2) Thermal change tests on the assembled suspension insulators, and on individual parts as well as assembled pin-type insulators. (3) Porosity tests. (4) Puncture tests. (5) High-frequency and combined mechanical and electrical tests on suspension insulators only.

TESTING ON THE LINE. Periodic testing of insulators on the line should be carried out to eliminate deteriorating units before they fail and interrupt service. Various patented methods are available for line testing of insulators. Generally these use the voltage gradient method. Measurement of the dielectric power factor is an excellent method for testing off the line.

Selection of Insulators

The first step in the selection of insulators is to determine the insulation level of the line relative to that of the terminal equipment. Both normal-frequency flashover voltages and lightning voltages should be considered. The type of supporting structures (wood or steel) has a considerable effect on the insulation efficiency of the line. The possibility of overvoltages due to switching surges and to arcing grounds on isolated neutral systems should be taken into account. The mechanical strength requirements should also be evaluated. Manufacturers' catalogs now give very complete and reliable data to aid in insulator selection.

Installation of Insulators

See the article on Line Erection.

29. INSULATOR PINS AND HARDWARE

Insulator pins are made of wood or steel. Insulator hardware is made of steel or malleable iron.

Wood Pins

All-wood pins are now used only for lines up to 7500 volts. They are unsatisfactory on higher voltages for they deteriorate rapidly owing to the combination of moisture and leakage current. Black and yellow locust are the most satisfactory woods for the purpose, although eucalyptus, oak, birch, osage orange, gum, and other woods have been used successfully. Fig. 40 shows the N.E.L.A. standard wood pin. It should be noted that the 4 1/4-in. shank will not develop the full strength of cross-arms 4 1/2 in. or more in depth.

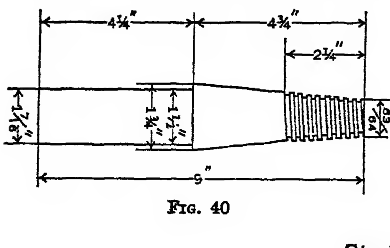

FIG. 40

Steel Pins

Steel pins are available in many designs for any voltage class of insulators. They are made of forged steel and are usually galvanized. Steel pins for low-voltage insulators

are made with long and short bolt shanks and also with lag screw shanks. The threaded head is made of cast lead, pressed steel, or a helix of spring steel wire. The lead head has the advantage of giving a tight fit without tending to burst the insulator under temperature changes. Fig. 41 shows a typical pin of this type.

Steel pins for higher-voltage insulators are similar to those for low voltages, except in size and strength. In addition to being made with lead heads they are also made with special threaded tops for screwing into thimbles which are cemented into the insulators before placing on the pins. Fig. 42 shows a pin of this general type.

Since steel pins may be designed to have greater strength than obtainable with wood pins they are more desirable for heavy conductors and long spans. Owing to the smaller size of shank, steel pins require less wood to be removed from the cross-arms and therefore do not reduce the cross-arm strength as much as wood pins do. Cross-arms rot around the pinholes rather quickly when wood pins are used, which is not the case when steel pins are used.

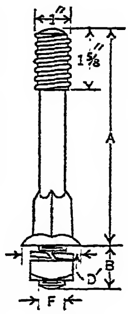

Fig. 41

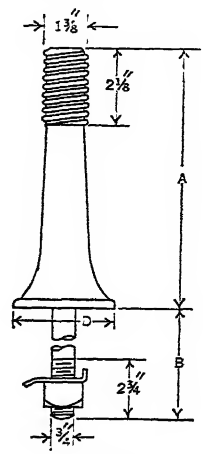

Fig. 42

Attachment of Pins to Arms

Pinholes in cross-arms for wood pins are bored $1\,^{17}/_{32}$ in. and the diameter at the top of the shank of pins is required to be $1\,^{1}/_{2}$ in. On account of swelling or shrinking of the wood the pins may fit tightly or loosely. In order to make sure that the pins will not pull out of the arm a 4 or 6 penny galvanized nail is driven through the arm and the pin. Pinholes for steel pins are bored $^{1}/_{16}$ in. larger than the shank diameter. The end of the pin shank is threaded, and in addition to the nut the pin is furnished with a locking washer. Drawing the nut tight insures a rigid connection and seals the pinhole against moisture, thus retarding decay.

Suspension Insulator Hardware

The suspension insulator type of construction requires a wide variety of hardware fittings. For attaching insulators to structures, use is made of eyes, shackles, clevises, or hooks. These are usually designed to permit free swing of the insulator string in every direction. For any particular situation fittings should be selected which will provide the simplest form of connection. Eyes of some form are usually provided on tower cross-arms for attaching insulators. Eye bolts or specially designed fittings are used to attach insulator strings to wood cross-arms. With parallel strings of insulators for extra strength, yokes are used to provide a common connection for the strings and to space them apart properly. These yokes are, of course, used at each end of the multiple string.

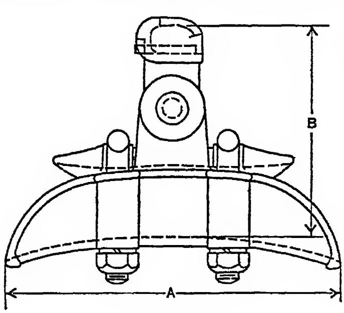

Fig. 43

Suspension clamps or strain clamps serve to attach conductors to insulator strings. Suspension clamps are used on insulator strings at all structures at which the conductor is not dead-ended. This includes tangent sections, slight angles, and angles which are turned with flying corner construction. Such clamps are generally made of galvanized malleable iron with steel U-bolts or J-bolts, although cast or forged steel has been employed in some cases. These clamps should have smooth, well-rounded seats and corners. They should be quite light in weight and therefore of small inertia to reduce conductor vibration. They are provided with aluminum liners, if desired, for use with aluminum cables. Fig. 43 shows a typical suspension clamp. Recent developments at Boulder Dam and elsewhere have led to the development of clamps for extra-long spans, with special features to prevent concentration of vibration on the cable near the clamp.

Strain clamps, used for dead-ending conductors, are made in a wide variety of styles and sizes to meet the tension requirements imposed by the line conductors. They are commonly made in such form as to put a bend in the conductor to provide some snubbing action and are also provided with steel U-bolts or J-bolts, and pressure pieces to hold the conductor by friction. Slight waves are often made in the surfaces of pressure pieces and conductor seats to increase the snubbing effect. Strain clamps are designed to hold without slippage the largest conductor they will fit. They are also provided with liners for aluminum cable, if desired. Fig. 44 shows a typical strain clamp. Clamp bodies are usually made of galvanized malleable iron or steel. Another form of a strain clamp which is coming into general use provides nearly 360 deg snubbing effect combined with clamping. This type is used with the smaller conductors on distribution lines.

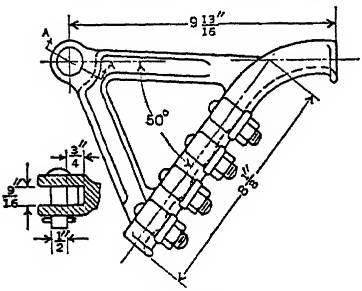

FIG. 44

30. CONDUCTOR INSTALLATION

Stringing conductors is the final major job in erecting overhead lines. For city distribution lines the process is somewhat different from that for transmission lines, although the underlying principle is the same.

On Distribution Lines

In stringing conductors on lines on city streets the conductors are either coiled on pay-off reels or left on shipping reels which are supported on reel jacks. The reels may either be mounted on the line truck or set up on the ground underneath the line. On account of the short spans the conductors may be pulled in by manila hand-lines running over the cross-arms. Power winches mounted on the line trucks are often employed for pulling heavy conductors. Secondary conductors to be run on vertical racks are often laid out along the line and lifted by hand-lines to the rack points where they are held loosely in place behind the rack rods. Where conductors are being strung on poles already carrying energized circuits, every possible precaution should be taken to prevent injury to the linemen. Throughout the process of stringing, sagging, and tying-in, the live conductors should be covered at the poles with rubber blankets, line hose, or similar protective devices, and the linemen should be required to wear their rubber gloves and glove protectors. They should be required to have their safety belts fastened around the pole at all times when in working position. Hand-lines should be perfectly dry and clean.

After pulling the wires over the arms and securing them temporarily at the dead-end arms, they are tied in permanently at one dead-end arm. They are then pulled up at the other end to proper sag for each span. It is not feasible to measure tension in the conductors for such construction, and therefore the sag is measured by sighting across targets fixed in proper position on adjacent poles. After completion of the sagging operation the other dead-end is tied in permanently, and then the wires are lifted upon the insulators at each intermediate pole and tied to them by tie wires. Long-span rural line conductors on wood poles are strung in much the same manner.

On Transmission Lines

Conductors for long-span transmission lines are shipped in long lengths on wooden reels. These reels of wire are distributed along the line in accordance with the length of wire on each. The reels are set up on reel jacks which allow the reels to revolve when the wire is paid out. Stringing sheaves which have very free-running rollers are hung on the towers in place of the insulator strings. The conductors are placed in the sheaves on the first tower away from the reel set-up and pulled to a point beyond the next tower. The pulling is stopped until the conductors are lifted to the sheaves on the second tower, and the pulling process is then continued as before until the next reel set-up is reached. When the first set of reels are emptied the conductors are tied temporarily to the adjacent dead-end tower. The conductors of the second set of reels are then pulled into their section of the line, and when the reels are emptied the conductors of both sections are spliced together. Pulling of conductors is usually done with horses. Under favorable conditions tractors provide excellent power for the purpose. In mountainous country oxen have

been used successfully when horses or tractors were out of the question. Locomotives have sometimes been used for lines along railroads. Care should be exercised in pulling conductors not to injure them by sharp bends, faulty cable grips, or dragging them over sharp stones.

This general procedure is followed until the next dead-end tower is reached, when the entire section between dead-ends is pulled up to proper sag and tension for the prevailing temperatures. If prestretching is done in the field the conductors should be pulled up to nearly the elastic limit before adjusting to normal sag and tension. (See article on Mechanical Design.) Dynamometers are used to measure the tension in conductors for prestretching for approximate sagging. Since dynamometers are not sufficiently accurate the final determination of correct sag and tension should be made by the use of surveying instruments. Wind loads on conductors at the time of stringing should be taken into account if they are of sufficient magnitude to affect the tension more than a negligible amount.

Where ground wires or telephone wires are also on the tower, it is equally important that they be strung at the proper tension; otherwise they may cross and ground the conductors.

Suspension towers (i.e., those intermediate between the dead-end towers) are ordinarily not strong enough to stand the strain of dead-ended cables during high winds and heavy sleet storms; consequently care must be used if cables are temporarily dead-ended on them during construction.

After the conductors are properly sagged the insulators are put in position and connected to the conductors. Care should be taken to connect the insulators at proper points on the conductors so that the tension will not be changed and so that suspension insulators will hang in a vertical plane. At dead-end towers the jumpers must be clamped together and bent to shape and not left so that they may ground to the tower due to twist of cable or wind pressure.

Conductor Splicing

Conductors are spliced by the use of twisting sleeves or compression sleeves or by twisting the conductors together without sleeves. The latter method is used only with small conductors and is being superseded by the other methods to some extent. Twisting sleeves are used quite generally for splicing conductors which are not too large to be twisted and where the conductors strength will be less than the strength of the twisted splice, by a safe margin. Fig. 45 shows a typical twisting sleeve and a twisted joint.

FIG. 45

Twisting sleeves are made with a figure-eight cross-section as well as elliptical. It is claimed that greater strength is obtained with the figure-eight shape. Twisting sleeve joints are twisted by hand wrenches which are of various sizes depending on the conductor size. Ratchet wrenches are quite popular for this purpose.

Compression sleeves are made in various forms and for various methods of application. A common form used for steel-reinforced aluminum cable really consists of two sleeves, a steel sleeve for the steel core and an aluminum sleeve covering the whole splice. In making the splice a machine known as a compressor is used which applies the pressure hydraulically to properly shaped dies. The aluminum sleeve is placed on the cable and slid back some

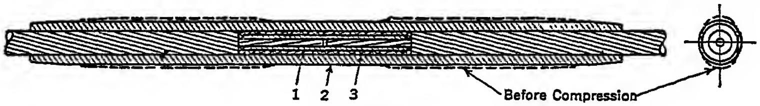

FIG. 46

distance from the joint. The aluminum strands are cut off to expose the steel core a little more than one-half the length of the steel sleeve. Both the aluminum and steel strands are wrapped near the ends with wire to prevent spreading. Both ends of cable are dipped into red lead paint to cover slightly more than the total length of the joint. The steel sleeve is slipped over the ends of the steel cores and centered and then compressed with the machine. The steel sleeve is wrapped with aluminum wire to the diameter of the outer aluminum strands, after which the aluminum sleeve is slipped over the joint, centered, and compressed. Fig. 46 shows such a joint. Item 1 of the figure is the steel sleeve, 2 is the aluminum sleeve, and 3 is the filler wire.

Compression joints for copper conductors are quite similar, and many patented methods have been devised to make them up in the field. One method for small conductors involves the use of a die which rolls from one end of the sleeve to the other. Another method employs stationary dies with the pressure applied by exploding gunpowder cartridges. Hydraulic compressors are also used. In general the strength of sleeve joints depends on the length of the sleeve to give adequate bond, and on its thickness to give adequate tensile strength.

Transposition of Conductors

Communication circuits closely paralleling a-c power circuits are susceptible to inductive interference. The interference is brought about by the linking together of the two separate systems by means of their own external electromagnetic or electrostatic fields. Interference may also arise due to the fact that the earth forms a common part of the circuits of both systems. Interference is proportional to the closeness of the two circuits, the length of parallelism or exposure, and the magnitude of the interfering voltage or current.

Certain frequencies produce more serious effects than others. In telephone circuits, frequencies from 800 to 1500 cycles per second are most troublesome from the standpoint of noise in the telephone circuit. Eleven hundred cycles is by far the worst noise frequency. Telegraph circuits are susceptible to frequencies of 60, 180, 300, and 420 cycles. The triple harmonics and their odd multiples together with the odd non-triple harmonics are those which may be present and which require attention from an interference standpoint.

Perfectly balanced symmetrical three-phase systems may have the fundamental frequency and all odd harmonics present, but there will be no single-phase or residual components of current or voltage. Unbalance either as to voltage between phases, currents, or capacity to ground produces a residual component. The third harmonic and its odd multiples may be produced by certain connections of transformers or by the generator wave shape. The third harmonic and its multiples are best taken care of by suppressing them. This may be accomplished by providing a delta-connected winding across the phases. (See Transformer Connections.) Residuals are best taken care of by repressing them either by delta-Y grounding banks or by wave traps. The inductive effects of balanced voltages and currents may be overcome by a coordinated system of transpositions of both power and communication lines.

Transposition of power lines is necessary only within the distance in which the lines are closely parallel. This distance is called the length of exposure. A transposition

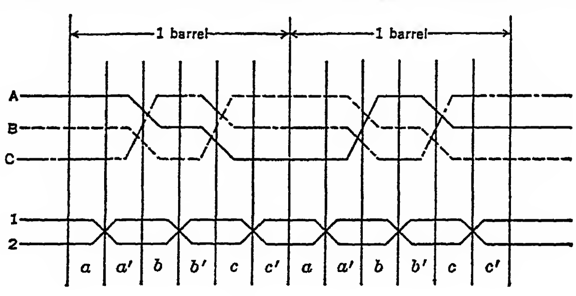

Fig. 47

scheme requires that each conductor of the power line shall have equal coupling to the communication line. This is accomplished in three-phase lines by successively bringing each of the three conductors into the position previously occupied by one of the other conductors. At each transposition structure such a replacement of conductors takes place in such a manner as to rotate the phases spirally along the line. The length of line in which each conductor occupies each position for an equal distance is called a "barrel." The number of barrels necessary in a given exposure depends upon the amount of inductive coupling between circuits.

In order to neutralize the voltages induced between the two sides of the communication circuit it is also necessary to transpose the communication circuit. The two transposition schemes must, therefore, be coordinated. Fig. 47 shows a typical coordinated scheme.

The conditions required for balance for such a coordinated scheme are shown in the following table.

Component of Voltage or Current in Power Line	Voltage Induced in Communication Circuit	Condition Required for Balance
Balanced	Between wires	$a - a' = b - b' = c - c'$
Balanced	To ground	$a + a' = b - b' = c + c'$
Residual	Between wires	$a + b' + c = a' + b + c'$

Specially designed structures are usually necessary at transposition points to provide proper clearances between conductors and between conductors and the structures. For more complete discussion of inductive interference and remedial measures see Pender & McIlwain's Handbook of Communication Engineering.

31. INSPECTION OF POLE AND TOWER LINES

All parts entering into a line are usually tested and inspected before shipment; therefore, in general, the final inspection of a line before putting it into service consists in inspecting the final assembly. This is ordinarily done by an inspection crew under the supervision of an engineer. This crew gives a visual inspection of all parts to detect breakage or other defects which can be seen. Tightness of bolts, position of insulators, alignment of structures, clearances of jumpers, conductor connections, rust spots on steel, and condition of right-of-way are among the items checked. Phasing out of the lines is usually done by the crews working on the electrical construction of the substations. After the line is in operation periodic inspections are made similar to the final construction inspection, and the inspection crews usually carry out the necessary maintenance work.

The proper maintenance of a line includes resetting foundations that have settled; covering of foundations with earth to proper depth after heavy rains; repainting of towers before they are affected by rust; renewal of rusted ground cables; replacement of cracked or partially defective insulators that have not failed; correcting sag of any cable where sag has changed as a result of stretch of cable, change of length during emergency repairs, etc.

In addition to the periodic inspections which are made one or two years apart, the lines should be patrolled every few days by regular patrolmen who should note and report the condition of foundations, poles, towers, insulators, and conductors. They should keep weeds, brush, and inflammable material away from the structures and also make minor and emergency repairs. Arrangements should be made for means of communication for patrolmen. If a private telephone line is constructed along the power line right-of-way, telephones for patrolmen should be located at convenient intervals. Emergency repair storerooms are also located at strategic points along the line.

UNDERGROUND CONDUITS

By W. A. Del Mar

33. TERMINOLOGY

There is no accepted standard terminology, but N.E.L.A. Reports have, in general, been consistent with the following definitions.

Duct, a pipe designed or used for accommodating electric cable.

Service Duct, a duct entering a consumer's premises.

Duct-bank, a group of ducts.

Manhole, or Splicing Chamber, a chamber giving access to a duct-bank.

Distributor Box, a small manhole for connecting distributing mains to consumer's service ducts.

Conduit, usually a duct-bank with its manholes, but sometimes used to designate a duct. The word will be used herein to designate a duct-bank with manholes.

Manhole Frame, a casting enclosing the entrance to a manhole.

Manhole Cover, a casting which closes the opening in a frame.

34. USE OF CONDUITS

Conduits are used for housing underground electric cables. They permit the installations and removal of cable at manholes without disturbing the surface of the street. They are used for transmission, distribution, and service cables.

Transmission conduits are generally laid with manhole spacings of 400 to 600 ft, and they are made as straight as conditions permit.

The length of sections between manholes is largely determined by local conditions. Large cables have been successfully pulled up to 1200-ft lengths, but difficulties encountered in replacing cables in such long sections indicate that 600 ft is the maximum length desirable. Pulling stresses vary from about 1000 lb in the shorter pulls to 7000 lb in the longer pulls of a 1000-ft cable, with cable weighing about 12 lb per ft.

The cost of replacement of street pavement constitutes a large part of the total. Duct lines are often run through parkways, side streets, and alleys, thus avoiding the expense of repaving. Manholes located at alley intersections also have the advantage of being more readily accessible than those at street intersections, where surface traffic is heavier.

Distribution conduits are usually shorter than those of a transmission system, and usually consist of one or two ducts, 3 1/2- to 4-in. diameter, placed over the transmission ducts, if these are in the same street. The routes follow main streets or avenues, and the cables are subject to frequent disturbances owing to changes in service connections. All classes of service which include feeders, secondaries, street lighting, and control cables are found in distribution duct-banks.

In the main avenues, secondary cable ducts usually are placed in the streets. Frequent distribution boxes are installed to provide for consumer service connections. For side streets in residential districts, it may be more desirable to install the ducts inside the curb, in order to avoid the cost of repaving the street.

Service pipes, run from distribution box to consumer's premises, usually consist of 2-in. steel or fiber pipe.

In localities where the soil is free from large stones, steel pipe may be pushed from the cellar wall by means of a pneumatic gun. Ordinarily it is laid by digging a trench, which, however, often necessitates breaking up some of the sidewalk.

Services are usually grouped by fours or less, so as to make each one not more than 80 ft long. Service boxes are located at least 50 ft apart in a heavily loaded district.

35. TYPES OF DUCTS

The most frequently used materials are tile, fiber, and monolithic concrete. Iron pipe and sometimes creosoted wood duct are often used for service connections.

Tile duct is less commonly used for power cable purposes than fiber duct, owing largely to the quicker installation of fiber duct with its longer lengths, lighter weight, and less trouble from breakage in transit.

Tile ducts are usually laid without any separation, which does not always isolate trouble to the duct in which it occurs. Tile ducts also fuse badly, sometimes making it difficult to remove cable after a burnout. They are likely to be rougher at the joints than fiber ducts because of the easier entrance of concrete at these points.

Multiple Tile duct is seldom used for power cables because of the danger from short circuits being communicated to other cables at the joints.

"Soapstone" duct is now being used, which consists of a mixture of cement and ground soapstone. The chief claim for it is low frictional losses. It is mechanically strong, and it possesses good arc-resisting properties, as it does not melt into sharp needles, but rather flakes away, leaving a smooth surface for the cable. The individual units are 3 ft long and weigh about 6 2/3 lb per ft.

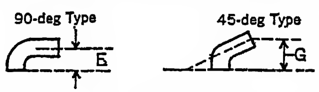
Fiber Conduit consists of tubes of wood pulp fiber formed on a mandrel, dried, and impregnated with a bituminous compound. The ends are tooled to the desired form for joint construction.

The standard sizes are as shown in Table I.

Table I. Standard Fiber Ducts

Inside Diameter, in.	Wall Thickness, in.
2	1/4
2 1/2	1/4
3	1/4
3 1/2	1/4
4	1/4
4 1/2	5/16
5	3/8

Table II. Standard Elbows for Fiber Conduit



Internal Diameter, in.	Radius of Center Line, in.	*E*	*G*
2	2	6	8 1/2
2 1/2	2 1/2	6 1/2	9
3	3	6 1/2	9
3 1/2	3 1/2	7	9 1/2
4	4	7 1/2	10 1/2
4 1/2	4 1/2	8	12
5	5	11	16

There are three types of joints, as follows:

Socket type, with mortise and tenon 3/8 in. deep, slightly tapered.

Sleeve (or Harrington) type, having a sleeve machined internally tapering from both ends to center, the bore being such that conduits do not butt.

Standard elbows are shown in Table II.

Tile ducts are made with either round or square bore and octagonal outside. They are made by mixing surface clay or fireclay to the proper consistency and pressing the plastic mass through a die. They are dried and burned, and covered inside and out with salt glaze. A well-made duct will give a clear ringing sound when struck with a piece of steel. A dull dead sound indicates softness or porosity. Standard sizes are shown in Table III.

Table III. Standard Single Tile Ducts

Bore of Duct Hole, in.		Length, in.	Approximate Outside Width, in.
Nominal	Actual		
3 1/4 Round	3 3/8	18	4 1/2
3 1/2 Round	3 5/8	18	4 3/4
4 1/4 Round	4 3/8	18	5 1/2
3 1/2 Square	3 5/8	18	5
4 1/4 Square	4 1/4	18	5 3/4

Pump Log, which comes in lengths 6 to 7 ft and may be installed without concrete, is used largely where traffic conditions compel rapid installation and immediate back-filling.

It is made of southern yellow pine or Norway spruce steamed and impregnated with creosote oil. It is joined by means of mortise and tenon joints about 1 1/8 to 1 1/4 in. long. Lengths are laid with joints staggered horizontally and vertically.

Monolithic Concrete is made by pouring concrete over long rubber forms and pulling out the rubber when the concrete sets.

Care must be exercised, in all concrete duct work, to use a grade of concrete which will not cause chemical corrosion of the cable sheaths.

The depth of top of duct structure below street surface is usually not less than 2 ft 6 in., but is often fixed by municipal ordinance.

Proper selection of manhole location will permit ducts to drain into manholes, using a minimum slope 3 in. in 100 ft. On very steep streets, it is best to build in 3 or 4 steps, alternating level and sloping, to avoid cable creepage.

36. SPLICING CHAMBERS

Splicing chambers are designed to permit the highest-voltage cables which they are to contain, to be trained around the walls and spliced without excessive bending. It is necessary to leave room for cable expansion and contraction. The dimensions should

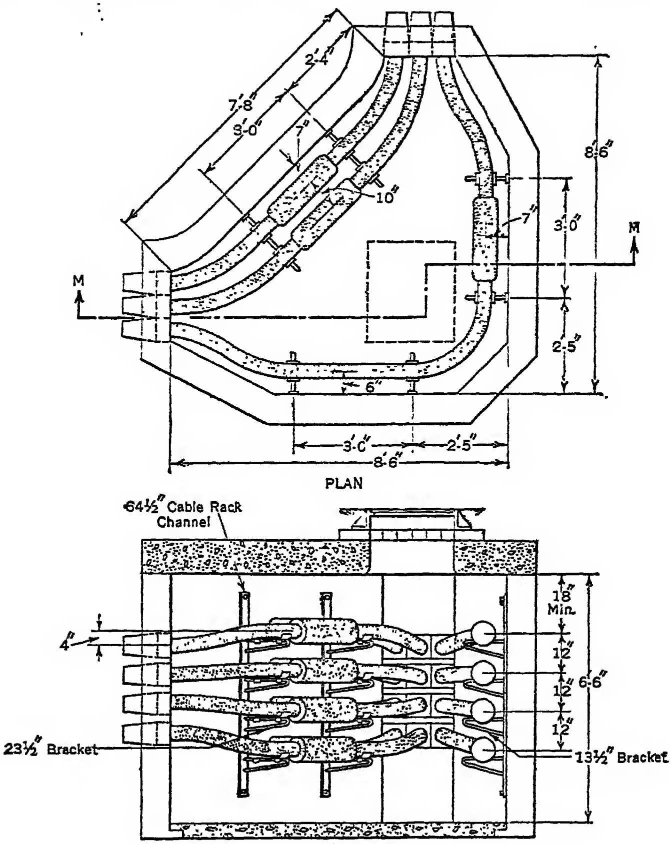


Fig. 1

also be ample to permit splicers to work efficiently. The height is usually 6 ft or more.

Roofs should be designed to withstand static wheel loads of 15,000 lb plus an allowance for impact, usually 50 per cent, making 22,500 lb. Dry earth is usually estimated to weigh 100 lb per cu ft. Horizontal pressures are usually taken as one-third the vertical.

The total vertical load varies from 2000 lb per sq ft at a depth of 1 ft, to 1000 lb per sq ft at 2 ft to 6 ft, then again rising to 2000 lb at 15 ft.

Typical Splicing Chambers are shown in Figs. 1 to 6, the dimensions being suitable for 12,000-volt cables. (From N.E.L.A. reports.) For higher voltages, the dimensions will have to be greater. In oil-filled cable systems, there must be space for reservoirs and other accessories.

FIG. 4

DUCT ENTRANCES. It is customary to construct the duct entrance into the manhole with a flare. This provides easier cable bending conditions and lessens the danger of damage to cable at the duct edge, at the same time increasing the effective length of the manhole and permitting the cable fireproofing being carried back into the entrance of the duct. The flare is sometimes constructed with a tapered wooden plug, made to fit the duct at one end and covered with paper so that it can easily be removed after the duct window has become firm. Often it is fashioned by hand with an appropriately shaped wooden tool, before the cement has become too hard. Another method is to use a form, which simplifies the procedure and can be used repeatedly.

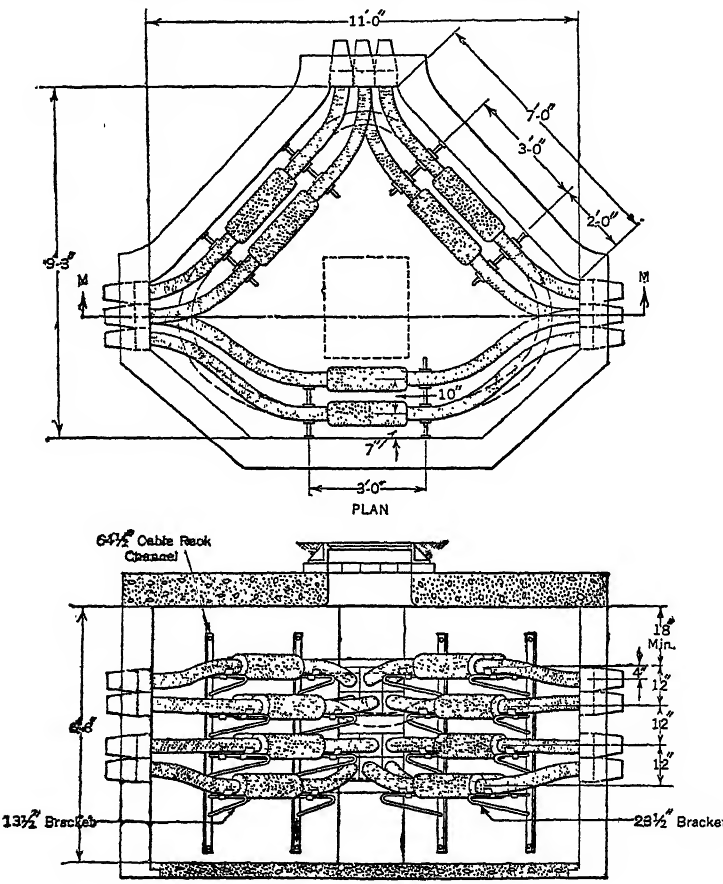

Fig. 6

MANHOLE FRAMES AND COVERS. Manhole frames are usually made with two covers, the outer of which should be strong enough to stand the weight of the heaviest vehicle, and the inner should be as light as consistent with the rough usage the frames receive in handling. Both covers should be provided with means to grip them with a hook-bar. Where power cables are used, it is essential to provide ventilating holes. Some companies lock the inner cover with a locking bar and substantial brass padlock with protected keyhole.

Round manhole covers are preferred to square, because they cannot slip through the hole. The hole in the frame should not be over any cable and should be well located to

give a clean sweep of cable in installation. A ratio of 1 sq in. of holes to 30 sq in. of cover is a good balance between strength and ventilation. A typical design is shown in Fig. 7.

The (clear) diameter of the opening is usually either 22, 24, 27, or 30 in., except for transformer vaults, where sizes 33, 36, 42, and 48 in. are used.

Frames with inner covers are 11 in. high; those without, 7 in.

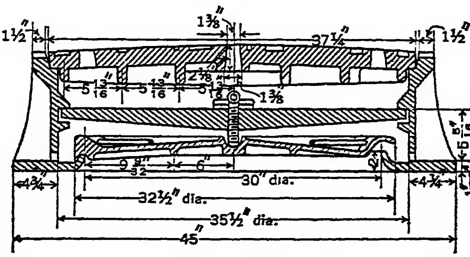

FIG. 7

WATERPROOFING AND DRAINAGE. There is some diversity of opinion with regard to the value of waterproofing splicing chambers, although the modern practice is to omit waterproofing and provide effective drainage.

Every chamber should be provided with a sump into which the water can drain, Fig. 8. It is desirable to connect the sump to the sewer through a syphon and backwater valve. If this is not practicable, the sump may be drained through the manhole opening by a hand pump.

Where natural drainage cannot be secured, as, for example, where the chamber is below the sewer level, it is good practice to provide a special drain pipe to which all the chambers

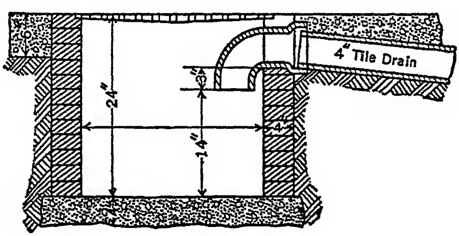

FIG. 8

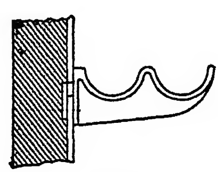

FIG. 9

are connected, the drainage being towards a general sump pit, which is kept dry by an automatic sump pump.

The sump of a splicing chamber should be covered with an easily removable grating; wooden ones are often used on account of their property of floating when the chamber is flooded, thereby leaving the sump open for the pipe of a hand pump.

CABLE SUPPORTS. Cables in splicing chambers are usually supported on iron brackets which engage steel uprights imbedded in the chamber walls, as shown in Fig. 9.

37. GENERAL DESIGN OF CONDUIT LINES

The duct line design should take into account the facility of heat dissipation from the cables to the earth. Assuming all ducts to be equally loaded, the ratio of the temperature rise of the hottest inside duct air to that of the coolest outer duct air will be 1.6 for a 2 wide by 6 deep bank and 2.5 for a 3 wide by 4 deep bank. The 2 by 6 construction, having all ducts outside, is the ideal type; and where the 3 by 4 type is used, the center ducts are commonly used for control, telephone, and pressure wires which are not heat-producing.

Sufficient spare ducts to take care of probable load increases and extensions should be provided.

Curves should be as gradual as possible. Tables IV and V give the recommended minimum lengths of curve to take care of offsets in the conduit line.

Manhole lengths are determined from the following details. The parts occupied by cable curves are usually based on radii of curvature of 7 1/2 times the cable diameter. The

straight part is the sum of the splice length, something slightly over the sleeve length, to allow for disposal of the sleeve in splicing. There should also be allowance for curves to change levels, horizontal bend space in L manholes, and expansion clearance to duct edge.

Network manholes must be specially designed to provide space for the network switches and apparatus.

38. RODDING AND WIRING OF CONDUITS

The only test which it is usual to apply to conduit lines is rodding with a mandrel in order to ascertain whether the ducts are continuous and unobstructed.

The rods used for this purpose are of hickory about 1 in. in diameter and 3 or 4 ft long and are fitted at the ends with steel couplings such as shown in Fig. 10. The first rod is attached to a mandrel and pushed into the duct. Another rod is coupled to the first and the pair pushed further into the duct. By successively coupling other rods and pushing them into the duct, the mandrel is made to travel from one chamber to another. As soon as the mandrel emerges into the receiving chamber, the rods are pulled through, dragging a cleaner, and uncoupled. If an obstruction stops the

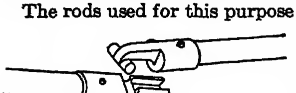

Fig. 10

mandrel, an attempt is made to force it through by repeated blows with a cutting tool attached to the rods, failing which, it becomes necessary to cut into the conduit line from the side.

MANDRELS FOR RODDING. Various types of mandrels are used for testing and clearing ducts, some hollow and smooth with sharp cutting edges (Fig. 11), and others

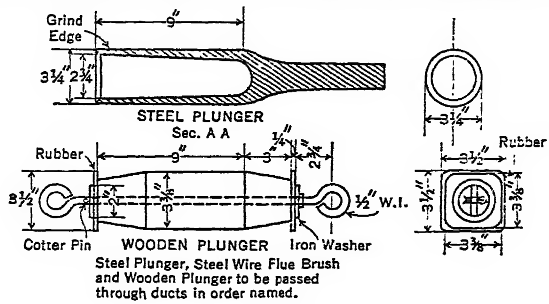

FIG. 11

fitted with numerous sharp projections and known as hedgehogs (Fig. 12).

WIRING THE DUCTS. It is usual to attach a galvanized steel wire (No. 8, 10, or 12) to the last rod and leave the wire in the duct after the removal of the rods. The ducts may also be "wired" by the use of a conduit machine. This consists of a reel of steel tape and means for winding and unwinding the tape into the duct at the rate of about 10 ft per sec. This tape or "snake," having been pushed through the duct, is pulled out again with the wire attached to its end. In recent years a piston pushed through the duct by compressed air has found favor.

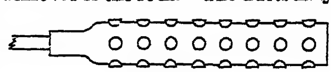

FIG. 12

39. SPECIFICATIONS FOR CONDUIT LINES

Many cable failures occur from injury to the lead sheaths during installation. Sharp projections in the ducts should therefore be carefully guarded against, as a cable pulled over such a projection will have a groove cut along much of its length and the effective thickness of the sheath will be thereby materially reduced. It is a matter of practical importance to give each duct length a rigid inspection before installation, rejecting any which have roughness or irregularity. Scarcely less important is rigid inspection during installation, in order to assure cleanliness and good alignment.

DETAILS OF CONSTRUCTION. The following items should be covered:

Tile Ducts:

Single-way, or four-way.

Holes circular or square with rounded corners.

Inside diameter and tolerances.

Outside diameter and tolerances.

Freedom from blisters, cracks, and other imperfections which, in the opinion of the engineer, will tend to injure the cables to be accommodated therein.

Good-quality tile, thoroughly glazed inside and outside.

Shall be straight and true.

Shall be provided with holes for dowel pins if ducts are four-way. Dowel pins may also be called for. The sides of single duct conduits shall be combed with two (2) sets of three (3) longitudinal combings each, each combing to have a width of one-quarter ($^1/_4$) inch and a depth of one-sixteenth ($^1/_{16}$) inch. Multiple-duct conduits shall be scored transversely near the ends.

Nominal length and tolerances. It is usual to call for a certain percentage of shorter lengths (generally 1 per cent), in order to finish runs or stagger joints.

Fiber Ducts:

Nominal inside diameter and tolerances.

Minimum wall thickness.

Nominal lengths and tolerance.

Shall be straight.

Type of joint.

Ability to resist warm water, oil, acid, alkali, and temperatures up to 80 deg cent. Suitable tests are suggested in Underground Systems Reference Book of N.E.L.A.

Cement Mortar:

Stated proportions of cement and sand (usually 2 $^1/_2$ to 1 of cement).

Concrete mortar shall not be laid in freezing weather, and shall not be used after initial set has taken place.

Excavation:

Shall always be of such depth as to leave a stated minimum distance between the top of the concrete over the conduits and the surface of the ground.

Ground on which conduits are laid shall be rammed solid before any concrete is laid.

Refilling Excavations:

The best part of the material excavated shall be used.

Surplus material shall be carted away by the contractor (or will be carted away by the company).

Filling shall be thoroughly tamped and rolled, or flushed, as seems necessary to the engineer, and shall be done in a manner to prevent, as far as possible, a settling of the earth after completion.

Obstructions:

Obstructions encountered in the course of the work shall be overcome in a manner to be approved by the engineer.

Laying Conduits:

Shall be laid with ends square so as to leave a tight, well-fitting joint.

Joints shall be staggered horizontally and vertically.

Ducts shall be laid in a bed of cement mortar of about $^1/_4$ in. thickness.

Each joint of tile duct shall be wrapped with two strips of burlap, muslin, or cheesecloth, 6 in. wide and coated with either asphaltic cement or neat cement mortar, the ends of the wrap to lap 4 in. (It will insure more careful work if it be specified that the contractor shall supply rubber gloves to the men who lay the burlap.) Where conduits are laid on curves, the wraps shall be doubled if required to protect the openings between the ends of the ducts on the outside of the curve, and to exclude mortar from said openings. (Wrapping is not universal. If another method is to be used, corresponding details should be given.)

Tile ducts shall be laid with a mandrel of specified length and width and provided at one end with a rubber washer for wiping the joints. Tile ducts shall be laid on a bed of concrete of stated depth, usually 3 in., shall be covered at the top with a stated depth of concrete, usually 3 in., and shall have a stated thickness of concrete on each side. Where the conduit line goes under railroad tracks, the concrete shall be suitably thickened and reinforced.

If tile ducts are four-way, they shall be laid with dowel pins at joints.

The alignment horizontally and vertically shall be satisfactory to the engineer.

Drainage of Conduit Lines. The grade of all conduit lines shall be such that water cannot stand in the ducts but shall drain into one or both splicing chambers.

Brick:

Shall be of good commercial hard-burned sewer brick, or other stated variety.

Concrete:

Stated proportions of cement, sand and stone (usually 1 part of cement, 2 parts of sand, and 4 parts of stone).

Maximum size of aggregate (usually $^3/_4$ in.)

If wraps are not used at the joints of tile ducts, the sand and cement shall be mixed dry and wetted with only sufficient water to make a stiff paste. If wrapped tile or fiber duct is used, the concrete may be of normal consistency. The stone having been previously wetted shall be added while wet and thoroughly mixed until all the stones are covered with mortar. It shall then be deposited as rapidly as possible. Machine-mixed concrete will be accepted if made in a manner approved by the engineer. (See Art. 40 under Laying Conduits.)

Terminals of Conduit Lines. Whether they go into power stations, etc.

Splicing Chambers. Shall be built according to plans supplied, unless local conditions interfere, in which case the suggested modifications shall be approved by the engineer.

State any details pertaining to the design of the chamber, duct windows, and cable supports which may not be clear from the plans.

Details of sewer connections or other drainage system should be clearly stated.

RODDING, CLEANING, AND WIRING.—After the conduits are laid and the cement is sufficiently set, they shall be rodded, and the contractor shall draw after such rods, wire brushes and a mandrel of specified dimensions. All mortar and other foreign matter shall be removed. If obstructions are found which cannot be removed by cleaners so as to pass the specified mandrel, the ducts shall be removed and relaid. Any expense incurred by such work shall be borne by the contractor. A galvanized wire of stated size shall be left in each conduit from splicing chamber to splicing chamber, and sufficient length shall be left at each end to permit it to be bent in order to prevent it from slipping into the duct.

40. INSTALLATION OF CONDUIT LINES

The problems connected with the installation of conduits vary greatly with the local conditions. They involve the choice of methods of trench excavation, drainage methods, removing or avoiding obstructions, concrete mixing, and so on. The following details are gleaned from first-class examples of the various kinds of work described but should in no sense be regarded as standard.

CROSS-COUNTRY CONDUIT LINES. Excavation for conduit lines in the country and suburban districts may often be made partly by a trenching machine and partly by a trench plow. A typical trenching machine of the " caterpillar " type will dig a trench 18 in. wide and 3 ft deep at the rate of 3 ft of clean trench for each minute of actual working time. An operator and two assistants are required to operate the machine, replacing, it is estimated, 50 laborers.

A wheel-type trenching machine has also been successfully used. This machine has a cutting wheel 7 1/2 ft in diameter, digging a trench 15, 18, or 21 in. wide and with a maximum depth of 5 1/2 ft. The machine weighs 9 tons and is operated, at a speed of 3 1/2 ft per min, by an operator and one helper.

CONDUIT LINES FOR RAILROADS are usually difficult to construct and operate for the following reasons:

1. Owing to the right-of-way being usually on made ground, excessive quantities of concrete and reinforcement are required to make a reasonably strong duct construction.

2. Owing to the width of the right-of-way being usually very restricted it is necessary to shore-up tracks in order to excavate close to them.

3. Owing to the vibration caused by heavy trains, it is necessary to bury the conduits at a greater depth, first to avoid undue stress on the conduit, and second to avoid intercrystalline fracture of the cable sheaths.

In order to have the conduits below the frost level, the depth of ballast must be neglected, as it has been found that, with stone ballast on top of the ground, the frost penetrates the ground about as far as if the ballast were not there, unless the ballast is very dirty.

4. There is considerable difficulty in obtaining best results from labor where there are continual interruptions from trains. On a busy section a duct construction gang engaged for 10 hours can possibly work 2 full hours.

5. Owing to the right-of-way being often quite low, in many cases alongside of rivers, duct construction is likely to be seriously impeded by the flooding of trenches.

6. Where the right-of-way shows signs of settlement, as, for example, on marshy ground, continuous piling is necessary to support the ducts. This involves the use of the track for construction purposes for long periods, and thereby not only impedes but also endangers traffic.

7. Duct-line construction generally involves interference with signal and interlocking apparatus, thereby introducing danger and expense.

8. Bridge abutments, bridges, culverts, and in fact all special right-of-way construction, present complicated problems which can be solved only at great expense.

CONDUIT LINES IN CITIES. The obstructions due to sewer, water, and gas pipes, car tracks, and foreign conduit lines render conduit construction in city streets a complicated problem. Plans made in the office can seldom be followed, without change, in the field, as municipal pipe plans are seldom exact, and the supervision of an experienced civil engineer is needed to solve the numerous problems which constantly arise. Excavation is almost invariably performed by hand labor, and when the conduits have been laid in covered with concrete, it is common practice to lay a plank over them in order to warn future excavators. Obstructions are often avoided by changing the grouping of the conduits.

LAYING CONDUITS. Conduits must be laid so that joints are mechanically strong and the ducts unobstructed. With this in view, joints should be staggered horizontally

and vertically. Some engineers require a muslin or cheesecloth wrap, 6 to 8 in. wide, at each joint, to keep out concrete, especially at curves. This is applied either with asphaltum cement or thin cement mortar. When wraps are used, the ducts may be laid in a thin concrete or mortar. As this may enter through the flutings, there is a general tendency to omit wraps and use a stiff concrete or mortar. The ducts are spaced with only sufficient cement mortar between, to bed them properly and fill the voids.

The ducts are laid on a concrete layer about 3 in. thick and covered all around with 3 in. of concrete.

When laying tile ducts it is necessary to have a long mandrel to remove loose cement. This mandrel is usually provided with a rubber washer at the rear, and a hook-eye at the front end. The conduit layer is provided with a hook rod by means of which he draws the mandrel after him as he lays the conduit.

It is general practice to lay fiber ducts with at least 1 in. of concrete separation, in order to lessen the danger of electrical faults spreading. Three inches of concrete are placed all around the duct bank.

FOUR-DUCT CONDUITS are usually provided with holes for dowel pins by means of which the ducts are aligned. The joints are wrapped in burlap soaked in asphalt and afterwards painted with asphalt. No mandrel is used in this type of construction.

CONCRETE COVERING. However the conduits may be laid, the complete group is always inclosed in concrete to secure rigidity and protection, and the finished ducts are cleared of rubbish and obstructions by pushing a steel plunger through them by means of the rods described above. A steel plunger for this purpose is shown in Fig. 11, in which is also shown a wooden plunger with rubber washers, which should be drawn through the ducts to collect the loose particles left behind the steel plunger.

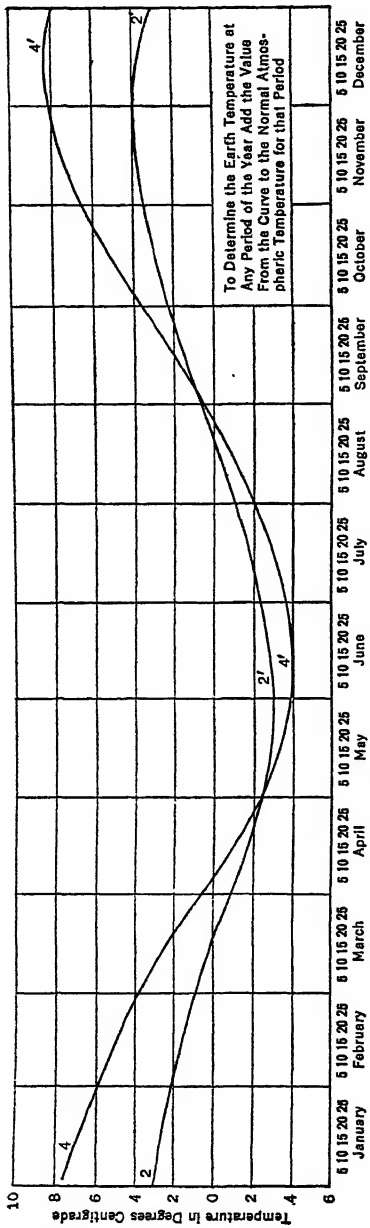

FIG. 13. Earth Temperature Curve (N.E.L.A. Report)

41. MAINTENANCE OF CONDUIT LINES

The principal items of conduit-line maintenance are those relating to keeping the line clean and safe, namely, pumping out water, blowing out gas, removing mud, opening and closing manholes for the benefit of cable workers, and inspecting the line to guard against theft and injury. Generally, large systems have one or more wagons equipped with apparatus required for these purposes, and men ready to go out with it upon emergency calls.

Removal of Water is usually the most important of maintenance items, especially where no drainage system is installed. When cable accidents occur, it is important to have the chambers accessible without delay, and a portable pump is required. For this purpose a small gasoline or electric pump is useful, having a capacity of about 50 gal per min.

Ventilation does not occur naturally in conduit lines, because the cold air contained in them has no tendency to rise. Noxious gases therefore tend to accumulate in splicing chambers, endangering workers and making explosions possible. No permanent system of ventilation has proved successful for general use, as it is found that pressure is maintained only at or near the blowing points. When it is necessary to blow out the chambers, it is therefore usual to employ a portable blower in conjunction with an air-tight false manhole cover.

TEMPERATURES. Cooling duct lines is sometimes desirable in order to increase the carrying capacity of the cables in them. L. E. Imlay accomplished this at Niagara by keeping the surrounding soil moist. The Duquesne Light Co. of Pittsburgh installed several blowers each of 600 cu ft per min capacity and forced air into alternate splicing chambers. A reduction of temperature from 125 to 96 deg fahr was obtained.

An N.E.L.A. Report gives the following data on earth temperatures.

1. The earth temperature varies with the depth below the surface, the maximum temperature decreasing and the minimum temperature increasing with the depth below the surface.
2. The temperature at the same depth varies, owing to the influence of the soil conditions, adjacent sources of heat, and the heat received from solar radiation.
3. The earth temperature at one particular locality seems to repeat itself with reasonable accuracy each year, following a cyclic almost sinusoidal curve (Fig. 13).
4. Paving, and a high percentage of moisture in the soil, ordinarily increase the maximum summer and decrease the minimum winter temperatures.
5. Below some depth, which may be somewhere between 25 and 80 ft below the surface, the earth temperature has no seasonal variations.
6. The maximum and minimum earth temperatures lag the corresponding air temperatures by a period which increases progressively with the depth, the lag at the surface probably being practically zero.

Fig. 14 gives data on the amount of air required for transformer manhole ventilation.

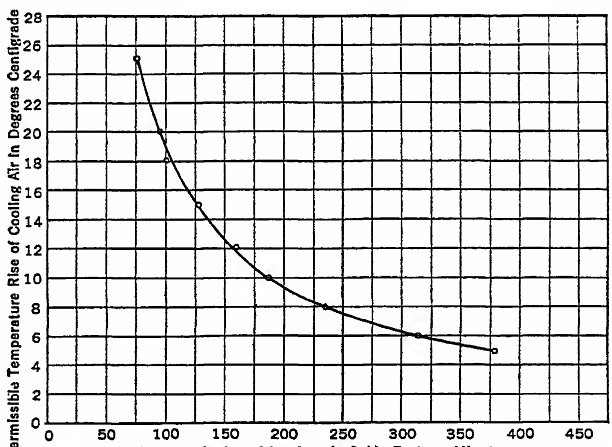

FIG. 14. Air for Manhole Ventilation (N.E.L.A. 1929)

Electrolysis is more fully treated in the article on Electrolysis. It should be noted that the prevention of electrolytic corrosion of cable sheaths depends more upon efficient drainage than anything else.

Corrosion of Lead Sheaths by lime is likely to occur if ducts are used before the concrete has been leached out by ground or rain water.

REPAIRS. The principal repairs to conduit lines are those due to settlement and to damage done by adjacent building operations, such as the construction of sewers or railway tracks. It is sometimes desirable to replace the conduit lines without disturbing the cables they contain. In such cases, the conduits are broken, the utmost care being taken to avoid injuring the cables. New conduits are then relaid on a firm foundation, after having been split longitudinally so as to fit over the cables. The whole construction is then rendered rigid by being inclosed in concrete.

DISTRIBUTION

By W. A. Del Mar

This section covers the distribution of energy for light and power from substations to customers' premises.

A distribution system consists of two parts: the **primary distribution**, which extends from substation to distribution transformers; and the **secondary distribution**, which extends from these transformers to the customers' premises, the latter being at the utilization voltage.

Two types of construction are employed, overhead and underground. Overhead construction has the following advantages (1) lower first cost, (2) easier to repair, (3) easier to change; underground construction has the advantages (1) less unsightly, (2) less dangerous to the public, (3) less subject to damage by external agencies. The majority of circuits in use are overhead. Underground circuits are principally used in the central portions of the larger cities. When underground circuits are used a large part of the construction consists of a composite of underground and overhead construction.

43. DISTRIBUTION CIRCUITS

Primary Systems

Primary distribution systems are usually 2300/4000 volt three-phase circuits with grounded neutrals. Various other systems are in quite extensive use, however, to meet special conditions, such as

2300	volts	delta
13,200	"	delta
6600/11,000	"	Y
4600	"	delta
2300	"	2-phase

RADIAL DISTRIBUTION. Radial distribution is a system of supplying power from a substation to a district by means of one or more feeders to which mains are connected. These mains run to the distribution transformers.

1. Radial Main. A feeder from a substation runs to a point near the load center of a district and mains branch therefrom to the distribution transformers, Fig. 1. This type of feeder is most suitable for areas of medium low load density. It permits the use of three-phase equipment over a large territory and load may be balanced between phases.

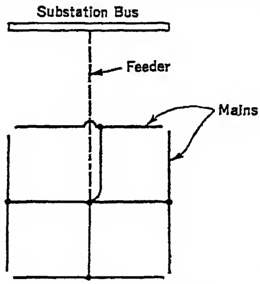

FIG. 1. Radial Main

The **tree** or **herringbone** type of feeder is where the feeder supplies the mains at a point near the substation instead of near the center of the load. Its application is principally in small towns and rural districts as the regulation and losses are greater.

2. Feeder and Main. A sectionalized main (4 conductors) runs through a district, and laterals run from each section to the distribution transformers, Fig. 2. Each section of the main is fed by a separate feeder from a substation, not necessarily the same substation.

This is the best type of circuit for narrow districts of medium load density with laterals reaching out to adjacent lower density load areas. The phases may be readily balanced and extensions made with little new construction. During low load periods, the feeder may be taken out of

service and the main tied to an adjacent main section. This permits maintenance of feeders and switches without interruption of service.

3. Segregated Phase. This is similar to the radial system except that each phase is run in a different direction and handles all the load in a definite phase area, instead of carrying the three phases into each district.

This type circuit is most economical for districts of low load density covering a considerable territory. It is difficult to balance phases, and three-phase equipment cannot be generally used. Extensive rearrangement is necessary to take care of added load.

4. Duplicate Service. This is a modification of the radial system, where each customer transformer is fed by two mains, one operating, and the other for emergency, Fig. 3. This system is used for important load areas where continuity of service is very important. It permits taking feeders out of service without serious interruption of service.

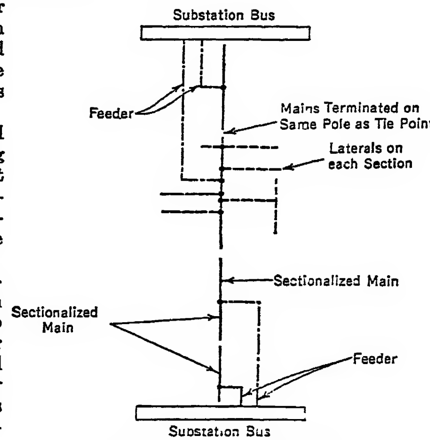

FIG. 2. Feeder and Main

Two oil switches or sets of fuses are required at each installation. It is the general opinion that, for supplying business areas, this system is seldom preferable to a multiple primary feed secondary network.

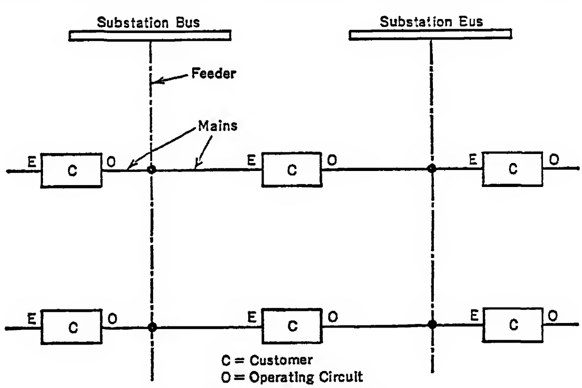

FIG. 3. Duplicate Service

LOOP DISTRIBUTION. Loop distribution is a system of supplying power from one or two substations by means of a sectionalized feeder which is fed from both ends.

1. Customer's Loop. A feeder extends from a substation to a group of customers connected in series and either back to the same substation or to one adjacent, Fig. 4. Protection equipment is provided on both sides of each customer's service.

2. Distribution Loop. A feeder extends from a substation to a number of automatic sectionalizing switches in series, Fig. 5. Lateral mains run from each section of the feeder. The loop is relayed with time delay relays or pilot wire protection so that the two switches nearest the trouble will open, leaving only that section out of service.

Either loop system is very reliable for combined power and light loads. It necessitates two oil switches at the substation for each circuit.

NETWORK. A number of radial transmission circuits extend from a substation each to a step-down transformer bank. The secondary of such bank, presumably at 4000 volts, would be connected to a bus through an automatic oil switch, from which lines extend in four directions, each tying with a similar bus some distance away. These tie lines, from which laterals would be installed, are protected by an automatic oil switch at

each end. Distribution transformers would be connected to these ties and laterals Fig. 6.

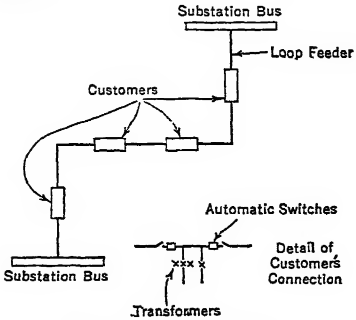

FIG. 4. Customers' Loop

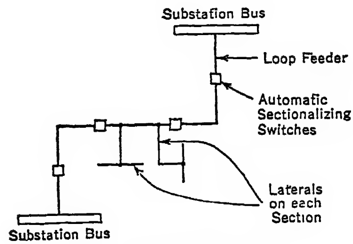

FIG. 5. Distribution Loop

This system permits a very reliable source of supply for moderately loaded areas where the service rendered by a secondary network is desirable but the load does not warrant its adoption.

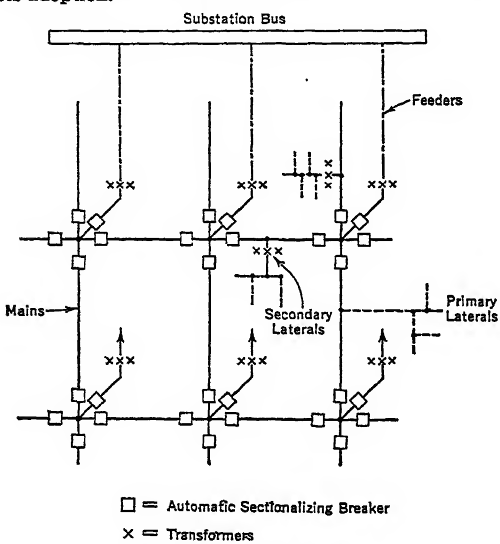

FIG. 6. Primary Network

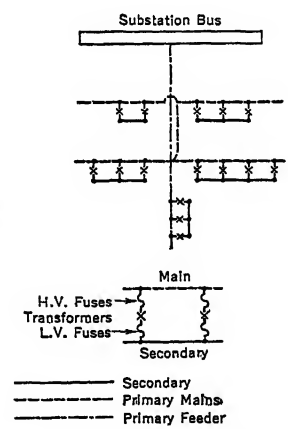

FIG. 7. Secondary Network with Radial Primary Feed

Secondary Systems

Secondary distribution systems are usually at 110 or 120 volts.

RADIAL. Radial distribution is a system of supplying power from distribution transformers to customers where a number of isolated secondaries are each supplied by one transformer or transformer bank.

NETWORK. Network distribution is a system of supplying power from distribution transformers to customers where several transformer banks feed into an electrically solid network of secondaries. Networks are used both for overhead and underground distribution, although those for the latter purpose are more common. The 3-phase, 4-wire system is usual, with small customers supplied by single-phase, 2-wire, 120-volt circuit. The secondary network may be associated with the following primary feeding systems.

Radial Primary Feed. Several sets of transformer banks common to the same primary and secondary lines are banked with protection on both the primary and secondary sides, Fig. 7. This ensures service on the secondary in the event of a transformer having failed. This system is especially suitable for overhead territories.

Multiple Primary Feed. All distribution transformers are tied solidly to a primary feeder of the radial type and in turn tied to a common secondary bus through automatic low-voltage network protectors (Fig. 8).

Multiple primary feed is especially adaptable to concentrated business areas, where continuity of service is of major importance. Any primary feeder may be out of service without materially affecting the transformer loadings or secondary voltage. It also permits the combination of light and power on the same secondary.

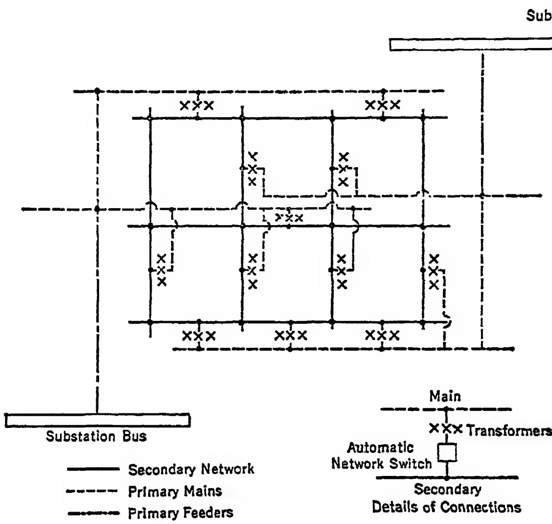

FIG. 8. Secondary Network with Multiple Primary Feed

Loop Primary Feed. All distribution transformers are tied to protected sections of a sectionalized loop feeder (Fig. 9). Such an installation does not necessitate so much spare transformer capacity, as only a small section of a feeder may be out in the event of a primary feeder failure.

Network Protectors and Cables. Network protectors are automatic circuit breakers between the distribution transformers and the secondaries. They are made in the submersible and non-submersible types to suit manhole conditions and are relay-controlled circuit breakers of either the solenoid or motor type, the former being generally used for ratings of 250 to 800 amp, and the latter for larger ratings. The relays are of the reverse-power type with low settings and function to open the breaker when there is a reverse power flow from the network to the transformer, thus isolating the primary circuit on which a fault has occurred without an interruption to the network. The relays also automatically reclose the circuit breaker when the voltage and phase relation are such as to feed power into the network.

Secondary network cables are usually 250,000- to 500,000-circular-mil single-conductor cables. These are tied solidly together at the intersections and connected to the transformers by 1,000,000-circular-mil cables.

Network voltage regulation methods include bus regulation and feeder regulation, the former for high-voltage primary feeders and the latter for 2.3/4.0 kv lines.

The permissible regulation at the customer's services varies from 1 to 8 per cent, the usual value, however, being 3 per cent.

The 120/208 volt system of secondary voltages is the most favored, but the following are also in use: 115/199, 115/230, 117/202, 120/208, 120/240 volts.

Any short circuit which is likely to occur will be burned off and cleared from the system. A current of 1740 amp will fuse the conductor of a 250,000-circular-mil cable in about 20 minutes. A current of 5000 amp will clear a 500,000-circular-mil cable. Fuses are used at remote parts of the network, where the current capacity of the system is insufficient to melt off a secondary cable.

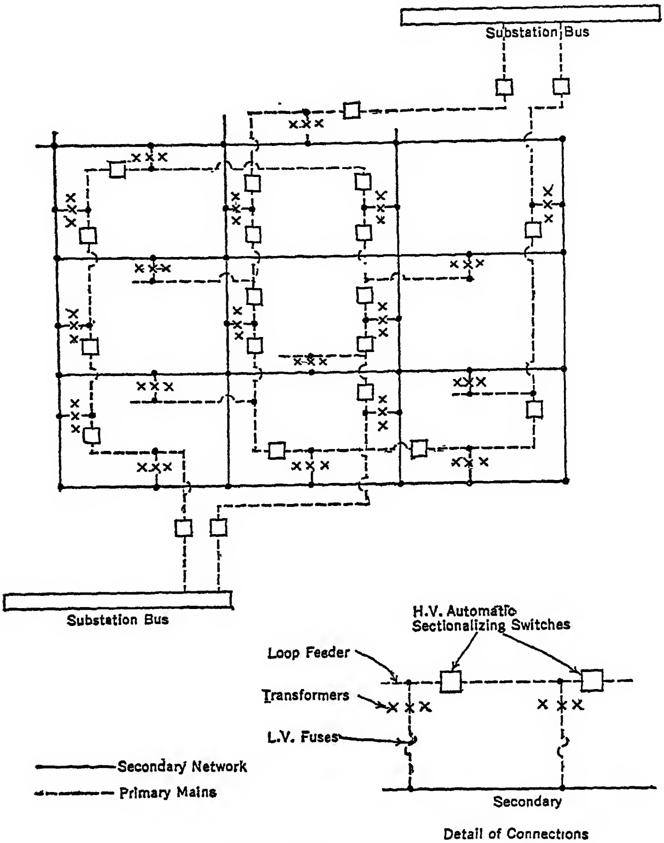

FIG. 9. Secondary Network with Loop Primary Feed

44. OVERHEAD DISTRIBUTION

Line Materials

CONDUCTORS. Overhead distribution is usually effected by means of weatherproof wire, i.e., copper wire covered with saturated braids. The usual sizes are Nos. 4 and 6 A.W.G., but larger sizes, up to 500,000 circular mils, are often used. Medium hard-drawn copper is preferred by most companies, but annealed copper is used to a large extent for spans up to 150 ft.

Special rubber-insulated service cables are often used for secondary distribution, and special rubber-insulated wire, known as tree wire, is used where the distribution lines have to run through dense foliage.

COVERING ON OVERHEAD WIRES. The covering on overhead conductors is solely for the purpose of limiting the short-circuit current due to an accidental cross or grounding. The normal insulation of the line is maintained by the insulators alone; any reinforcement obtained from the insulation on the conductors is neglected in practice. While weather-proof braid is an imperfect insulator, it serves to eliminate the greater proportion of the short-circuits and arcs which would occur, due to momentary contact, were bare wires used.

Bare wire is generally used on circuits operating at 10,000 volts and above to avoid giving a false sense of security. For voltages between 2500 and 10,000 weatherproof wire is often used, though the protection afforded against short circuits is doubtful.

INSULATORS FOR OVERHEAD LINES. City distribution circuits are ordinarily carried on double-petticoat deep-groove glass (D.P.D.G.) insulators; see Art. 28.

Tie Wire. The conductor is attached to the insulator by a tie wire of the same material as the conductor, though soft wire is usually employed even for hard-drawn conductors; the tie wire is either bare or insulated to correspond to the conductor. The size of tie wire is often the same as that of the conductor; for small wires it is merely a piece of conductor. With large conductors it may be as much as three sizes smaller. See Art. 30.

Design of City Overhead Distribution Lines

City distributing systems should be designed so that service may be given to any building in the city and ultimately to every building present and future. On certain streets pole lines may be omitted without defeating this object. The arrangement of lines which will serve scattered customers with the least number of poles will usually contain many poles which should not be used if the ultimate arrangements were immediately constructed. Preliminary studies and designs should be made, first, of arrangements suitable for servicing the initial expected customers; second, of arrangements for ultimately servicing customers on every lot in the city; third, of a plan of extension by which the initial arrangement can be extended to the ultimate with the minimum expense in changing lines and services.

THE POLE LINE. The pole lines perform two functions: (1) of carrying feeders from the station to the mains, and (2) of carrying the mains supplying services to buildings immediately adjacent. In old cities where the streets are crooked, general rules for systematic line work cannot be followed far. In the newer cities the streets are laid out at regular intervals and at right angles, dividing the city into rectangular blocks of equal size. In such cases the following rules should be followed:

1. A pole line should continue on the same side of the street throughout its entire length and disconnected lines built in the same street should be on the same side, so that they may be connected when desired without crossing the street.

2. The spacing between poles should be an exact divisor of the length of a block (including cross street), giving a uniform number of poles per block.

3. Whenever the line crosses a street where there is, or may be, an intersecting line there should be a corner pole on the proper side of the intersecting street for making a junction.

Trunk Lines. If the location of power house or substation is fixed, trunk lines must be laid out from such point, but often a study of possible trunk-line arrangements made before the location of the power house is fixed will show that other locations are more advantageous. If distributing station (power house or substation) is centrally located, there should be at least four main trunk lines (of poles) from it, say north, east, south, and west. A short distance from the station they should be divided into branches, then subdivided into smaller branches, and finally merged into the service lines. The trunk lines should be laid out: (1) on back streets where the large poles, numerous and heavy wires, and heavy guying will not be conspicuous; (2) on side streets or streets little built up so that interruption to service due to fire in adjacent buildings will be infrequent; (3) on streets where there are few trees; (4) on streets where there are no jogs or offsets to weaken the line and require heavy guys; (5) on streets which lead directly to the section supplied, penetrate its center, and intersect the maximum number of service lines. Even when the station location is excellently chosen these desirable conditions will have to be compromised to a considerable degree.

Street and Alley Service Lines. With the symmetrical arrangement of lots described above there is often an alley through each block parallel with the principal streets. Under these conditions there is therefore a choice of two methods of laying out the lines: (1) run the lines on the principal streets servicing the houses from the front, and (2) run the lines in the alleys servicing the houses from the rear. The disadvantages of the first are unsightliness of the poles and wires, difficulty of avoiding or of trimming shade trees; the disadvantages of the second are discontinuity of alleys, proximity of buildings (inflammable barns and outbuildings in residence districts and of windows and fire escapes in business districts), and lack of established grade.

COMPOSITE DISTRIBUTION. Where underground distribution is used it is sometimes desirable to have overhead services. In such cases a pipe runs from the conduit line into the interior of each block, where the pipe comes to the surface at the foot of a terminal pole up which the cables run. At the top the cables connect to overhead wires. The interior of each block contains a complete overhead distribution system of poles, transformers, secondary mains, and services. Sometimes the servicing is done from a single centrally located pole; at other times there may be a pole line of several spans length run-

ning longitudinally through the block. The most serious disadvantage of this method is that the poles and wires frequently have to be on private property, where no permanent rights may be obtained.

The composite system has the advantage of the overhead system in less unsightliness, less accessibility of public to high-voltage wires, and less trouble from trees. In thickly built-up blocks its use results in a tangle of wires over roofs and along walls which may be as dangerous in case of fires or high winds as an overhead system. The composite system is used (1) in small cities where the load density is small, and (2) in large cities in an annular district between overhead and underground construction; in either case it is usually an intermediate step from overhead to underground construction.

CROSSING OF WATERWAYS; SUBMARINE CABLES. Where a distributing system is divided by a navigable waterway the connection is usually made by submarine cables laid on the surface of the bottom, or better, below the surface in trenches dredged for the purpose. Cables may be single or multiple conductors, the latter being usually used for alternating currents to avoid reactance due to wire armor of cable. In laying cables it is desirable to keep them approximately parallel. Where one crosses under another it may be impossible to remove it. Each cable should be in a single length without joints, and the length should be made as short as possible, as repairs are very difficult and often impossible. At ends unimportant cables may be brought up a pole and connected to overhead wires; important cables should land in a splicing chamber with suitable provision for disconnecting the cable or for transferring the overhead circuit to a spare cable in case of trouble. Submarine cables are weak links in a distribution system and may sometimes be avoided by aerial crossings at sufficient height to clear the masts of ships.

CALCULATION OF SIZE OF WIRES. The size of wire to be used depends upon the voltage drop which should be permitted, considering the probable growth of the load. The following table of per cent voltage drop in the various lines is representative of ordinary practice.

	Per Cent		Per Cent
House wiring	2	Transformers	2
Service wires	2	Primary mains	5
Secondary mains	5	Primary feeders	10

The drop in the feeders is usually compensated for by raising the voltage at the substation or power station or by using voltage regulators.

Formulas for calculating the size of wire for a given length of line, given load, and given distribution of load are given in the chapters on Electrical Design and Wiring of Buildings. On account of the uncertainty regarding the probable increase of load, a close calculation of the size of wire is seldom made, the engineer relaying largely on his experience and judgment, making only a rough calculation as a check.

EFFECT OF DIVERSITY OF FACTOR. It should be noted that in a distribution circuit the maximum load on a feeder is less than the sum of the maximum loads on the mains which it feeds, these in turn are less than the sum of the maximum loads on the transformers connected to these mains, and so on. Therefore, whenever a circuit divides or subdivides, the aggregate sectional areas should ordinarily be greater after division than before. The total drop in voltage from power house or feeding point to a customer's lamp or motor is also usually less than the sum of the maximum drops in the parts of the circuit which are in series (such as house wiring, services, secondary mains, etc.) because these component drops do not have their maximum value simultaneously.

Poles

ARRANGEMENT OF WIRES ON POLES.—The arrangement of wires is governed by mechanical, electrical, and practical considerations. For mechanical reasons it is desirable that:

1. The largest wires be on the lowest cross-arm, in order to reduce the bending stress on the pole to a minimum.

2. The largest wires be on the pins nearest the pole, in order to reduce the bending stress on the cross-arm to a minimum.

3. The wires be arranged symmetrically on the two sides of the pole, especially those which end at the pole, in order to reduce the twisting stress on the pole to a minimum.

For electrical reasons (which, however, are of minor importance) it is desirable that:

4. The wires of any one circuit be as close together as practicable (on adjacent pins), in order to reduce the self-inductance of the circuit.

5. The wires of a three-phase circuit be arranged to form the edges of an equilateral prism and the wires of a two-phase circuit be arranged to form the edges of a square prism, in order to render the inductances and capacities of the wires respectively equal.

6. The wires of different circuits be placed as far apart as practicable, in order to reduce their mutual inductance.

For practical reasons it is desirable that:

7. The highest voltage wires be on the top cross-arms and on the pins farthest from the pole, in order to reduce the danger of accident to linemen.

8. The mains, which have the greatest number of taps, be on the lowest cross-arms, in order to avoid danger of accidental crossing (with contact) of the wires.

9. The arrangement be systematic throughout; this is absolutely essential for safe and economical operation.

As it is impossible to meet all of these conditions the actual arrangements used are compromises and are governed by the relative importance attached to the several desirable conditions. In some cases the electrical requirements (4) to (6) have been considered of most importance, resulting, for example, in an arrangement subordinated to the idea that the three wires of a three-phase circuit must be arranged exactly in an equilateral triangle. It appears, however, that these electrical requirements are really the least important of the considerations and that in most practical cases can be entirely neglected.

TRANSPOSITIONS. Due to the effect of mutual electromagnetic induction an alternating or varying current flowing in one circuit will induce a voltage, and therefore a current, in any parallel circuit; and due to the effect of mutual electrostatic induction (see Capacitance) an alternating or varying voltage in one circuit will induce currents in a parallel circuit, even though there is no metallic connection between the two circuits. It is possible, however, by properly transposing equal alternate lengths of the wires forming the two sides of each of the parallel circuits, to neutralize these effects. Fig. 10 shows diagrammatically a scheme of transposition whereby a two-wire circuit can be protected from both electromagnetic and electrostatic induction from a parallel circuit and vice versa, provided neither circuit is grounded. The more frequent the transpositions the more thoroughly are the effects due to inequality in the spacing of wires and poles eliminated. Transpositions cannot be made effective in eliminating inductive effects when either circuit is grounded, otherwise than at the neutral point. See also Art. 30.

Fig. 10

Methods of calculating the induced voltage and induced currents in one line due to currents and voltage in a neighboring line are indicated in Art. 22.

TREES. Trees constitute a serious obstacle to the proper construction and operation of overhead lines. The principal methods of meeting this difficulty are (1) avoiding them, (2) going over them, (3) going under them, (4) going through them. In most cases a combination of these methods is used. Where trees are a serious factor it is necessary to examine the route of every line in detail, and the size and location of the trees may become the determining feature of the whole design. In such cases nearly all rules of good construction and systematic arrangements are violated in the interests of expediency.

The methods by which trees may be avoided are: using alleys instead of streets, or vice versa; choosing streets without trees for important lines; taking side of street with fewer trees; and finally the very bad arrangement of crossing the street back and forth to avoid the trees either individually or in groups.

The plan of going over the trees is a proper one in the case of all small trees and is perfectly satisfactory until the trees grow up and touch the wires. It is therefore only a temporary method, especially where the trees are of tall, quick-growing varieties. In going over small trees it is well to have poles tall enough to allow for wires clearing after several years' growth. It is usually impracticable to go over large full-grown trees because of cost of poles, unsightliness of very tall poles, and the difficulty of properly guying them to resist wind and the unbalanced pull of wires, which is magnified by the great leverage. It is also difficult or impracticable to take off service wires over the tops of tall trees.

With trees of moderate size it is usually necessary to take the wires through the trees among the leaves and small branches. Special **tree wire** should be used for this purpose. It is rubber insulated and covered with abrasion-resistant braid or armor. It is carried on insulators. The branches and leaves should be trimmed from around the wires as much as possible, including not only those in contact with the wires but such as will be brought into contact by wind or which will grow into contact during the season. Another plan is to protect the wires by split tubes of wood or rolls of baekelized fabric.

Pole Transformers

POLE TRANSFORMERS. The primary (2300–4600 volts) mains are usually run to transformers mounted on poles and the voltage there stepped down to the lamp or motor voltage (110 or 220 volts), and secondary mains run from the transformer to the buildings

in the immediate vicinity. These transformers range in size from 1 1/2 to 100 kv-a, but transformers larger than 100 kv-a are sometimes used in factory districts where the unsightliness of the supporting structure (several poles framed together) does not have to be considered.

Use of Single- and Three-phase Transformers. The main advantage of three single-phase transformers over one three-phase transformer is the greater flexibility in connections, voltage combinations, and spares. For example, if one unit of a delta-delta bank fails, the other two can be operated in open delta at 58 per cent of the capacity of the bank. Initial expenditure at customers' substations may often be kept down by installing two single-phase transformers in open delta, a third one being added when the load has increased sufficiently, thus increasing the bank capacity 73 percent.

The main advantages of the three-phase transformers are higher efficiency, lower cost, saving in space, and simplicity of connections.

Voltage Ratios of Pole Transformers. The usual voltages are 2300 and 4000 volts on the high-tension side and 115, 120 and 125 volts on the low-tension side.

Services

SERVICE WIRES. The service drop wires are those which connect the house wiring with the main on the street. Usually these wires extend in a single span from the nearest pole to the house. At the house they are fastened to insulators similar to those used on the line and mounted on brackets attached to the house. These brackets are often the ordinary wooden bracket used in line work, though the special iron brackets made for the purpose are neater and more secure. The bracket should take the strain of the span, so that, where the service passes through the wall it will not be under strain.

At the pole the service wires are sometimes attached directly to the mains that supply them; although this is the easiest method it has the disadvantage that the strain in the service wire will come on the mains, which may also be injured by the attaching and detaching of numerous service wires. When the service wires do not slope upward or downward at a considerable angle they are likely to become crossed with the main of opposite polarity. Since the general direction of the service wire is at right angles to the main, the service wire should naturally originate on a cross-arm at right angles to the arm carrying the mains. In good service work consequently a cross-arm is generally attached to the pole below the main, and all the service wires to both sides of the street run from this. One tap to each of the wires constituting the main can then be used for a number of service wires.

Present-day tendencies are toward the substitution of two-, three-, or four-conductor cables for the separate wires. A construction which is much favored consists of a group of rubber-insulated wires, with asphalt-saturated braids on each, twisted together without any overall covering.

Where the service entrance and distribution point are in the attic, the service wires pass through the wall in individual porcelain bushings and should have a drip loop between the bracket and bushing so that water will not follow the wire into the building. Where service wires do not conveniently reach the house at point of entrance, they are carried along the wall to such point, being supported at intervals by insulators on brackets. (See also Wiring of Buildings.)

More commonly, however, the service entrance and distribution point are in the basement, and in that case the service drop wires or cables terminate outdoors at the supporting insulators, and there is a separate cable, called a **service entrance cable**, which runs from a service head to the meter. This cable may be in a conduit, in which case it is braid covered; or it may be simply clamped to the wall, in which case it is armored or partially armored in steel wire or steel tape. In some cases, the neutral is bare and is placed over the other conductor or conductors. (See Art. 78.)

The **service head** is a metal hood with its opening covered with a porcelain bushing plate, the opening and plate facing downward so that rain drip will not enter. The single conductors of the service entrance cable run through separate holes of the bushing and, after forming a rain drip loop, curve up to the service drop cable, to which they are connected.

FRONT AND REAR SERVICING. When houses are serviced from a pole line on the street the service wires usually enter the front of the house; if serviced from alley, they enter the rear. Service wires can be run around detached houses from front to rear on brackets on the wall, but this is unsightly and expensive, and it increases the service wire drop. Service entrances can be changed by changing the inside wiring, but the expense is usually heavy and the damage to decoration of rooms sometimes makes it prohibitive.

Sectionalizing of Distribution Circuits, Fuses and Cut-Outs

An overhead a-c system supplied from a single bus is sectionalized: (1) at the switchboard in power station or substation into circuits having no external interconnection by knife switches or oil switches with fuses or automatic trip; (2) at the poles where long branches leave, by transformer cut-outs, either fused or solid, or by pole-type oil switches; (3) at transformer primaries by fused cut-outs. Switches and fuses are used but sparingly in the primary mains, and in a small compact circuit none are necessary. No switches or fuses are used on the secondary side of transformers or on secondary mains except as described in Art. 43.

When several transformers feed the same secondary main, the opening of a primary cut-out, either by blowing of fuse or by hand, does not make the transformer primary dead, as it is still alive from the secondary side. If the fuse of one transformer on a secondary network blows, the additional load thrown on an adjacent transformer may cause the fuse of that to blow, and all transformers to go out in succession. Under these conditions the fuses cannot be replaced in one transformer at a time. To avoid the interruption to service involved in leaving the fuses out until a time of day when one transformer can carry the whole load temporarily, or in having the whole primary circuit out while the fuses are replaced, **secondary network protectors** are essential as described in Art. 43.

Lightning Protection

(See also Section 12, Art. 22.) Practically all disturbances from lightning enter a system through the overhead distributing circuits. The most serious effects are not to the distributing circuit itself but to the switchboard and machinery in the station. The effects on the circuit consist of splitting of poles, puncturing of insulators, puncturing of transformers, blowing of transformer fuses. There may also be damage to meters or appliances on the premises of consumers. The protection principally used includes (1) lightning arresters and choke coils in the station (principally to protect station apparatus); (2) lightning arresters at intervals on the lines; (3) ground wires over the lines; (4) lightning rods on poles; and (5) grounding of the circuit.

USE OF LIGHTNING ARRESTERS. On alternating circuits lightning arresters are used at intervals on the primary but not on the secondary circuits. The amount of line which a lightning arrester will protect is less the more severe the lightning discharge. It is impracticable, and probably impossible, to space the arresters close enough together to protect a circuit absolutely. Theoretically the number of arresters used should be such that the sum of the loss due to the damage by lightning and the expense of providing and maintaining arresters to avoid damage is a minimum. The effects of lightning are too variable and the money loss due to interruption of service is too indeterminate to admit of correct distribution of arresters being determined by calculation. In practice it has been found that when no arresters are used many lightning discharges of considerable intensity do no great amount of damage; also that where the arresters are used much of the damage done is to the arresters themselves, and that their failure is likely to be a cause of interruptions to service. Ordinarily it is well to begin by using arresters sparingly on the lines and putting additional arresters on if found necessary. The maximum number of arresters would be reached when one was provided for each transformer bank.

The importance of **lightning protection** is greatest in a composite system, and in most cases **underground or submarine cables** under 2000 ft in length should be protected by lightning arresters wherever they connect to exposed overhead circuits. Longer ones are considered to be self-protecting.

Ground wires are principally used over transmission lines but may be used to advantage over city distribution wires in exposed places. Where adjoining buildings and trees are higher than the pole line, these foreign objects answer the same purpose and little additional screening effect will be obtained from a special ground wire.

Records of Circuits

Overhead line construction is constantly changing because of erection, moving, and removal of poles; extension of mains; connection and disconnection of service; erection and changing of location and size of transformers. The ease with which changes may be made in the lines necessitates a system of records in such form that any details can be changed at frequent intervals without making a completely new record. The great amount of complicated detail subject to frequent change makes it impracticable to record every feature.

Maps of circuits have usually become useless, soon after they have been prepared, either because obsolete from lack of correction or unintelligible because of successive

erasures and interlineations. The following method of keeping map records has been found to give good results: (1) a map of the circuits is prepared on tracing cloth, giving the circuits on the date of preparation; (2) a blueprint is taken from this tracing, and all changes marked in pencil or crayon on this print, the print and not the tracing being used for correcting and reference; the tracing is not subject to wear or tear; (3) before the blue print becomes illegible from correction or wear the accumulated corrections are made on the tracing and a new up-to-date blueprint substituted, and the process repeated. The corrections on the blueprint can be made by line foremen or other unskillful persons, at the time that the line changes are made; those on the tracing should be made by a draftsman who will do them neatly and with minimum damage to the cloth. If no colored inks are used on parts subject to change, such a tracing will last a long time and will have to be redrawn only when changes have become so numerous or radical as to amount to a rebuilding of the circuits.

45. UNDERGROUND DISTRIBUTION

CONDUCTORS. Underground primary distribution is effected equally by means of three-conductor and single-conductor cables, either of the paper-lead or rubber-lead type, but four-conductor cables are used to a considerable extent, and the two-conductor type in a few places. The usual sizes are No. 4/0 A.W.G. to 350,000 circular mils, although the range extends from No. 6 A.W.G. to 1,500,000 circular mils.

In underground networks it is desirable to have secondary distribution cables which will withstand grounding without creating such disturbance as to necessitate the opening of circuit breakers or fuses. With this in view, cables without lead sheaths are favored in some quarters, and insulation which has the least tendency to burn or to form explosive mixtures with air, when volatilized, are desired. At the present time (1936) there is no thoroughly waterproof insulation which has the desired explosion-proof qualities.

Secondary distribution of the radial type usually employs paper-lead cables, but rubber-lead is also used in many cities. Paper has the advantage of greater carrying capacity, whereas rubber presents less of a problem at its terminations.

SECTIONALIZING DEVICES are almost invariably of the oil cut-out or oil switch type, without remote control.

It is general practice to have fuses on the primary side of transformers, and therefore, fused cut-outs may be used for disconnecting purposes. These are, of course, totally enclosed and provided with wiped outlets and means for venting the gases liberated when fuses operate. Such fuses are usually rated on the basis of faults in the transformer, rather than overload.

Figs. 6 to 9, inclusive, show the use of fuses and sectionalizing switches in networks.

For details of apparatus, see Section 10.

CONDUIT LINES. See Underground Lines, Arts. 33–39.

TRANSFORMERS. Transformers are placed in manholes or vaults under the street or sidewalk. Sometimes, however, they are placed on the upper floors of large buildings. Subway-type transformers differ from the line type in being equipped with a waterproof case, the cover being gasketed and tinned brass wiping sleeves being provided for connecting to cable sheaths.

As for line transformers, the single-phase type is generally preferred, but the three-phase type is coming into favor for networks, as the loss in transformer connection flexibility is compensated by the more flexible circuit. The average size of single-phase transformers is 100 kva, but sizes range from 50 to 150 kva. Three-phase transformers run to three times these capacities.

Primary voltage ratings of 2300, 4000, 11,000, 13,200, and 27,000 volts are in very general use, with delta-connection. The usual secondary voltages are 115, 120, and 125 volts. With three-phase transformers, the secondary voltages are usually 199, 208, and 216 volts, so as to give 115, 120, or 125 volts between line and neutral with star connection.

Network transformers usually have high impedance, often as high as 10 per cent, as compared with about 2.5 per cent for 2300 and 4000 volts, and 4 1/2 to 5 per cent for 11,000 volts and higher, in transformers of the ordinary type.

BARE WIRES AND CABLES

By W. A. Del Mar

47. DIMENSIONS, WEIGHTS, AND RESISTANCES

A wire may be either solid or stranded, i.e., made up of a number of smaller wires twisted or braided together. A large bare stranded wire is usually called a bare cable. Data on the insulation and protection of wires and cables will be found in the next chapter. Data on **resistance wires** will be found in Section 2, Art. 6.

Resistance of Wires and Cables

CONDUCTIVITY. Per cent conductivity refers to the "**International Annealed Copper Standard.**" On the assumption of a resistivity temperature coefficient of 0.00393 at 20 deg cent this per cent conductivity is 0.283 per cent higher than the conductivity referred to Matthiessen's Standard. If the length of a given wire is L centimeters, its cross-section A square centimeters, and its resistance at 20 deg cent is R_{20} ohms, then the conductivity of this wire is

$$C = \frac{15.328\,L}{88{,}900\,AR_{20}} \text{ per cent}$$

Annealed copper usually has a conductivity of about 100 per cent; hard-drawn copper, a conductivity of about 97 per cent. Ordinarily hard-drawn aluminum has a conductivity of 61 per cent. The conductivity of iron or steel wire ranges from 8 to 16 per cent.

RESISTANCE AT ANY TEMPERATURE. The tables give resistances at 20 deg cent. These may be converted to resistances at other temperatures by the following formulas.

Let C = per cent conductivity.

R_{20} = resistance of 100 per cent conductivity wire at 20 deg cent (from table).

R_t = resistance of wire of conductivity C at temperature t deg cent.

For copper, $$R_t = \frac{100}{C} R_{20}[1 + 0.00393(t - 20)]$$

aluminum, $$R_t = \frac{61}{C} R_{20}[1 + 0.004(t - 20)]$$

steel, see Table VIII.

Solid Wires

TABLES. Tables I–VII for copper and aluminum are compiled from tables in Circular 31 of the Bureau of Standards. Table VIII is compiled from data published by the American Steel and Wire Co.

TROLLEY WIRE. Trolley wires of two different sections are in use in the United States. The sections shown in Fig. 1 are known as the "American Standard," and

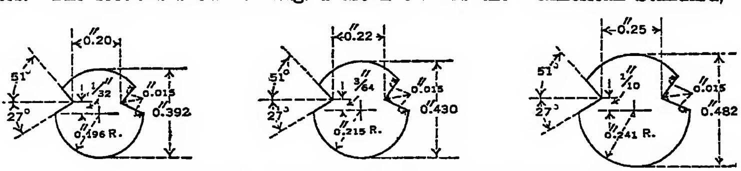

Fig. 1. Grooved Trolley Wire Sections (American Standard)

those in Fig. 2 as the "figure 8" sections. The American Society for Testing Materials recommend that the sizes be specified in circular mils, and not as gage numbers; the

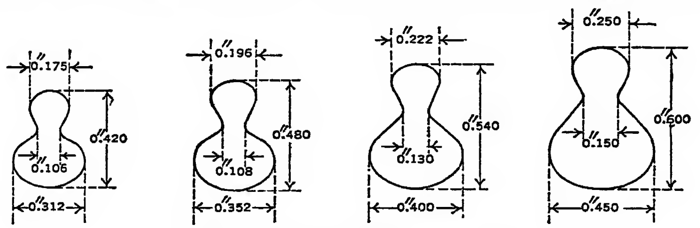

Fig. 2. Figure 8 Trolley Wire Sections

sizes shown in the figure differ in the area of the cross-section from the gage numbers given in parentheses by less than 5 parts in 1000.

Trolley wires are usually of hard-drawn copper; the electrical and mechanical properties are the same as for round hard-drawn wire of the same cross-section. Copper alloys are sometimes used for trolley wires.

COPPER-CLAD STEEL WIRE. This wire consists of a steel core and a concentric coat of copper permanently welded thereto. It is used chiefly for long-span transmission and telephone wire. It is made in several grades, which differ in the relative amounts of steel and copper. The grades are designated by the corresponding conductivity expressed as percentages of the Annealed Copper Standard: e.g., 40 per cent grade has a conductivity of 40 per cent.

* Let C = per cent conductivity,
$R_{23.9}$ = resistance of 40 per cent conductivity wire at 23.9 deg cent (from table),
R_t = resistance of wire of conductivity C at temperature t deg cent; then

$$R_t = \frac{40\,R_{23.9}}{C}[1 + 0.00432(t - 23.9)]$$

The temperature coefficient is approximate only.

ALLOY WIRES OF HIGH TENSILE STRENGTH. Copper alloys having a low conductivity but a tensile strength from 50 per cent to 100 per cent greater than that of copper are sometimes used where strength or hardness is a primary requisite, as in long spans of small wires or for trolley wires. See Art. 48.

Stranded Conductors

FACTORS AFFECTING DIMENSIONS, WEIGHT AND RESISTANCE OF STRANDED WIRES. Individual stranded wires or cables are of four different types, namely: (*a*) bunched wire; (*b*) wire braids; (*c*) concentric-lay cables; and (*d*) rope-lay cables.

Bunched Wires. Bunched wires are used especially for those extra-flexible cables known as cords, wherein the individual wires are so small that concentric stranding is not necessary to keep them together. The wires are assembled parallel and then generally given a slight twist. Sometimes they are kept together by being wound with soft cotton thread which also serves to prevent adhesion between the insulation and wires.

Wire Braids. In the flat form, wire braids are used for potential leads, etc., in lighting cables, where a flexible flat conductor is necessary. Tubular wire braids, known as **basket weave,** are also frequently formed over the insulation of cables in order to afford mechanical protection. Cables for naval or marine purposes and for automobile work are frequently thus protected.

Concentric-lay Cables. A concentric-lay cable is a stranded conductor composed of a central core surrounded by one or more layers of helically laid wires. A rope-lay cable is a stranded wire made up in the same manner by using stranded wires instead of individual solid wires for the core and layers. The cores of concentric-lay cables may be composed of one, two, three, or four wires of equal diameter. A five- or six-wire core would not be symmetrical, and seven wires would themselves constitute a core and a layer.

Number of Wires in Concentric-lay Cables. Table X gives all the possible concentric-lay cables with eight or less layers of equal size wires and formulas for calculating the number of wires with any number of layers. (See Table XIII.)

Table X. Number of Wires in Concentric-lay Cables

(All wires of same diameter)

Number of Layers over Core	Number of Wires in Core			
	1	2	3	4
0	1	2	3	4
1	7	10	12	14
2	19	24	27	30
3	37	44	48	52
4	61	70	75	80
5	91	102	108	114
6	127	140	147	154
7	169	184	192	200
8	217	234	243	252
n	$3n^2 + 3n + 1$	$3n^2 + 5n + 2$	$3n^2 + 6n + 3$	$3n^2 + 7n + 4$

The number of wires per layer increases by six for each successive layer when the core has one wire, the first layer over the core having six. With cores having more than one wire, the increment per layer is not constant.

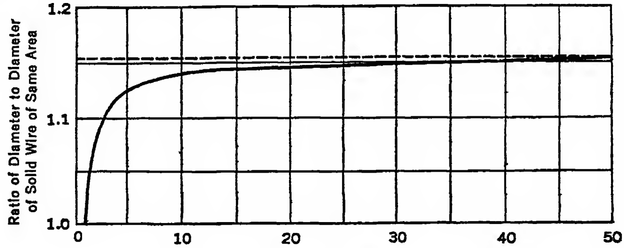

Fig. 3

Diameter of Concentric-lay Cables. The diameter of the circumscribing circle of any of the above cables is equal to $(2n + b)$ times the diameter of each wire, where n is the

number of layers over the core and b has the following values: 1 wire in core, $b = 1$; 2 wires in core, $b = 2$; 3 wires in core, $b = 2.155$; 4 wires in core, $b = 2.414$.

The relation between the number of component wires and the diameter of the cable is shown in Fig. 3.

Rope-lay Cables. As already noted, a rope-lay cable is made up in the same way as a concentric-lay cable except that stranded wires are used for the core and layers instead of individual solid wires. Rope strands are used for large conductors which would be too stiff if stranded concentrically. The formulas for regular concentric-lay cables may be readily modified to apply to rope-lay cables, as each stranded wire bears the same relation to the rope as each individual solid wire does to the concentric-lay cable. Table XI gives the principal forms of rope-lay cables.

Table XI. Wires in Rope-lay Cables

Number of Layers over Core	Number of Strands *	Total Number of Wires				
		Wires per Strand *				
		7	19	37	61	91
0	1	7	19	37	61	91
1	7	49	133	259	427	637
2	19	133	361	703	1159	1,729
3	37	259	703	1369	2257	3,367
4	61	427	1159	2257	3721	5,551
5	91	637	1729	3367	5551	8,281
6	127	889	2413	4699	7747	11,557
n	$3(n^2+n)+1$	$21(n^2+n)+7$	$57(n^2+n)+19$	$111(n^2+n)+37$	$183(n^2+n)+61$	$273(n^2+n)+91$

* By "strand" is here meant the group of stranded wires of which the rope is built up.

The number of wires in a rope-lay cable is frequently designated by a product; thus, 7 × 19 indicates a conductor made up of 7 strands, each strand containing 19 wires.

Table XII. Properties of Concentric-lay Cables

		Regular; $d_c = d$	Special; $d_c \neq d$
I.	Number of wires in terms of number of layers (and core diameter)	$N = 3(n^2+n)+1$ (including core)	$N = 3\left(n\frac{d_c}{d}+n^2\right)$ (excluding core)
II.	Diameter of cable in terms of diameter of wires and number of layers	$D = d(1+2n)$	$D = d_c + 2nd$
III.	Diameter of cable in terms of total area and number of wires	$D = 10^{-3}\sqrt{\frac{1}{3}\left(4-\frac{1}{N}\right)}\cdot\sqrt{A}$	
IV.	Ratio of wire area to area of circle circumscribing the outside of cable	$R = \frac{3(n^2+n)+1}{(2n+1)^2}$	
V.	Weight of cable in terms of weight of wire, number of layers and pitch factors	$W = w(1 + 6p_6 + 12p_{12} + \text{etc.})$	$W = w_c + w(6p_6 + 12p_{12} + \text{etc.})$
VI.	Strength of cable in terms of strength of the component wires and the pitch factors	$T = \frac{\pi}{4}d^2\left[s + t\left(\frac{6}{p_6}+\frac{12}{p_{12}}+\text{etc.}\right)\right]$	$T = \frac{\pi}{4}\left[sd_c^2 + d^2 t\left(\frac{6}{p_6}+\frac{12}{p_{12}}+\text{etc.}\right)\right]$
VII.	Minimum pitch in terms of wire diameter and core diameter	$\frac{3\pi d_p}{\sqrt{(\pi+3)(\pi-3)}} = 10.1$ times pitch diameter	$\frac{\pi d_p l d}{\sqrt{(\pi d_p)^2-(ld)^2}}$
VIII.	Diameter of wires in terms of total conductor area and number of wires	$d = \frac{1}{1000}\sqrt{\frac{A}{N}}$	

Diameters of Component Wires in Commercial Stranded Conductors. Table XVII gives the diameters of the component wires in the types of stranded conductors ordinarily used.

Effect of Lay on Resistance and Weight. In Tables XIV, XV, and XVI, for stranded cables, the values given for "ohms per unit length" and "weight per unit length" are 2 per cent greater than for a solid rod of cross-section equal to the total cross-section of the wires of the cable. This increment of 2 per cent means that the values are correct for cables having a lay of 1 in 15.7. For any other lay, equal to 1 in n, resistance or mass may be calculated by increasing the above tabulated values by

$$\left(\frac{484}{n^2} - 2\right) \text{ per cent}$$

Table XIII. Number of Wires for Concentric Standing

General Formulas for Properties of Cables in Terms of the Properties of the Constituent Wires. Table XII gives the principal formulas for concentric-lay cable having a core of one wire.

A = total area in circular mils of the component wires measured at right angles to their axes, when laid out straight.
D = diameter of cable overall, in inches.
d = diameter of each of the component wires, in inches.
d_c = diameter of core, in inches.
d_p = pitch diameter, in inches, of any layer (= mean diameter of the helix made by any layer).
e = elongation, per cent, at which the wires (other than the core) break.
l = number of wires in any layer having pitch diameter d_p.
N = total number of wires except where the core is of special size, in which case N is the number of wires exclusive of the core.
n = number of layers of wire over the core.

P = pitch of any layer of wires = distance in inches measured along the axis of the cable for one complete turn of the helix formed by any wire of this layer.
p = pitch-factor of any layer of wires = ratio of the actual length of a wire to the corresponding axial length of the cable.
R = ratio of wire area to the total area of the circle circumscribing the outside of the conductor.
s = stress in pounds per square inch in the core when the elongation is e.
t = tensile strength of each outer wire, in pounds per square inch.
T = tensile strength of conductor, in pounds.
W = weight of conductor, in pounds per foot.
w = weight of each wire of the cable, in pounds per foot.
w_c = weight of the core of the cable, in pounds per foot.

48. STRENGTH, ELASTICITY, AND EXPANSION COEFFICIENTS OF WIRES

The strength and elasticity of a wire of any material depend to a considerable extent upon the method of manufacture, heat treatment, etc. The tensile strength of soft copper is between 25,000 and 35,000 lb per sq in., as against 60,000 lb per sq in. for hard-drawn copper. Again, because of the greater relative thickness of the hard " skin " and comparatively soft " core " of small hard-drawn copper wires as compared with large wires, the tensile strength, in pounds per square inch, of a small hard-drawn copper wire is greater than that of a large hard-drawn wire. For example, a No. 0000 A.W.G. hard-drawn copper wire has a tensile strength of about 50,000 lb per sq in. as against approximately 65,000 lb per sq in. for a No. 18. A similar but smaller variation holds for soft annealed wires. The tensile strength of steel wire depends to a very great extent upon the composition of the steel.

Metals Available for Conductors

The following table gives, for a No. 0 A. W. G. wire, representative values of the various quantities stated for representative metals and alloys used for wires and cables. These values do not hold, except to a rough approximation, for other sizes of wire.

Strength, Elasticity, and Coefficient of Expansion
Of a No. 0 A. W. G. Wire

Kind of Wire	Tensile Strength, lb per sq in.	Elastic Limit, lb per sq in.*	Modulus of Elasticity, lb-in. units	Coefficient of Linear Expansion	
				per °F	per °C
Copper, soft-annealed......	36,000	....	....	9.6×10^{-6}	17×10^{-6}
Copper, hard-drawn.......	57,330	30,000	16×10^6	9.6×10^{-6}	17×10^{-6}
Aluminum, soft-annealed...	16,000	....	....	12.8×10^{-6}	23×10^{-6}
Aluminum, hard-drawn....	25,000	25,000	9×10^6	12.8×10^{-6}	23×10^{-6}
Copper-clad steel, 40% grade	60,000	51,000	22×10^6	6.7×10^{-6}	12×10^{-6}
P. M. G. (Phelps-Dodge) bronzes...............	60,000 to 140,000	27,000 to 63,000	15×10^6	9.6×10^{-6}	17×10^{-6}
Anaconda copper alloys....	69,000 to 135,000	....	13×10^6 to 15×10^6	....	....
Phonoelectric bronze.......	75,800	55,000	18×10^6	8.3×10^{-6}	14.9×10^{-6}
Steel, ordinary............	68,000	40,000	24×10^6 to 30×10^6	7.0×10^{-6}	12.6×10^{-6}
Steel, Siemens-Martin......	90,000	45,000		7.0×10^{-6}	12.6×10^{-6}
Steel, high-strength........	150,000	82,000		7.0×10^{-6}	12.6×10^{-6}
Steel, extra high-strength...	225,000	135,000		7.0×10^{-6}	12.6×10^{-6}

* There is no elastic limit for soft annealed copper, and the elastic limits of hard-drawn copper and aluminum are not precise quantities.

TENSILE BREAKING LOAD. The tensile strength in pounds for solid wires from $^1/_{16}$ to $^1/_2$ in. in diameter are given in Table XIX.

Table XIX. Breaking Load for Solid Wires in Pounds per Wire

Gage No. A.W.G. or B. & S.	Diameter In.	Diameter Mils	Hard-drawn Copper (A.S.T.M.) *	Hard-drawn Aluminum (23,000 to 33,300 lb per sq in.)	Copper-clad Steel, 40 per cent Grade	Steel (100,000 lb per sq in.) †

Hard-drawn Copper Cables

Table XX gives the mechanical properties of hard-drawn copper transmission cables.

MODULUS. Tests by B. Welbourne (*J. I.E.E.*, 1917, Vol. 56, p. 53) indicate that the elastic modulus of copper cables varies with the number of strands, as shown in Table XXI.

Table XXI

Strands	Modulus, lb-in. units
7	20.0×10^6
19	17.5×10^6
37	15.5×10^6
61	14.0×10^6
91	12.5×10^6

49. CABLES FOR HIGH VOLTAGES AND LONG SPANS

Hollow Copper Cables

LARGE-DIAMETER CABLES. Aerial cables for high voltages should be of sufficiently great diameter to keep the corona loss down to an economic minimum. The diameter required may be calculated from the formulas in Art. 19. As the cross-section is generally determined by the current, conductivity and span, high-voltage lines often require conductors whose cross-section and diameter must be independent of each other, if minimum weight and cost are to be attained. Such conductors are made in a variety of forms, as follows:

P.D.C.P. Hollow Core Cable. This consists of a thin-walled copper core tube which is concentrically stranded with one or more layers of copper wires. These wires may be either solid or hollow, or a combination of solid and hollow wires, as shown in Fig. 4.

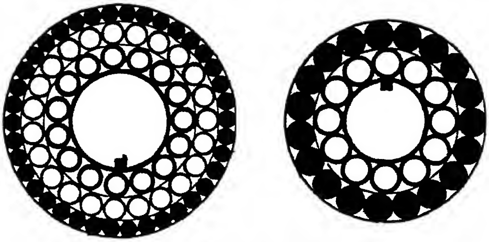

Fig. 4. Type P.D.C.P. Conductors

Anaconda I-Beam Cable. A copper section like a thin I-beam is given a helical twist and used as the core on which one or more layers of wire are stranded, as shown in Fig 5.

Type HH (or Heddernheim) Cable. Interlocking segments of copper are stranded together as shown in Fig. 6, forming a single flexible tube.

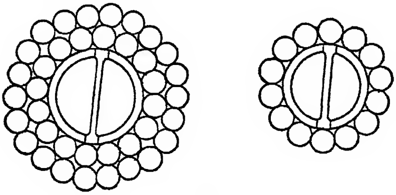

Fig. 5. I-Beam Type Conductors

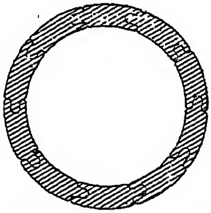

Fig. 6. Type HH Conductor

A.S. & W. Type Cable. Similar to Type HH except that the segments are grooved at both ends and held together by flat elliptical key wires which fit into opposing grooves.

These various types differ somewhat in diameter, corona-suppression, a-c resistance, ease of installation and splicing, ability to resist vibration, and general mechanical stability in tension with and without lubrication, all of which properties should be given due weight. On long spans, consideration must be given, especially during installation, to proper balance of turning moments of the helically laid wires. Where members have substantially different lays, the distribution of load between members must also be considered.

Aluminum-steel Cables

Cables made of a central core of steel, solid or stranded, surrounded by one or more layers of aluminum wire are in extensive use for aerial lines. Their great advantages are that they may be erected not only with less sag than aluminum but with from 60 to 70

Table XXII. Aluminum-steel (A.C.S.R.) Cable *

* From Electrical Characteristics of A.C.S.R. Cable, issued, 1934, by Aluminum Co. of America.

† A-c resistances are higher, owing to skin effect, especially at high current densities. Values for various current densities are given in Electrical Characteristics of A.C.S.R. Cable, which also gives tables of inductance, reactance, and capacitance and a chart for calculating carrying capacity.

per cent of that of hard-drawn copper and that their diameter is often sufficiently great, except at the highest voltages, to prevent corona formation.

The modulus of elasticity and temperature coefficient of expansion depend upon the relative cross-section of aluminum and steel. The anchor clamps hold both the aluminum and steel, so that at low temperatures the load is divided between the two metals. As the temperature rises, the aluminum expands faster than the steel and the load gradually shifts over to the steel which in turn stretches more to keep pace with the expanded length of aluminum, tending to eliminate relative motion between the two metals. Eventually the steel carries the total load, and the expansion follows the coefficient for steel only.

Let H_a = fraction of area covered by aluminum.
H_s = fraction of area covered by steel.
M_a = modulus of elasticity of aluminum (9,000,000).
M_s = modulus of elasticity of steel (30,000,000).
M = modulus of elasticity of aluminum-steel cable.
G_a = coefficient of expansion of aluminum (0.0000128).
G_s = coefficient of expansion of steel (0.0000064064).
G = coefficient of expansion of cable.

$$M = M_a H_a + M_s H_s = (9 \times H_a + 30\,H_s)10^6,$$

$$G = \left\{\frac{1}{1 + \dfrac{M_a H_a}{M_s H_s}}\right\} G_s - \left\{\frac{1}{1 + \dfrac{M_a H_a}{M_s H_s}} - 1\right\} G_a$$

$$= 0.0000064 \left\{\frac{1}{1 + 0.3\dfrac{H_a}{H_s}}\right\} - 0.0000128 \left\{\frac{1}{1 + 0.3\dfrac{H_a}{H_s}} - 1\right\}$$

Table XXII gives the principal characteristics of aluminum-steel cables.

Steel Cable for Catenary Construction

A modulus of 22×10^6 lb-in. units is representative of ordinary steel messenger cable. Table XXIII compiled from tables published by the General Electric Co. (*Bulletin 4538*). " High " and " Extra-high " strength steel should be used only where absolutely necessary, as, on account of its stiffness, it requires special mechanical fastenings.

Table XXIII. Steel Cable for Catenary Suspension

50. SKIN-EFFECT AND A-C RESISTANCE

The a-c resistance of conductors is greater than the d-c resistance given in the preceding tables, owing to skin effect. (See Section 3, Art. 24.) The **skin-effect ratio** is the ratio

of the a-c resistance to the d-c resistance. Table XXIV gives these ratios for concentric-lay conductors, and Table XXV for annular conductor cables, such as are used in insulated cables. The skin-effect ratios for annular and similar cables for aerial transmission should be obtained from the manufacturers.

Table XXIV. Skin Effect in Large Concentric-lay Conductors

Class B Stranding (see Table XIII)

Size, cir mils	Skin Effect Ratio at 65° C		Size, cir mils	Skin Effect Ratio at 65° C	
	25 Cycles	60 Cycles		25 Cycles	60 Cycles

51. CURRENT-CARRYING CAPACITY OF BARE WIRES AND CABLES

Values of Thermal Constant K
Deg cent per watt per sq in.

Diameter, in.	Tarnished	Bright
0.1	850	605
0.2	670	490
0.3	490	410
0.4	410	340
0.5	380	302
0.6	340	264
0.7	320	245
0.8	302	226
0.9	282	208
1.0	282	208
1.1 and larger	264	188

Let d = diameter of conductor in inches, T = permissible temperature rise in degrees centigrade above surrounding medium, r = resistance of conductor in ohms per 1000 ft at final temperature, I = current per conductor in amperes.

$$I = \sqrt{\frac{1000T}{rR}}$$

where R is the thermal resistance from conductor surface to ambient air per foot and equals $\dfrac{0.0041\,K}{d}$, where K depends upon the condition of the surface of the wire, and upon the amount of heat convection due to air currents. Values of the constant K for still air are given in the accompanying table.

From data by George E. Luke, based on tests for a temperature rise of 40 deg cent.

52. TESTS OF BARE WIRES AND CABLES

The usual tests on bare wires are gaging diameter, measuring tensile strength, elongation, modulus, elastic limit, and electrical conductivity.

GAGING DIAMETER. (See also Art. 53.) The best type of gage for measuring wire diameters is that shown in Fig. 7. The wire is placed between the measuring surfaces and the screw adjusted until a click occurs. The number of large divisions exposed on the axis is multiplied by 100; the number of small divisions exposed on the axis is multiplied by 25; and the sum of these two items added to the number indicated on the revolving scale. The sum will be the diameter of the wire in mils.

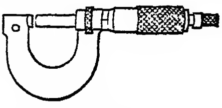

FIG. 7

TENSILE STRENGTH, ELONGATION, MODULUS, AND ELASTIC LIMIT. The essential features of a wire-testing machine are a means of applying a measurable pulling force to the wire, and a means of taking up the elongation. Accordingly, the usual testing machine consists of two pairs of jaws for gripping the wire, one pair being connected to a balance lever and the other to a power-driven mechanism which draws it in the direction of the axis of the wire. A typical machine is shown diagrammatically in Fig. 8, where *A* and *B* are the two pairs of jaws between which the wire is stretched. The machine is operated by setting in motion the mechanism which makes the jaw *A* move steadily in the direction indicated. The operator then moves the counterpoise *C* by hand, in the direction indicated, so as to keep the beam balanced. This operation is continued until the wire breaks, when the elongation of the sample is measured by the travel of the jaw *A* and its breaking strength by the weight indicated on the balance beam at the counterpoise *C*.

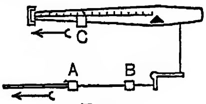

FIG. 8

Measurement of Strain. The amount by which the wire is stretched is measured by means of an extensometer which consists of a pair of clamps to grip the wire at points a definite distance apart, and a magnifying scale for measuring the increase of distance between these clamps as the wire stretches. The stress-strain curve obtained by plotting the elongations thus measured against the stresses measured by the machine described above is not a true one, as there is initially an abnormal elongation due to the straightening of the wire, as shown by curve *OA* in Fig. 6. The standard method of overcoming this, is described in Section 8 of the A.S.T.M. Specification for Hard-drawn Copper Wire.

Modulus of Elasticity. The modulus of elasticity is obtained from the slope of the straight part of the corrected curve. In Fig. 9 the modulus of elasticity is *OD–CD* pound-inch units.

Elastic Limit. The elastic limit can be obtained only by applying a series of increasing loads, releasing the load (leaving, however, a sufficient load to keep the wire straight), and measuring the elongation between successive loads. The load at which a permanent elongation begins is the elastic limit.

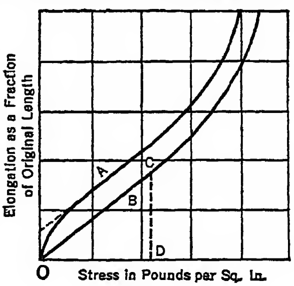

FIG. 9

CONDUCTIVITY. In order to maintain a wire at a uniform and known temperature, it must be short. Unless the wire is very small the test sample will therefore have a very low resistance, and an ordinary Wheatstone bridge will not be sufficiently accurate to measure it. This difficulty is avoided by using a bridge of either the Kelvin, Hoop, Willyoung or Reeves type (see Section 5, Art. 7).

53. SPECIFICATIONS FOR COPPER WIRE AND CABLE

The specifications almost universally used for bare copper wire and cable are those prepared by the American Society for Testing Materials, which are abstracted below.

Specification for Soft or Annealed Copper Wire

GENERAL. This specification covers untinned, drawn, and annealed round wire.

SHIPMENT; COILS, SPOOLS AND REELS. Wire may be shipped in coils or on reels as agreed upon by the purchaser and manufacturer. In Table XXVI (below) there are stated the maximum and minimum weights of wire of the stated sizes which may be

shipped in any one package, whether coil, reel, or spool; for wire larger than 0.010 in. in diameter, the maximum and minimum package weights are net, and for wire 0.010 in. and less in diameter, the maximum package weights are gross, and the minimum package weights are net. The table also states the limiting dimensions of the coils, reels, and spools on which wire may be shipped.

Table XXVI

Diameters, in.	Package Weights, lb		Diameter of Draw-block for Final Drawing, in.	Dimensions of Reels and Spools, in.		
	Maximum	Minimum		Maximum Diameter	Maximum Length	Diameter of Hole for Rod
0.460 to 0.360	520	290	24	32	21	1 1/2 to 2 1/2
0.359 to 0.258	430	290	24	32	21	1 1/2 to 2 1/2
0.257 to 0.129	290	140	22	24	12	1 1/2 to 2 1/2
0.128 to 0.102	230	95	22	24	12	5/8 to 1 1/2
0.101 to 0.083	230	75	22	24	12	5/8 to 1 1/2
0.082 to 0.081	200	75	16	24	12	5/8 to 1 1/2
0.080 to 0.064	200	50	16	24	12	5/8 to 1 1/2
0.063 to 0.051	120	50	16	24	10	5/8 to 1 1/2
0.050 to 0.041	100	50	16	24	10	5/8 to 1 1/2
0.040 to 0.032	50	20	8	24	8	5/8 to 1 1/8
0.031 to 0.020	25	15	8	10	6 1/2	5/8 to 7/8
0.019 to 0.011	10	5	8	5 1/2	4	3/8 to 11/16
0.010 to 0.008	5	2 1/2	8	4	4	3/8 to 11/16
0.007 to 0.0056	2 1/2	1	6	2 1/2	4	3/8 to 11/16
0.005	1 1/2	5/8	6	2 1/2	4	3/8 to 11/16
0.004	1 1/2	3/8	6	2 1/2	4	3/8 to 11/16
0.003	1	1/4	6	2 1/2	4	3/8 to 11/16

SPECIFIC GRAVITY. For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be take as 8.89.

SIZE AND GAGING. (*a*) Size shall be expressed as the diameter of the wire in decimal fractions of an inch.

(*b*) Wire shall be accurate in diameter; permissible variations from nominal diameter shall be:

For wire 0.010 in. in diameter and larger, 1 per cent over or under.

For wire less than 0.010 in. in diameter, 0.1 mil (0.0001 in.) over or under.

(*c*) Each coil shall be gaged at three places, one near each end and one approximately at the middle; from spools, approximately 12 ft shall be reeled off, and the wire shall be gaged in six places between the second and twelfth foot from the end. The coils or spools will be rejected if the average of the measurements obtained is not within the limits specified in (*b*).

Table XXVII. Annealed Copper Wire

Diameter, in.	Tensile Strength, lb per sq in.	Elongation in 10 in., per cent
0.460–0.290	36,000	35
0.289–0.103	37,000	30
0.102–0.021	38,500	25
0.020–0.003	40,000	20

TENSILE STRENGTH AND ELONGATION. Wire shall be so drawn and annealed that its tensile strength shall not be greater and its elongation not less than the values stated in Table XXVII. For wire whose nominal diameter is between listed sizes, the requirements shall be those of the next larger size included in the table.

RESISTIVITY. Electric resistivity shall be determined upon fair samples by resistance measurements at a temperature of 20 deg cent (68 deg fahr) and it shall not exceed 891.58 lb per mile-ohm (0.15614 ohm per meter-gram).

Specification for Hard-drawn Copper Wire

GENERAL. These specifications cover hard-drawn round wire, grooved trolley wire, and figure-eight trolley wire, as hereinafter described.

A section of wire containing a braze must show at least 95 per cent of the tensile strength of the unbrazed wire. Elongation tests are not to be made upon test sections including brazes.

SPECIFIC GRAVITY. For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.89 at 20 deg cent.

HARD-DRAWN ROUND WIRE. (*a*) *Size* shall be expressed as the diameter of the wire in decimal fractions of an inch, using not more than three places of decimals; i.e., in mils.

(*b*) Permissible *variations from nominal diameter* shall be:

For wire 0.100 in. in diameter and larger, 1 per cent over or under;

For wire less than 0.100 in. in diameter, 1 mil over or under.

(*c*) Each coil is to be *gaged* at three places, one near each end, and one approximately at the middle; the coil may be rejected if, two points being within the accepted limits, the third point is off gage more than 2 per cent in wire 0.064 in. in diameter and larger, or more than 3 per cent in the wire less than 0.064 in. in diameter.

Wire shall be so drawn that its *tensile strength* and *elongation* shall be at least equal to the value stated in Table XXVIII.

Electric Resistivity shall be determined upon fair samples by resistance measurements at a temperature of 20 deg cent (68 deg fahr).

The wire shall not exceed the following limits:

For diameters 0.460 in. to 0.325 in., 900.77 lb per mile-ohm at 20 deg cent.

For diameters 0.324 in. to 0.040 in., 910.15 lb per mile-ohm at 20 deg cent.

GROOVED TROLLEY WIRE. *Standard sections* shall be known as the " American Standard " grooved trolley-wire sections, the shape and dimensions of which are as shown in Fig. 1, above.

Table XXVIII. Hard-drawn Copper Wire

Approximate Gage No., B. & S.	Diameter, in.	Area, cir mils	Tensile Strength, lb per sq in.	Elongation, per cent
				in 10 in.
0000	0.460	211,600	49,000	3.75
000	0.410	168,100	51,000	3.25

	0.092	8,464	65,400	0.97
11	0.091	8,281	65,400	0.97
12	0.081	6,561	65,700	0.95
	0.080	6,400	65,700	0.94
13	0.072	5,184	65,900	0.92
	0.065	4,225	66,200	0.91
14	0.064	4,096	66,200	0.90
15	0.057	3,249	66,400	0.89
	0.051	2,601	66,600	0.87
16	0.045	2,025	66,800	0.86
18	0.040	1,600	67,000	0.85

(*a*) Size shall be expressed as the area of cross-section in circular mils, the standard sizes being as follows:

211,600 cir mils, weighing 3386 lb per mile.
168,100 cir mils, weighing 2690 lb per mile.
133,200 cir mils, weighing 2132 lb per mile.

(*b*) Grooved trolley wire may vary 4 per cent over or under in weight per unit length from standard, as determined from the nominal cross-section.

The **physical tests** shall be made in the same manner as those upon round wire. The tensile strength of grooved wire shall be at least 95 per cent of that required for round

wire of the same sectional area; the elongation shall be the same as that required for round wire of the same sectional area.

The requirements for electric resistivity shall be the same as those for round wire of the same sectional area.

FIGURE-EIGHT TROLLEY WIRE. Standard sections of figure-eight trolley wire shall be as shown in Fig. 2, above.

The requirements for weight, physical properties, and electric resistivity of figure-eight trolley wire shall be the same as for the same sizes of grooved trolley wire.

Specification for Bare Concentric-lay Copper Cable: Hard, Medium-hard, or Soft

PRODUCTS COVERED. These specifications cover bare concentric-lay cables made from round copper wires laid helically around a central core in one or more layers. The central core shall be made of wire having the same quality and temper as the concentric layers, unless otherwise especially provided for in separate specifications governing the individual case.

NOTE: Class A cable, sizes 4/0 and 3/0, is usually 7-strand when bare and 19-strand when weatherproof, etc.

CLASSES. The purpose for which the several classes of concentric-lay cables are generally used are as follows:

Class *A*, for bare, weatherproof, slow-burning, and slow-burning weatherproof cable for aerial use;

Class *B*, for various insulated cable, such as rubber, paper, varnished cloth, etc.

Class *C*, for cable where greater flexibility is required than in Class *B*.

REQUIREMENTS OF WIRES. The copper wires entering into the construction of standard concentric-lay cable shall, before stranding, meet all the requirements of that one of the Standard Specifications of the American Society for Testing Materials for Hard-drawn, Medium Hard-drawn, or Soft or Annealed Copper Wire (Serial Designations: *B* 1, *B* 2, or *B* 3), which applies.

BRAZES. Brazes may be made in the wire when finished and ready for cabling. No brazes in cable made from hard, or medium hard-drawn copper wire may be closer together than 50 ft.

PITCH AND LAY. The pitch of standard cable shall not be less than 12 nor more than 16 diameters of the cable, and the lay may be right or left-handed, unless one direction of lay is specified by the purchaser.

TESTING. Tests for the physical and electrical properties of the wire composing the cables may be made before, but not after, stranding. Experience indicates that the tensile strength of concentric-lay copper cable of standard pitch is at least 90 per cent of the total strength required of the wires forming the cable.

WEIGHTS AND AREA. For the purpose of calculating weights, cross-sections, etc., the specific gravity of copper shall be taken as 8.89 at 20 deg cent. Two per cent shall be taken as the standard increment of resistance and of mass. If the lay is definitely known, the increment shall be calculated and not assumed.

VARIATION IN AREA. The area of cross-section of the completed cable shall not be more than 2 per cent below the area specified, as determined by weight.

CONSTRUCTION. The area of cross-section, number, and diameter of wires, in standard cable Classes *A*, *B*, and *C*, shall be as specified in Table XXIX.

INSPECTION. All testing and inspection, both of individual wires entering into the construction of the cable, and of the completed cable, shall be made at the place of manufacture. Tests on individual wires shall be made on samples taken before cabling, and not on wires removed from the completed cable.

INSULATED WIRES AND CABLES

By W. A. Del Mar

55. TERMINOLOGY

WIRE. A wire is a slender rod or filament of drawn metal. The definition restricts the term to what would ordinarily be understood by the term "solid wire." In the definition, the word "slender" is used in the sense that the length is great in comparison with the diameter. If a wire is covered with insulation, it is properly called an insulated wire; though primarily the term "wire" refers to the metal, nevertheless when the context shows that the wire is insulated, the term "wire" will be understood to include the insulation.

CONDUCTOR. A conductor is a wire or combination of wires not insulated from one another, suitable for carrying an electric current.

STRANDED CONDUCTOR. A stranded conductor is a conductor composed of a group of wires, or of any combination of groups of wires. The wires in a stranded conductor are usually twisted or braided together.

STRAND. A strand is one of the wires, or groups of wires, of any stranded conductor.

CABLE. A cable is either a stranded conductor (single-conductor cable), or a combination of conductors insulated from one another (multiple-conductor cable).

The first kind of cable is a single conductor; the second kind is a group of several conductors. The component conductors of the second kind of cable may be either solid or stranded, and this kind of cable may or may not have a common insulating covering.

The term " cable " is applied by some manufacturers to a solid wire heavily insulated and lead-covered; this usage arises from the manner of the insulation, but such a conductor is not included under this definition of " cable." The term " cable " is a general one, and in practice, it is usually applied only to the larger sizes. A small cable is called a " stranded wire " or a " cord," both of which are defined below. Cables may be bare or insulated, and the latter may be sheathed with lead, or armored with wires, or bands.

CORD. A cord is a small very flexible insulated cable. There is no sharp dividing line in respect to size between a " cord " and a " cable."

CONCENTRIC-LAY CONDUCTOR. A concentric-lay conductor is a conductor composed of a central core surrounded by one or more layers of helically laid wires. In the most common type of concentric-lay conductor, all wires are of the same size and the central core is a single wire.

ROPE-LAY CONDUCTOR OR CABLE. A rope-lay cable is a cable composed of a central core surrounded by one or more layers of helically laid groups of wires. This kind of cable differs from the preceding in that the main strands are themselves stranded. In the most common type of rope-lay conductor or cable, all wires are of the same size and the central core is a concentric-lay conductor.

CONCENTRIC-LAY CABLE. A concentric-lay cable is either: (*a*) A concentric-lay conductor as defined. (*b*) A multiple-conductor cable composed of a central core surrounded by one or more layers of helically laid insulated conductors.

***N*-CONDUCTOR CABLE.** An N-conductor cable is a combination of N conductors insulated from one another. It is not intended that the name as here given be actually used. One would instead speak of a "three-conductor cable," a "twelve-conductor cable," etc. In referring to the general case, one may speak of a "multiple-conductor cable."

***N*-CONDUCTOR CONCENTRIC CABLE.** An N-conductor concentric cable is a cable composed of an insulated central conductor with $(N - 1)$ tubular stranded conductors laid over it concentrically and separated by layers of insulation. This kind of cable usually has only two or three conductors. Such cables are used particularly for alternating currents. The remark on the expression " N-conductor " given for the preceding definition also applies here.

DUPLEX CABLE. A duplex cable is a cable composed of two insulated stranded conductors twisted together. They may or may not have a common insulating covering.

TWIN CABLE. A twin cable is a cable composed of two insulated stranded conductors laid parallel, having a common covering.

TWIN WIRE. A twin wire is a cable composed of two small insulated conductors laid parallel, having a common covering.

TWISTED PAIR. A twisted pair is a cable composed of two small insulated conductors, twisted together, without a common covering. The two conductors of a " twisted pair " are usually substantially insulated, so that the combination is a special case of a " cord."

TRIPLEX CABLE. A triplex cable is a cable composed of three insulated single-conductor cables twisted together. They may or may not have a common insulating covering.

SECTOR CABLE. A sector cable is a multiple-conductor cable in which the cross-section of each conductor is substantially a sector, an ellipse, or a figure intermediate between them. Sector cables are used in order to obtain decreased overall diameter and thus permit the use of larger conductors in a cable of given diameter.

ROUND CONDUCTOR. A round conductor is either a solid or stranded conductor of which the cross-section is substantially circular.

SPLIT CONDUCTOR CABLE. A split conductor cable is one in which each conductor is composed of two or more insulated conductors normally connected in parallel.

SHIELDED CONDUCTOR CABLE. A shielded conductor cable is a cable in which the insulated conductor or conductors is/are enclosed in a conducting envelope or envelopes.

FACTOR OF ASSURANCE. The factor of assurance of wire or cable insulation is the ratio of the voltage at which it is tested to that at which it is used.

INSULATION RESISTANCE. The insulation resistance of an insulated conductor is the resistance offered by its insulation, to an impressed direct voltage tending to produce a leakage of current through the same.

MIL. A mil is the one-thousandth part of an inch. There are 1974 circular mils in a square millimeter.

CIRCULAR MIL. A circular mil is a unit of area equal to $\pi/4$ ($= 0.7854 \ldots$) of a square mil. The cross-sectional area of a circle in circular mils is therefore equal to the square of its diameter in mils. A circular inch is equal to one million circular mils.

LAY. The lay or pitch of any helical element of a cable is the axial length of a turn of the helix of that element.

Among the helical elements of a cable may be each strand in a concentric-lay cable, or each insulated conductor in a multiple-conductor cable.

DIRECTION OF LAY. The direction of lay is the lateral direction in which the strands of a cable run over the top of the cable as they recede from an observer looking along the axis of the cable.

56. DESIGN AND CONSTRUCTION

Materials

CONDUCTORS. Round copper wire, solid or stranded, is almost invariably used for insulated wires and cables. Aluminum, requiring a larger cross-section for the same conductance per unit length, requires more insulating material for the same thickness of insulation.

Stranding. Conductors are stranded in order to make them more flexible. The flexibility is approximately proportional to the square root of the number of strands. In large cables, flexibility is required first in order to permit them to be put on reels; second, to permit easy installation; and third, to permit them to be bent around the walls of splicing chambers. Cords, elevator cables, mining machine cables, etc., must have considerable flexibility in order to permit them to be readily shifted from place to place in service.

For conduit work it is found unnecessary to strand conductors smaller than No. 6 A.W.G., although some contractors use stranded conductors as small as No. 12.

Sector-shaped Conductors. Two-, three-, and four-conductor cables, with sector-shaped conductors are in general use, the three-conductor type being most common. The principal advantage of this type of cable is the greater carrying capacity for a given outside diameter.

PREPARATION OF CONDUCTORS FOR INSULATION. Where rubber insulation is used it is necessary to cover the conductor with a thin film of tin or lead alloy, or with a separator, as described below.

Tinning. Copper and rubber when brought into contact react upon one another chemically. It was formerly thought that this action was due entirely to the sulfur in the rubber compound combining with the copper. Pure rubber, however, also reacts with the copper, the rubber breaking down into a gluey, sticky mass. Tinning the copper affords the necessary protection as tin does not react with either dry rubber or sulfur.

Separators. Small stranded conductors are usually covered with a winding of soft cotton threads for the following purposes:

1. To protect the copper and rubber from mutual chemical action where a coating of tin on the copper cannot be used.
2. To hold together a group of fine wires so that individual wires will not stand up and penetrate the insulation during the manufacturing process.
3. To prevent adhesion between the rubber and copper in order that the copper may be easily bared for making connections.

A separator composed of a wind of soft cotton is used on cords of various types for the first and second reasons. A similar cotton wind on small conductors, or a paper or dry muslin tape on large conductors, is used on cables for car wiring for the third reason given above.

INSULATION. The materials used for insulation are vulcanized rubber, gutta-percha, varnished cloth, impregnated paper, asbestos, cotton and silk thread, enamel, etc.

RUBBER INSULATION. There are two processes by which rubber compound is ordinarily put on the wire, the strip and the tube or seamless processes. By the former, the compound is first made into long narrow strips and then pressed around the wire; by the latter, the wire is run through a die through which the compound is pressed onto the wire. Insulation made by the former process shows a seam or ridge where the sides of the strip have united, which is often partially obliterated by a tape applied before vulcanization; that made by the tube process is seamless.

Rubber insulating compounds are made by mixing new rubber with some or all of the following ingredients:

Vulcanizing agent—either sulfur or sulfur-bearing organic compound capable of liberating sulfur at vulcanizing temperatures.

Accelerator—either litharge or an organic compound, usually of the basic nitrogenous type.

Activator—usually zinc oxide.
Filler—inert mineral matter, such as talc, clay, etc.
Hardener—usually carbon black or clay.
Softener—paraffin wax, ozokerite, resins, reclaimed rubber.
Anti-oxidant—an organic compound usually of nitrogenous type.
Ozone-resistant—vulcanized oil, ceresin, etc.
Vulcanizing is effected in dry steam at a temperature of about 300 deg fahr.
Several processes for direct deposition of **rubber latex** on wire are also in use.
Percentages of rubber vary from about 20 per cent in Code compounds to 60 per cent in low-capacity communication cable compounds.
The principal grades of rubber compound are as follows:

Quality Controlled by Composition	Code grade, for ordinary house wiring (N.E. Code Specification). Intermediate grade, for house wiring where a better quality is desired (N.E.M.A. Specification). Thirty per cent, Type A, formerly the highest grade for wiring of buildings (A.S.T.M. & N.E.M.A. Specifications).
Quality Controlled both by Composition and Accelerated Life Tests	Thirty per cent, Type AO, an improvement on Type A in regard to aging qualities (A.S.T.M. Specification).
Quality Controlled by Accelerated Life Tests	Performance Test Type, the quality of which is gaged entirely by accelerated life tests (A.S.T.M., N.E.M.A. and "Performite" Specifications). High Tension Type, an ozone-resistant or corona-deterrent type of high dielectric strength.
Special Compounds Requiring Special Tests to Control Quality	Submarine Communication Cable Grade—low S.I.C. low water absorption compound with 50–60 per cent of rubber. Cord Sheath Grade—abrasion-resistant compound of high carbon-black content with 40–60 per cent rubber.

VARNISHED CAMBRIC. Cotton fabric coated with multiple layers of varnish is applied to the conductor in the form of tape, the successive turns being staggered. A thin layer of oil or petroleum is applied between layers. Where the cable is to be used for vertical risers, only a small quantity of this "slipper compound" should be used.

IMPREGNATED PAPER. Tapes of special wood pulp paper, 5 to 8 mils thick, are applied to the conductor and then dried and thoroughly impregnated with heavy oily compound, sometimes containing about 15–20 per cent of rosin. The utmost care is required in the drying, evacuating, and impregnating to keep out every trace of air and moisture, especially for high-voltage cables. The lead is applied after impregnation. Oil-filled cable is similar except that a thin oil is used and impregnation is effected after application of the sheath.

ASBESTOS. Asbestos may be applied in felted form, as a tape, or as a braid. Sometimes it is impregnated with asphaltic material, and it is often associated with varnished cambric, as its own electrical properties are very poor.

COTTON AND SILK. Cotton or silk insulation consists of one to three layers of thread spun on to the wire. It is usually paraffined or varnished.

ENAMEL. Wire is passed through successive baths of quick-drying enamel until the requisite thickness is attained.

FILLERS. Fillers, used to round out multiple-conductor cables, are usually made of crinkled paper for paper-insulated cables and of jute for rubber or varnished-cambric insulated cables. The jute may be paraffined, tarred, or vacuum-impregnated with asphaltic compound, depending on the degree of waterproofness required.

PROTECTIVE COVERINGS. Coverings of lead, steel wire, steel tape, treated cotton, asphalted jute, rubberized cotton tape, reinforced rubber, hardened rubber, vulcanized oil, treated paper, etc., are used to protect cable insulation from mechanical injury or water.

Cotton Braid. The most usual covering for rubber-insulated conductors is a cotton braid saturated with asphaltic material and filled with stearine pitch. The larger sizes of cables have a rubberized cotton tape under the braid.

Weatherproofing. Saturated cotton braid is also put on uninsulated hard-drawn copper wire for overhead service, in order to protect the wire from destructive arcing due to accidental contact with tree branches and other foreign bodies.

Lead Sheath. Lead sheath is put over the insulation by passing the cable through a die, while hot lead is pressed hydraulically around it through an annular die, forming a continuous and close-fitting pipe. Were it not for electrolytic corrosion, it would be practically permanent. Unfortunately, lead is subject to electrolytic and even chemical corrosion. It is also rendered brittle and eventually breaks into pieces when exposed to vibration, this effect being due to separation along intercrystalline surfaces. Pure lead is suitable for cables which are hard and compact. Other cables require a small quantity of tin, antimony, or calcium to harden the lead. For a given thickness pure lead is cheaper, but for a given tensile strength, alloy is cheaper. The usual proportions for alloy sheath are either 2 per cent of tin or $^3/_4$ per cent of antimony. Ternary alloys of lead, tin, and cadmium are also used. Such alloyed lead is more resistant to intercrystalline cracking, at atmospheric temperatures, than pure lead.

Non-metallic Sheaths. Sheaths of vulcanized oil, thiokol, asphalt-saturated asbestos, and other materials water-resistant in various degrees, are being largely used for rubber-insulated cables which are to be buried underground.

Armor Wire and Tape. Submarine cables are usually covered with steel wire armor, and cables to be buried direct in the ground are usually covered with galvanized steel tape armor. In either case the armor is usually covered with asphalted jute.

57. APPLICATIONS OF VARIOUS TYPES

The type of insulation and protection to employ in any instance depends upon the purpose for which the conductor is to be used and the place in which it is to be installed.

Power Wires and Cables, that is, those for the transmission or distribution of electric energy, may be installed in buildings, in cars, in underground conduits, on pole lines, buried in the ground, or under water.

Wires and cables for **buildings** are usually rubber-insulated and covered with a saturated braid. Varnished cambric with saturated braid is often used for the larger sizes.

Wires and cables for **power houses** are usually varnished-cambric insulated with either a saturated or a flameproof braid.

Wires and cables for **underground conduit lines** are generally paper-insulated, but rubber or varnished cambric is sometimes used.

Wires for **mining** machinery and for **railway signals** are rubber-insulated.

Submarine Power Cables are usually insulated with rubber, sometimes sheathed in lead, and armored with steel wire. Paper-insulated lead-sheathed and armored submarines are in extensive use for high voltages.

Insulated Conductors for Instrument and Machine Windings: Enameled wire or wire insulated with cotton or silk is used for the former, while varnished cambric, mica, and asbestos compounds are used for the latter.

58. DESIGN

Insulation Thickness

The thickness of insulation required for low-voltage cables is merely that necessitated by inevitable irregularities of manufacture and roughness in handling. At voltages above 1000, the dielectric stress begins to have an influence and, when 2000 volts are reached, becomes the dominant factor. If certain assumptions are made, the thickness of insulation corresponding to a given dielectric stress may be calculated, but these assumptions are only partially realized in practice. These assumptions are:

(*a*) That the radial depth of the insulation or dielectric is the same at all points, i.e., that the cross-section of the cable is bounded by a perfect circle with the conductor section (also a perfect circle) exactly in the center of the insulation. Owing, however, to the crinkling of tape, the pressure of the braid, or other accidents of manufacture, this is never the case. The eccentricity of the conductor with respect to the insulation may, however, be allowed for by adding to the theoretical thickness of insulation an additional thickness, known as the " error thickness " or excess thickness.

(*b*) That the dielectric is perfectly homogeneous throughout. This is never realized in practice. It is probable that even in the most carefully made insulation there is a minute amount of air and moisture, but sufficient to modify considerably any conclusions based on absolute homogeneity of the dielectric.

(*c*) That when the electric stress, or potential gradient, at any part of the dielectric exceeds a certain value F_s known as its dielectric strength, that part of the dielectric becomes a partial conductor even though there be no actual rupture or puncturing.

THEORETICAL THICKNESS OF INSULATION. Let

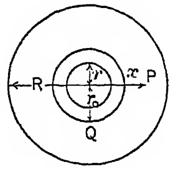

FIG. 1

F = potential gradient, in volts per mil, at any point P in the dielectric at a distance x mils from the center of the wire, Fig. 1.
E = volts between wire and sheath (or outside surface of insulation).
r = radius of wire, in mils.
R = outside radius of insulation, in mils.
F_s = dielectric strength of the insulation, in volts per mil.

Then, on the assumption of a perfectly homogeneous dielectric and perfect symmetry between conductor and insulation,

$$F = \frac{E}{x \log_\epsilon \left(\frac{R}{r}\right)}$$

That is, the potential gradient is the greatest at the surface of the conductor and decreases toward the outer surface of the insulation as shown in Fig. 2. The potential gradient at the surface of the conductor is

$$F_{\max} = \frac{E}{r \log_\epsilon \left(\frac{R}{r}\right)}$$

For the same outside diameter of the insulation this stress at the surface varies with the radius of the conductor as shown in Fig. 3, and has a *minimum* value theoretically when $r = R/2.72$, but actually when R/r is somewhat greater than 2.72.

The volt-ampere characteristics of insulation are generally of the form shown in Fig. 4. Owing to the form of the curve at high stresses, it is evident that, when the critical stress F_c is reached, the current will rise indefinitely, i.e., the insulation will fail, even if the stress is lowered. If, however, in the case of cylindrical insulation, the inner layers are stressed to the value F_c, the remainder may act as a ballast resistor to keep the current down. Then

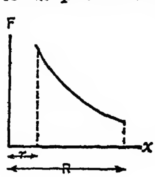

FIG. 2

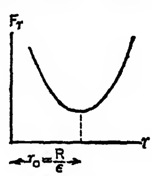

FIG. 3

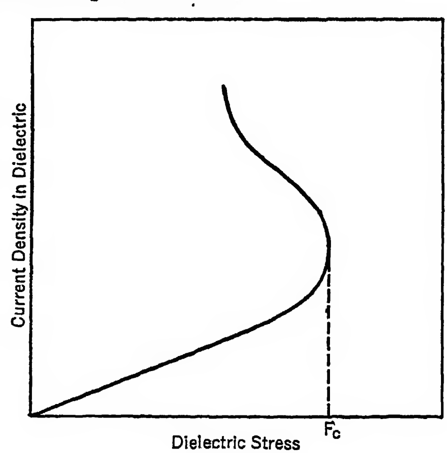

FIG. 4

the inner insulation will be overstressed but uninjured. The above formulas for stress, therefore, are not applicable at or near the breakdown point.

In impregnated-paper insulation, a potential gradient of about 50 volts per mil at the conductor surface will start ionization of occluded gas, but ionization is likely to die out unless the stress is about 60 volts per mil. Oil between paper tapes ionizes at an overall stress of about 230 volts per mil, at atmospheric pressure. (Inge & Walther.)

Rubber insulation is more likely to be injured by excessive minimum than maximum stress as air at the outer surface of the insulation may be ionized and converted into ozone, which rapidly destroys the rubber.

Tables I to VI inclusive give the standard thicknesses of insulation in American practice.

RUBBER INSULATION. The thicknesses of insulation in Table I for use with grounded neutral voltages are practically in agreement with A.I.E.E. Standards. Tabulated

thicknesses for use with ungrounded neutral voltages are based on the same standard but assume that the effective voltage across the insulation is intermediate between the circuit voltage and the voltage to ground. From 0 to 5000 volts the thicknesses are in accord with N.E. Code of 1935.

The thicknesses in Table I apply to single-conductor cable and the individual conductors of multiple-conductor cables, leaded or braided, except special applications such as aerial, non-leaded submarine, vertical riser, and series street lighting. For series street lighting cables, find the *rated voltage* from Table III and the corresponding thickness from Table IV.

Code, intermediate, or other compounds inferior in quality to 30 per cent grades are not acceptable for circuit voltages 5001 volts and above.

The thickness of insulation for the various systems shall be determined as follows,

(*a*) For three-phase systems with grounded or ungrounded neutral, use thickness values in accordance with the respective columns in Table I.

(*b*) For single- or two-phase systems up to and including 5000 volts, use thickness values in accordance with the grounded neutral column of Table I. Where a single-phase line is a tap from a three-phase line, experience indicates that rule (*a*) should be followed.

(*c*) For single- or two-phase systems operating at over 5000 volts with one side grounded, multiply the circuit voltage (phase to phase) by 1.73 and use the resulting voltage value to select the corresponding insulation thickness in the grounded neutral column of Table I.

(*d*) For single- or two-phase systems operating at over 5000 volts with the center grounded, multiply the circuit voltage (phase to phase) by 0.866 ($= 1/2\sqrt{3}$) and use the resulting voltage value to select the corresponding insulation thickness in the grounded neutral column of Table I.

(*e*) For single- or two-phase ungrounded systems operating at over 5000 volts, multiply the circuit voltage (phase to phase) by 0.866 ($= 1/2\sqrt{3}$) and use the resulting voltage value to select the corresponding insulation thickness in the ungrounded neutral column of Table I.

For non-leaded submarine cables, 1/32 in. should be added to the specified respective walls of insulation in Table I for all sizes and voltages.

See below for Shielding standards.

VARNISHED-CAMBRIC INSULATION. Table V gives the recommended thickness of insulation for lead-covered cables, for braided cables up to 7500 volts between phases, and for braided cables for all voltages when strung on insulators. See Shielding.

The thicknesses of insulation for various systems shall be determined as follows:

For three-phase systems with grounded or ungrounded neutral, use thickness values in accordance with the respective columns in Table V.

For single- or two-phase systems up to and including 5000 volts, use thickness values in accordance with the ungrounded neutral column of Table V.

For single- or two-phase systems operating at over 5000 volts with one side grounded, multiply the circuit voltage (phase to phase) by 1.73 and use the resulting voltage value to select the corresponding insulation thickness in the grounded neutral column of Table V.

Table II. Thickness of Rubber Insulation for Railway Signal Cables (A.A.R.)

666 Volts or Less			
Single Conductor		Multi-conductor

15	3,090	2,272	4,000	3,000	70	14,500	10,600	15,000	11,000

* Where protectors are used for economy rather than for added security.

Table IV. Thickness of Rubber Insulation for Series Lighting Cable (I.P.C.E.A., 1934)

(See Table III for rated voltage in terms of power rating and operating voltages.)

Rated Voltage	Insulation Thickness 64ths inch		Rated Voltage	Insulation Thickness 64ths inch	
	No. 8 A. W. G.	No. 7–No. 4 A. W. G.		No. 8 A. W. G.	No. 7–No. 4 A. W. G.
600	4	4	8,000	12	12
1,000	4	5	9,000	13	13
2,000	5	6	10,000	14	14
3,000	7	8	11,000	15	15
4,000	9	9	12,000	16	16
5,000	10	10	13,000	17	17
6,000	10	10	14,000	18	18
7,000	11	11	15,000	19	19

For single- or two-phase systems, operating at over 5000 volts with the center grounded, multiply the circuit voltage (phase to phase) by 0.866 ($= \frac{1}{2}\sqrt{3}$) and use the resulting voltage value to select the corresponding insulation thickness in the grounded neutral column of Table V.

For single- or two-phase, ungrounded systems operating at over 5000 volts, multiply the circuit voltage (phase to phase) by 0.866 ($= \frac{1}{2}\sqrt{3}$), and use the resulting voltage value to select the corresponding insulation thickness in the ungrounded neutral column of Table V.

For d-c systems up to and including 2000 volts, use thickness values in accordance with the grounded neutral column of Table V.

For d-c systems over 2000 volts, consult the manufacturers.

For series lighting cables, use Tables III and VII.

See next article for Shielding standards.

* The ratings marked * are those recommended by the N.E.M.A.-N.E.L.A. Joint Committee on Voltage Standardization as "Preferred Voltage Ratings" for "general apparatus" except 1000 which has been added because of the large amount of very low-voltage cable used.

† N.E. Code specifies No. 8 minimum size and does not mention shielded cable.

All cables have an operating tolerance of 5 per cent above the rated voltage except those rated at 15,000 volts and below which have no operating tolerance. All cables for three-phase circuits are rated on the conductor-to-conductor basis.

Unless otherwise specified, two-conductor cable will be of the round type; when laid parallel, the thickness of the insulation shall be the same as that for single-conductor cable for the same voltage.

The thicknesses given for 7500 volts and over should be used for single-conductor braided cables only if supported on insulators, or suitably shielded.

* The ratings marked * are those recommended by the N.E.M.A.-N.E.L.A. Joint Committee on Voltage Standardization as "Preferred Voltage Ratings" for "general apparatus" except 1000 which has been added because of the large amount of very low-voltage cable used.

† N.E. Code specifies No. 8 minimum size.

All cables have an operating tolerance of 5 per cent above the rated voltage except those rated at 15,000 volts and below which have no operating tolerance. All cables for three-phase circuits are rated on the conductor to conductor basis.

Unless otherwise specified, two-conductor cable will be of the round type; when laid parallel, the thickness of the insulation shall be the same as that for single-conductor cable for the same voltage.

IMPREGNATED-PAPER INSULATION. The thicknesses given in Table VI are considered to be representative of good practice for normal conditions, i.e., where impregnation can be maintained, voltage transients are not unusual, etc. See below for Shielding standards.

Oil-filled Cable uses thinner walls, as shown in Table VIII, owing to the absence of gaseous ionization. These walls apply to hollow core conductors of 0.5 or 0.69 in. internal diameters.

Pressure Cables use insulation walls about the same as oil-filled cable, but no standards have been published.

For Circuits Other Than Three-phase, the thickness should be that for grounded neutral with the rated three-phase voltage which gives the same voltage across the insulation. See above under Varnished-cambric Insulation.

Table VI. Recommended Minimum Thickness of Insulation and Minimum Size Conductors

Impregnated-paper Cable

(I.P.C.E.A., 1934)

(The thicknesses for grounded neutral are also "recommended" by A.E.I.C. specifications.)

13,000	—	15
15,000	—	16

Shielding

It is customary to shield the outer layers of insulation, where danger from gaseous ionization exists, with a metallic screen in close contact with the insulation. The standard practice for shielding is given in Table IX.

Such shielding, however, is useful for other reasons. It eliminates stresses along the surface of the insulation, in three-phase cables, i.e., tangential stresses, which are likely to exist because the insulation has to carry the circuit voltage along the axes between conductors and $1/\sqrt{3}$ of the circuit voltage along the radii between conductors and ground. Shielding of unleaded cables also affords a protection against shock, as the shield is always grounded and may be connected to give a good return path for the short-circuit current, in the event of a failure of the insulation, thereby making the operation of protective devices more certain. Shields should always be terminated in cones of insulating tape (usually of varnished cambric) to eliminate edge stresses.

Certain rubber compounds have been developed which are substantially ozone-proof and under some conditions may be used without shielding. Examples are the wires used for 7500–15,000 volt neon gas tubes and for ignition systems of internal-combustion engines.

* Shield may be over belt, in a belted cable.

Coverings

LEAD SHEATHS. Standard lead sheath thicknessess are given in Table X. These apply to both pure and alloyed lead.

ARMOR. Table XI gives the standard dimensions of armor and jute for armored cables. The I.P.C.E.A. " Metallic Coverings " Specifications also give standards for interlocked armor, duck tape over sheaths, and braid over sheaths.

BRAIDS. Three grades of braid are in use, as follows:

(a) **Class A (N.E.M.A.) Braid Specifications,** which are to be used only for code and intermediate grade wires and cables. The thickness shall be as specified in Table XII.

(b) **Class B (A.S.T.M. "Standard") Braid Specifications,** which are designed for indoor service, installation in conduits, or as the inner braids for multiple-conductor cables, both for rubber and varnished cambric. The thickness is given in Table XIII.

(c) **Class C (A.S.T.M. "Heavy") Braid Specifications,** which are designed for outdoor and rough service. The thickness is given in Table XIV.

(d) Unless otherwise specified, Class B (A.S.T.M. "Standard") Braid Specifications are used for 30 per cent grade.

Table X. Lead Sheath Thickness

64ths Inch

(I.P.C.E.A., 1934)		(I.P.C.E.A. & A.E.I.C., 1934)		(A.E.I.C., 1934)	
Core Diameter, in.	For Rubber or Varnished Cambric	Core Diameter, in.	For Paper "Solid Type" Cable	Core Diameter, in.	For Paper Oil-filled Type
0–0.425	3	0–0.400	5	up to 1.800	8
0.426–0.700	4	0.401–1.000	6	1.801 to 2.800	9
0.701–1.050	5	1.001–1.800	7	2.801 and over	10
1.051–1.500	6	1.801–2.900	8		
1.501–2.000	7	2.901–3.200	9		
2.001–3.000	8	3.201 and over	10		
3.001 and over	9				

For twin flat construction use major core diameter.
Submarine cable sheath should never be less than 5/64 in.
Pressure cable of the Hochstadter type has thinner lead than ordinary solid or oil-filled cable.

Table XI. Armor Dimensions and Thickness of Jute Bedding for Armored Cable

(I.P.C.E.A., 1934)

59. TESTS

GENERAL. Rubber-insulated Cables are tested for imperfections by means of a high-voltage test, Table XV, and for dryness by a megohm test. General quality is tested by tensile strength, elongation, and permanent set measurements. Life expectancy is estimated by accelerated aging tests in which oxidation is accelerated by heat.

High-voltage rubber is tested for corona suppression by noting the voltage at which visual corona appears when viewed in the dark, and for ozone resistance by exposure to ozone of concentration 0.02 per cent.

Water resistance is tested by noting the rise of S.I.C. when immersed in water either at room temperature or 70 deg cent.

Varnished-cambric Cables are given high-voltage and megohm tests for the reasons given above for rubber (Table XVI). They are occasionally tested for power factor and ionization. See I.P.C.E.A. specifications.

Impregnated Paper Cables are given high-voltage and megohm tests for the reasons given above (Table XVII).

Cables for circuit voltages of 7500 and above are tested for power factor and dielectric loss both as an economic measure and to guard against accumulative heating which might result from high dielectric loss.

The limiting power factors of A.E.I.C. (1936) are as follows:

Temperature of Cable, ° C	Power Factor, %	
	7.5 to 20 kv	20.1 kv and over
Room to 60	1.1	0.90
70	1.6	1.30
75	1.9	1.50
80	2.3	1.80
85	2.8	2.20
90	3.4	—

Cables for circuit voltages of 7500 and above are tested for ionization, i.e., rise of power factor from 20 to 100 volts per mil, average stress, to detect entrained gas. The usual ionization limits are as follows:

No. of Conductors	Rated Kilovolts	Ionization Factor Rise of Power Factor
Single	7.5–20.0	0.3
	20.1–35.0	0.2
	35.1 and over	0.1
Multiple, shielded	7.5–20.0	0.3
	20.1 and over	0.2
Multiple, belted	7.5 and over	0.5

TEST VOLTAGES. Factory test voltages on full reel lengths are given in Tables XV, XVI, and XVII.

In all cases, if a test voltage is to be applied after armoring it should be 80 per cent of that applied before armoring.

Tests after installation and proof tests at intervals are made at the following values, the percentages being taken on the full reel final factory test voltage unless otherwise stated.

	Rubber	V. C.	Paper
Test after installation	80% for same period	70% for 5 min	60% for 4 hr 80% for 1/4 hr
Proof test	60% for same period	60% for 5 min or 150% of rated voltage	60% for 5 min. or 175% of rated volts
Ratio of d-c to a-c test	2.2	2*	2.4*

* The d-c test may be made in place of any of the a-c tests listed. If the cable temperature exceeds 25 deg cent the tabulated ratio shall be reduced by 0.013 for each degree over 25 deg cent.

BENDING TESTS. These tests are made to ensure flexibility of paper and varnished-cambric cables. In paper cables they are made at diameter of 12 times the diameter of the cable, and in varnished cambric, at a diameter ratio of 8.

Table XV. Test Voltages for Rubber Insulation

Kilovolts for { 5 min, 30% grade; 3 min, Intermediate; 1 min, Code (see Note 1, below) }

Over 10	Test voltage kv = $10 + 1\,1/2\,(T - 10)$ where T = thickness in 64ths inch; e.g., if insulation thickness is 20/64 in., $T = 20$ and the test voltage equals $10 + 1\,1/2\,(20 - 10) = 25$ kv					

* 3.5 on No. 8 A.W.G.

1. The word "Code" is here used in the sense of Code Grade Insulation. Where National Electrical Code labels are to be applied, the tests should be in accordance with National Electrical Code Specifications.

The "Code" requirements for 0–600 volt wire and cable are as follows:

Size A.W.G. or 1000 in mils	Test Voltage 1 min	Size A.W.G. or 1000 in mils	Test Voltage 1 min
14–9	1.5	225–500	3.0
8–2	2.0	525–1000	3.5
1–4/0	2.5	Over 1000	3.5

2. These tests are based on A.I.E.E. Standards but certain departures therefrom have been made, as dictated by experience obtained since those Standards were formulated. These departures are all confined to thicknesses below 9/64ths inch.

Table XVI. Voltage Tests for Varnished-cambric Insulation

Kilovolts for 5 min

(From Standards of I.P.C.E.A., 1934)

Insulation Thickness, 64ths in.	Size A.W.G. or Cir Mils

30				55.0	55.5	56.5	57.0

The above table is for single-conductor and multiple-conductor shielded cables.

For multiple-conductor non-shielded cables, the test between conductors shall be twice that given above for a single-conductor cable having the same insulation thickness as each conductor. The test pressure to sheath or ground shall be 58 per cent of this value except for multiple-conductor cables for ungrounded circuits over 6000 volts working pressure, where the test pressure shall be 80 per cent of the pressure between conductors.

Table XVII. Voltage Tests for Impregnated-paper Cables

(From Specifications of A.E.I.C., 1934)

(a) Test Voltages (Kilovolts) for Stranded Conductor Cables Rated at 7.5 kv or Less, Phase to Phase

Time of application, 5 min

Thickness of Insulation, 64ths in.	Single-conductor cable Test volts, kv (cond.-sheath)				Multiple-conductor cable, belted Test volts, kv (cond.-cond.)	
	No. 1 to No. 4/0	213,000 to 500,000	501,000 to 1,000,000	Over 1,000,000	No. 1 to No. 4/0	225,000 and larger
4	5.0	5.0	—	—	6.0	—
5	8.0	8.0	6.0	—	14.0	14.0
6	12.5	12.5	11.0	7.5	25.0	25.0
7	18.0	18.0	17.0	13.0	93.0	39.0
8	24.0	24.0	23.0	22.0	—	—
9	31.0	31.0	31.0	31.0	—	—

Note 1. Three conductor belted cables shall be tested from conductor to sheath at $\frac{1}{\sqrt{3}}$ times the tabulated (c-c) value, except that, whenever a separate c-s test is required, it shall be made at an average stress (c-s) equal to 80 per cent of the average stress (c-c) determined from the above table.

Note 2. Cables having stranded conductors smaller than No. 1 A.W.G. shall be tested at 85 per cent of the voltage specified for No. 1 A.W.G. and larger. If such cables have solid conductors, they shall be tested at 70 per cent of the voltage specified for stranded cables with conductors No. 1 A.W.G. and larger.

(b) Test Voltages for Cables Rated at Over 7.5 kv, Phase to Phase

Time of application, 15 min

Type of cable	Test volts, volts per mil of specified insulation thickness
Single-conductor	
up to 50 kv	220
over 50 kv	230
Multiple-conductor	
Shielded	200
Belted, cond.-cond.	180
Belted, cond.-sheath	145*

* The conductor-sheath test voltage for three-conductor cable may be $\frac{1}{\sqrt{3}} \times$ conductor-conductor test voltage.

Concentric conductor cable to be tested as single-conductor cable.

(c) Oil-filled Cable. Single-conductor cable is tested at 300 volts per mil and three-conductor cable at 270 volts per mil of specified insulation thickness for 15 minutes.

INSULATION RESISTANCE. The insulation resistance of a cable is usually expressed in megohm-miles, sometimes erroneously called megohms per mile. The total insulation resistance of a cable varies inversely as its length; e.g., a cable 2 miles long has half the resistance between conductor and sheath that 1 mile of this cable has. The formulas for insulation resistance of various types of cables are given below.

The insulation resistance of a single-conductor cable of length l centimeters is

$$R' = \frac{\rho}{2\pi l} \log_\epsilon \frac{D}{d}$$

where d = diameter of conductor, D = outside diameter of insulation, R' = insulation resistance, l = axial length centimeter, and ρ = specific resistance.

From the above formula the megohm-miles are

$$R = K \log_{10} \frac{D}{d}$$

where R = the insulation resistance in megohms for a specified unit length.

K = megohms constant—when the insulation resistance is to be determined in megohm-mile units, K equals 0.00000228 times the resistivity of the insulation expressed in megohm-centimeter units.

D = outside diameter of insulation.

d = diameter of conductor.

* Solid conductor. Conductors larger than No. 8 are assumed to be stranded. For intermediate thickness interpolate.

The value of K for various types of insulation at 60 deg fahr, after an electrification of approximately 1 min under a constant d-c voltage, is given in the accompanying table. K varies with the time of electrification, the temperature, and the humidity.

Insulation	K at 60° F (15.5° C)	
	Limits	Usual Values
Vulcanized rubber	780 to 10,000	2,000 to 6,000
Gutta-percha	500 to 4,000	2,500
Varnished cloth	400 to 2,000	1,000
Impregnated paper	500 to 3,000	1,000
Commercial Grades of Rubber		
Code		3,800 for 1,000 ft
Intermediate		8,000 for 1,000 ft
30% and performance type		21,120 for 1,000 ft

Table XVIII gives the value of $\log_{10}\frac{D}{d}$ for various sizes of wire and thicknesses of insulation.

If the insulation resistance be measured with alternating current, it will appear to be much less than with direct current because of the dielectric loss.

Multiple-conductor Cables, Concentric. The insulation resistance between the inner conductor and the adjacent conductor of a concentric cable is calculated as for a single-conductor cable. The insulation resistance between any other conductor and its adjacent conductors, or conductor and sheath (if the sheath is adjacent), of a concentric cable, is the product divided by the sum of the resistances of the layers of insulation adjacent to such conductor, each being calculated separately as for a single-conductor cable.

Multiple-conductor Cables, Non-concentric, Round or Sector Type. The insulation resistance of each conductor to all other conductors connected to the sheath or water shall be calculated assuming the multiple conductor cable to be replaced by a single-conductor cable having a round conductor of the same cross-sectional area and an outside diameter over insulation of

$$D = \frac{(d + 3c + 2b)}{d}$$

where d is the diameter of a round conductor of the same cross-sectional area, c is the thickness of conductor insulation, and b is the thickness of belt insulation.

Where the braid or outer surface of the insulation acts as a conducting surface (as is sometimes the case in multiple-conductor, rubber-insulated cables), the values of D are as in single-conductor cables (A.I.E.E. Standard No. 30).

60. CURRENT-CARRYING CAPACITY OF WIRES AND CABLES

The maximum permissible temperature rise of insulated conductors is limited by the effect of heat upon the insulation. The highest temperatures which may be safely attained continuously are given in Table XIX. The voltage E is taken as line voltage for three-conductor belted cable and voltage to ground for three-conductor shielded and single-conductor cables. Minimum temperature for impregnated paper 60 deg cent, maximum temperature 85 deg cent. The first three items are A.I.E.E. Standards.

Table XIX.

Insulation	Maximum Permissible Temperature Centigrade	
	Low voltage	At E kv between conductors
Impregnated paper	85	$90-E$
Varnished cambric	75	$75-E$
Rubber insulation (30% hevea)	60	$60-0.25E$
Rubber insulation (Code)	50	......
Oil-filled cable 75° C for 69 kv and lower.		
" " " 70° C for over 69 kv.		

When rubber is heated, the usual order of events is as follows: Oxidation is accelerated if air is present, "devulcanization" commences; i.e., the rubber molecule breaks up without, however, liberating any sulfur. In varnished cambric, both the insulation resistance and dielectric strength fall quite rapidly after the limiting temperature is attained. The same applies to impregnated paper in a less degree. Furthermore, at high voltages, the dielectric loss is often considerable, and if neglected in calculating carrying capacity, is likely to make one overlook possibilities of temperatures, far in excess of those to be expected on the basis of I^2R losses alone.

Continuous carrying capacity is calculated by equating for each conductor the sum of the I^2R loss and equivalent dielectric loss at the conductor surface, with the temperature rise per unit of heat resistance from each conductor to the ambient earth or air. With current in amperes, resistance in ohms per foot, temperature rise in degrees centigrade, the thermal resistance will be in watts per foot per degree centigrade. The following tables are calculated on this basis. Recent work by Schering has shown that the temperature rise between conductor and sheath for a given loss in the dielectric is half as much as if the loss were at the conductor.

Current-carrying Capacity of Impregnated-paper Insulated Cable

(Publication A14 of E.E.I., 1933)

The tables for ordinary, "solid type," paper-insulated cable are based on standard conditions adopted by the Edison Electrical Institute and are representative of conservatively average field conditions in this country. These are:

(*a*) Thermal resistivity of insulation 700 (watt-cm units).

(*b*) Emissivity of sheath 1200 (watt-cm units).

(*c*) Daily load factor 50, 75, and 100 per cent and corresponding loss factors of 33, 62.5, and 100 per cent in underground ducts, and any load factor from 50 to 100 per cent in air.

(*d*) Duct constants, H, for

1 cable = 1.45 thermal-ohms
3 cables = 1.04 "
6 cables = 0.82 "
9 cables = 0.75 "
12 cables = 0.72 "

(*e*) All cables in group of similar size, equally loaded and in outside ducts only.

(*f*) Average soil conditions (not dry or "hot spot" conditions).

(*g*) Groups of cable in ducts are referred to ambient earth temperature without external source of heat.

(*h*) Groups of cable in air are referred to surrounding air temperature at full-load (corresponding to duct temperature underground).

(*i*) A.I.E.E. Standard Temperature Rule for paper cable, as given above.

(*j*) A.E.I.C. Standard thicknesses of insulation, adopted in 1930, were used in calculating these tables. See Table VII. Deviation, within reasonable limits, from these standard thicknesses in any one voltage class does not introduce serious error in current rating.

(*k*) Standard logarithmic formula was used in calculating the thermal resistance of single-conductor cable. The thermal resistance of three-conductor cable, both round and sector, was determined by methods given in *Elec. J.*, July, 1932, p. 336.

DIELECTRIC LOSS. The reduction in carrying capacity due to dielectric loss, as included in the tables, is based on the following 1934 A.E.I.C. *maximum* dielectric power-factor values:

Temperature, °C	Per Cent Power Factor—60 Cycles		Temperature, °C	Per Cent Power Factor—60 Cycles	
	7.5 to 20 kv	20 kv and over		7.5 to 20 kv	20 kv and over
Room to 60	2.0	1.5	80	4.0	3.5
70	2.9	2.4	85	4.7	4.2
75	3.4	2.9	90	5.5	5.0

The S.I.C. of the paper insulation is assumed to have its maximum value of 4.0 for all temperatures, and the calculated dielectric loss is based on uniform temperature for the cable cross-section; also, this loss is added directly to the copper loss. This, of course, results in slightly lesser carrying capacity, but is on the safe side and is practically negligible.

ADDITIONAL A-C LOSSES. In addition to dielectric loss, both single- and three-conductor cables have other a-c losses produced by magnetic induction, such as skin-

effect and **proximity-effect** losses in the conductors, losses in the lead sheath, and relatively small losses in the metal shielding and metal binding tape, where used.

The correction factors used for three-conductor cable of both the belted and shielded types, exclusive of dielectric loss, are as follows:

Conductor Size, 1000 cir mils	Reduction Factor for Current Rating	Conductor Size, 1000 cir mils	Reduction Factor for Current Rating
0 A.W.G.	0.99	500	0.94
0000 A.W.G.	.98	600	.93
300	.97	750	.91
350	.96		

For single-conductor cable, the tables include only dielectric and skin-effect losses (proximity-effect losses are negligible). No attempt is made to include induced sheath current loss for " short-circuited sheath operation " since this varies with spacing between cables, etc. See below. The tables, therefore, represent " open-circuited sheath operation " of single-conductor cable, i.e., cases where there are practically no sheath losses.

D-C CARRYING CAPACITY. The following table gives the factor by which the a-c rating of single-conductor standard strand cables at 5000 volts should be multiplied to obtain the d-c rating, for d-c voltages up to 1500 volts.

Conductor Size, cir mils	Correction Factor	Conductor Size, cir mils	Correction Factor
300,000	1.005	800,000	1.025
350,000	1.006	1,000,000	1.036
400,000	1.009	1,250,000	1.054
500,000	1.011	1,500,000	1.072
600,000	1.016	1,750,000	1.092
700,000	1.020	2,000,000	1.115
750,000	1.023		

FORMULAS USED

T_c = copper temperature.
T_a = ambient air temperature.
T_e = ambient earth temperature.
W = watts loss per foot of single cable.
R_{th} = thermal ohms per foot of cable.
$R_{th} = R_i + R_s$, where:
R_i = thermal ohms from conductor to sheath.
R_s = thermal ohms from sheath to ambient air.

For single conductor cable,

$$R_i = 8.40 \log_{10} \frac{d_2}{d_1}$$

$$R_s = \frac{4.92}{d_3}$$

where d_1 is diameter of conductor.
d_2 is outside diameter of insulation.
d_3 is outside diameter of sheath.
H = duct constant or thermal ohms per foot of total duct bank.
D = duct correction factor for a single cable of conduit group.
N = number of cables in duct bank.
L = daily loss factor, per cent.

For a single, isolated cable in still air:

$$T_c - T_a = W \cdot R_{th} \tag{1}$$

For one of a group of equally loaded cables in a duct bank:

$$T_c - T_e = W(R_{th} + D) \tag{2}$$

where:

$$D = H.L.N/100 \tag{3}$$

Table XXI. Single-conductor Annular Paper Cables in Ducts

Based on 60-cycle alternating current, and an earth temperature of 20 deg cent

50	0.73			0.72			0.68			0.60		

NOTE: This table can be used for either sector or round conductor cable but the minimum sizes are for round conductors.

For multiple-conductor cable,

$$R_i = \frac{3.65G_1}{n}$$

where n is the number of conductors in the cable and G_1 is the geometric factor, values of which are given by D. M. Simmons, *Trans. A.I.E.E.* 1923, vol. XLII, p. 600, and *Elec. Jour.* 1932, vol. 29, p. 339.

Table XXIV. Single-conductor Paper Cables in Air

40	1.00	1.00	1.00	1.00
50	0.88	0.88	0.85	0.80

(a) Any load factor from 50 to 100 per cent.
(b) This table can be used for either sector or round conductor cable.
(c) The above minimum sizes are for round conductors.

Current-carrying Capacity of Varnished-cambric Insulated Cable

(I.P.C.E.A.)

The tables for varnished-cambric insulated cable are based on standard conditions adopted by I.P.C.E.A. and are representative of conservatively average field conditions in this country. These are:

(*a*) Thermal resistivity of varnished-cambric insulation 600 (watt-cm units).

(*b*) Emissivity of lead sheath or braid 1200 (watt-cm units).

(*c*) Daily load factor 50, 75, and 100 per cent in underground ducts, and any load factor from 50 to 100 per cent in air.

(*d*) Duct correction factor, D:

Cables in Duct Bank	Load Factor...50%	75%	100%
	Loss Factor....33%	62.5%	100%
3	1.0	1.9	3.1
6	1.6	3.0	4.9
9	2.2	4.2	6.8
12	2.8	5.4	8.6

(*e*) All cables in group of similar size, equally loaded and in outside ducts only.

(*f*) Average soil conditions (not dry or "hot spot" conditions).

(*g*) Groups of cable in ducts are referred to ambient earth temperature without external source of heat.

(*h*) Groups of cable in air are referred to surrounding air temperature at full load (corresponding to duct temperature underground).

(*i*) A.I.E.E. Standard Temperature Rule for varnished cambric cable, Table XIX.

(*j*) I.P.C.E.A. standard thicknesses of insulation were used in calculating these tables. See Table V. Deviation, within reasonable limits, from these standard thicknesses in any one voltage class, does not introduce serious error in current rating.

(*k*) Standard logarithmic formula was used in calculating the thermal resistance of single-conductor cable. The thermal resistance of three-conductor cable was determined by methods cited on p. 199.

(*l*) The tables include correction for standard 60-cycle I.P.C.E.A. dielectric loss and all other forms of extra a-c losses as outlined in the following.

DIELECTRIC LOSS. The reduction in carrying capacity due to dielectric loss, as included in the tables, is based on the following I.P.C.E.A. maximum dielectric power-factor values:

Temperature in deg cent	Single- or Multiple-Conductor Shielded Cable	Multiple-Conductor Non-shielded Cable
Room to 40	7.0	10.0
60	10.0	15.0
80	16.0	25.0

The S.I.C. (specific inductive capacity) of the varnished-cambric insulation is assumed as 5.5 for all temperatures, and the calculated dielectric loss is based on uniform temperature for the cable cross-section; also, this loss is added directly to the copper loss. This, of course, results in slightly lesser carrying capacity, but is on the safe side. It is the most practical method for general use and introduces discrepancies only in extreme cases of large groups of extra high-voltage cable.

ADDITIONAL A-C LOSSES. For single-conductor cable, the tables include only dielectric and skin-effect losses (proximity-effect losses are negligible). No attempt is made to include induced sheath current loss for "short-circuited sheath operation," since this varies with spacing between cables, etc. See below. The tables, therefore, represent "open-circuited sheath operation" of single-conductor cable.

For three-conductor cable, the tables include corrections for dielectric loss, and, also, all other forms of 60-cycle extra a-c losses, such as skin-effect, proximity, and sheath losses. The correction factors used for three-conductor cable of both the belted and shielded types, exclusive of dielectric loss, are as given above for paper cables.

These factors hold, within acceptable limits, for all types of cable and thicknesses of insulation.

If current-carrying capacity for other values of extra a-c loss is desired, it can easily be obtained by first dividing the current value in the table by the above correction factor. This gives a value of current without correction for extra a-c loss. This value of current should then be divided by the square root of the ratio of watts loss including extra a-c losses, and watts loss without including extra a-c losses.

The above correction factors for extra a-c loss assume this as part of the copper loss. This is, of course, approximate but is always on the safe side and introduces no appreciable discrepancy except, possibly, for very large conductors. For belted and non-magnetic binder, shielded-type cable the greater part of the total extra a-c loss occurs in the sheath.

For magnetic binder, shielded type cable, on the other hand, the greater part of the extra loss occurs in the conductor. Where the exact proportions of such loss are known, the carrying capacity value in the table can be corrected by an obvious variation of the methods described.

Table XXVII. Three-conductor Shielded Type H Cable in Ducts

Based on 60-cycle alternating current and an earth temperature of 20 deg cent

50	0.61	0.60	0.58	0.48	0.41	0.32

The figures for extra a-c loss were based on data taken on lead-sheathed cables without armor. They will apply approximately to rubber-hose-jacket cable without lead sheath, but with magnetic armor, or for lead-sheathed cable, with magnetic armor and binder. They should not be used for lead-sheathed cable, with magnetic armor, and non-magnetic binder.

BRAIDED CABLE. It would appear at first sight that a cable with black weatherproof braid should have a greater current-carrying capacity than a leaded cable, since the braid has better radiating qualities than a lead sheath. However, it must be remembered that the braid is not so stable chemically as a lead sheath. If run at too high a temperature over an extended period of time, it will tend to become dry and eventually to rot off. Moreover, braided cables are commonly used around stations where practice should always be very conservative. For these reasons it is recommended that the same ratings be used for braided cables as for leaded cables.

GENERAL USE OF TABLES. In using these loading tables, the preceding conditions and limitations should be kept in mind. Where the actual conditions depart from these, proper allowance should be made.

It should be emphasized that these loading tables are based on standard *maximum* allowable copper temperature, and therefore, represent *maximum* allowable loading. Conservative loading (oversize conductors) is always a wise investment. It is recommended that conservative current loading practice be followed wherever possible. *When in doubt select the next largest size conductor.* Reduction in line losses and surplus capacity for emergency use justify this practice.

The column headings of the tables refer to N.E.L.A.–N.E.M.A. " Standard Preferred Voltage Ratings " for General Apparatus. If current-carrying capacity at other voltages and temperatures is desired, it can be obtained by interpolation.

FORMULAS USED. The formulas used in calculating the current tables are those given above for impregnated-paper cables.

Table XXVIII. Three-conductor Belted Type Cables in Ducts

Based on 60-cycle alternating current and an earth temperature of 20 deg cent

Conductor Size in A.W.G. or M.C.M.	Rated Three-phase Line Voltage, Neutral Grounded

Current-carrying Capacity of Rubber-insulated Wires and Cables

At the date of publication there are no tables of carrying capacity of rubber-insulated cables which take into account different types of cables and installations, but I.P.C.E.A. has such tables in preparation.

The values given in Table XXXV are those now approved by the National Board of Fire Underwriters for indoor installations.

The formulas given under Paper and Varnished Cambric may be employed, however, using the following constants.

Thermal resistivity....................................500 (watt-cm units)
Thermal emissivity of braid............................950 (watt-cm units)

Braid emissivity resistance values with age, color, diameter and conditions of installation, over a range of 600 to 1200.

Maximum permissible continuous operating temperature.

Heat-resisting rubber.................................. 70 or 75 deg cent *
30 per cent hevea...................................... 60 deg cent
Code... 50 deg cent

There are special rubber compounds that may be operated at higher temperatures. No allowance need be made for dielectric loss, as it is low and changes little with temperature.

Formula for Carrying Capacity in Earth

The carrying capacity of a cable buried in the earth may be derived from that in air, by the following relation:

Let I_a = continuous carrying capacity in air.
I_e = continuous carrying capacity buried in the earth.

* As recommended by manufacturer.

Table XXXV. Carrying Capacities, in Amperes, for Interior Copper Conductors, Rubber Insulated, National Board of Fire Underwriters

(For aluminum 84 per cent of these currents is allowed)

Single-conductor cables or each conductor of multiple-conductor cable

Size		Amperes	Size		Amperes	Size		Amperes
A.W.G.	Area, cir mils		A.W.G.	Area, cir mils		A.W.G.	Area cir mils	
18	1,624	3	0	105,500	125	...	900,000	600
16	2,583	6	00	133,100	150	...	1,000,000	650
14	4,107	15	000	167,800	175	...	1,100,000	690
12	6,530	20	...	200,000	200	...	1,200,000	730
10	10,380	25	0000	211,600	225	...	1,300,000	770
8	16,510	35	...	250,000	250	...	1,400,000	810
6	26,250	50	...	300,000	275	...	1,500,000	850
5	33,100	55	...	400,000	325	...	1,600,000	890
4	41,740	70	...	500,000	400	...	1,700,000	930
3	52,630	80	...	600,000	450	...	1,800,000	970
2	66,370	90	...	700,000	500	...	1,900,000	1010
1	83,690	100	...	800,000	550	...	2,000,000	1050

Then, assuming the same ambient temperature in both cases,

$$I_e = I_a\sqrt{\frac{R_i + R_s}{R_i + R_e}}$$

where R_s = thermal resistance from the surface of the cable to the air, in degrees centigrade per watt-foot.

R_i = thermal resistance of insulation, etc., from conductor to the surface of the cable, in degrees centigrade per watt-foot.

R_e = thermal resistance of earth from the surface of the cable to the surface of the ground in degrees centigrade per watt-foot.

$$= 0.008\, g \log_{10} \frac{48\, L}{D}$$

where L = depth of conductor, feet

g = thermal resistivity of soil in watt-centimeter centigrade units, usually taken as 180.

	H_2O%		
g	Sandy Loam	Heavy Clay	Chalky
340	0	1	2
180	5	17	10
120	10	..	16
90	15	..	20

D = overall diameter of cable, in.

Table XXXVI. Approximate Carrying Capacity of Cables Buried in the Earth

600 volt cables 18 in. deep; 15° to 65° = 50° C temperature rise

11,000 volt cables 36 in. deep; G = 180 watt-cm-C°

300,000	540	340	310				

Sheath Losses and Carrying Capacity

The effect of sheath currents on the carrying capacity may be calculated by substituting for the thermal resistance from conductor to ground, $R_1 + R_2$, the larger quantity

$$R_1 + R_2\left(1 + \frac{W_s}{W_c}\right)$$

where R_1 = thermal resistance from conductor to sheath.
R_2 = thermal resistance from sheath to ambient earth or air.
W_c = watts loss in conductor plus dielectric loss.
W_s = watts loss in sheath.

Temperature Rise of Cable with Variable Load

$$T = T_m(1 - \epsilon^{-t/t_1}).$$

where T = temperature rise at time t hr deg cent.
T_m = ultimate temperature rise, deg cent.
ϵ = base of Naperian logarithm.
t_1 = time constant or time (hr) required to reach 63 per cent of final temperature rise with a constant power loss.
= SH
where H = heating factor or thermal resistance in degrees centigrade per watt per foot.
S = thermal storage factor in watthours to raise the copper in 1 ft of cable 1 deg cent.
This may be calculated from the following factors:

Material	Watthours stored per lb per deg cent
Copper	0.048
Paper	0.137
Oil	0.237
Lead	0.016

The ratio $\frac{T}{T_m}$ or $(1 - \epsilon^{-t/t_1})$ for a period $t = 1$ hr is called the hourly attainment factor, A. Its usual value is between 0.4 and 0.8.

This factor may be used to calculate the copper temperature curve for any load curve which may be divided for convenience into hourly steps. If the copper temperature rise at the beginning of any hour is represented by T_0 and the ultimate temperature rise by T_m, corresponding to the average watts lost during that hour, the change in temperature rise during the hour will be $A(T_m - T_0)$. The copper temperature rise at the end of the hour (T_t) is then equal to $T_0 + A(T_m - T_0)$, and the copper temperature is equal to $T_t + T_d$ where T_d is the temperature of the air in an adjacent empty duct, which may be assumed constant. By evaluating $T_0 + A(T_m - T_0)$ for each hourly period, the entire temperature curve may be plotted step by step.

61. A-C RESISTANCE AND REACTANCE

Ratio of A-c Resistance to D-c Resistance, Three-conductor Cables

The following are maximum values of this ratio, at 60 cycles, which may be expected in cables (I.P.C.E.A.) having concentric stranding with alternately reversed layers. Lower values for the larger sizes are obtained with compactly crushed conductors with all layers in the same direction.

Size of Each Conductor, cir mils	Ratio A-c/D-c Resistance
0	1.00
200,000	1.05
300,000	1.07
400,000	1.10
500,000	1.13
600,000	1.16
700,000	1.19
800,000	1.23

For single-conductor cables, see chapter on Bare Wires and Cables, Tables XXIV and XXV.

REACTANCE OF TRIPLEX CABLES. The reactance of three-conductor cables without magnetic binder tapes or armor, may be calculated by the ordinary formulas for reactance of parallel conductors. See Arts. 16 and 22. It is of the order of 0.027 to 0.035 ohm per 1000 ft at 60 cycles. The effect of steel binder tape is to increase the reactance about 25 per cent.

62. FLEXIBILITY

Table XXXVII

Thickness of Conductor Insulation	Minimum Bending Radius as a Multiple of Overall Diameter	
	Up to 500,000 Cir Mils	500,000 Cir Mils and over
Up to 8/64 in.	6	8
9/64 to 12/64 in.	8	10
13/64 to 20/64 in.	10	12
21/64 in. and over	12	12

RUBBER-INSULATED CABLES. The minimum permissible radius to which rubber-insulated cables may be bent is as given in Table XXXVII.

VARNISHED-CAMBRIC CABLES. A minimum bending radius of 5 1/2 times the cable diameter is recommended for voltages up to 10,000. Above 10,000 volts, the minimum ratio should be 7.

PAPER CABLES. A minimum bending radius of 8 times the cable diameter is recommended for 0 to 20,000 volts, and a minimum ratio of 10 for over 20,000 volts.

63. SINGLE-CONDUCTOR CABLES FOR THREE-PHASE SYSTEMS

It is common practice, for transmission lines operating at 40,000 volts or over, to use three single-conductor, paper-insulated, lead-sheathed cables, for three-phase systems. Voltages are induced along the sheaths, and therefore considerations of safety make it necessary to ground them. If any sheath is grounded, or connected to another sheath at more than one point, current will flow, which will lower the carrying capacity of the cable and cause expensive energy loss. Means for keeping down the sheath voltages and currents have been devised, such as by transposition of sheatns. (See Halperin and Miller, *Trans. A.I.E.E.*, 1929, Vol. 48, p. 399.)

The following formulas are approximate, the exact ones being unwieldy for practical purposes:

Let b = radius of conductors, inches, carrying I_c amperes each.
e = inner radius of lead sheath, inches.
f = outer radius of lead sheath, inches.
D = distance between centers of conductors, inches, assuming them to be set in an equilateral triangle.
M = mutual inductance of conductor and sheath, henrys per 1000 ft.
W_s = power loss in sheath, watts per 1000 ft of each cable.
E_s = emf, volts, induced per 1000 ft of sheath. The potential difference between sheaths at 1000 ft from any bond will be $1.73E_s$.
$\omega = 2\pi f$, where f = frequency.
L_0 = inductance of each cable, with sheath open-circuited, henrys per 1000 ft.
L_c = inductance of each cable with sheath short-circuited, henrys per 1000 ft.
L_s = inductance of the sheath of each cable, henrys per 1000 ft.
I_s = sheath current, amperes when bonds of negligible resistance are used.
R_s = resistance of sheath, ohms per 1000 ft.

$$M = 1.405 \times 10^{-4} \log_{10} \frac{2D}{e+f}$$

$$E_s = \omega M I_c.$$

$$L_0 = \left[0.152 + 1.4 \log_{10} \frac{D}{b}\right] \times 10^{-4}$$

$$L_c = L_0 - M.$$

$$L_s = \frac{1.4}{10^4} \log_{10} \frac{D}{f}$$

$$R_s = \frac{0.036}{f^2 - e^2} \text{ at 40 deg cent.}$$

$$I_s = \frac{E_s}{\sqrt{R_s^2 + (\omega L_s)^2}}$$

$$W_s = I_s^2 R_s$$

An important group of papers on this subject will be found in *J.I.E.E.* (London), 1928 and 1929. Halperin and Miller, *Trans. A.I.E.E.*, April, 1929, p. 399, give formulas for groupings other than equilateral.

EFFECT OF MAGNETIC ARMOR.

Let μ = permeability of armor.

$$a = \frac{1-\mu}{\mu}.$$

k = ratio of total flux in magnetic armor to flux that would exist if armor were replaced by air, usually from 20 to 40.

Then
$$k = \frac{1}{a}\left\{\frac{\pi}{2} - \frac{2}{\sqrt{1-a^2}}\tan^{-1}\frac{1-a}{1+a}\right\}$$

Let L = inductance, millihenrys per mile.
d_1 = diameter over armor.
d_2 = diameter under armor.
D = distance between wires.
d = radius of conductor.

$$L = 0.0805 + 0.741\left[\log_{10}\frac{D}{d} + k\log_{10}\frac{d_1}{d_2}\right]$$

This assumes perfect magnetic contact between armor wires. In practice, owing to loose contact, the inductance will be about 0.7 of the above value. This formula requires some assumption to be made regarding the permeability of the wire, a factor which depends both on the material of the armor and the current in the cable. Numerical calculations require the permeability to be deduced from the magnetic flux density in the armor, a quantity which may be estimated from k and the conductor current.

64. EXPANSION AND CONTRACTION IN IMPREGNATED-PAPER CABLES

The ordinary impregnated-paper cable is characterized by high resistance to fluid flow both radially and longitudinally, due to the density of the paper, the compactness of construction, and the viscosity of the oil. As the oil has a large coefficient of thermal expansion, compared to the other materials of the cable, the effect of thermal cycles is to create, alternately, local high pressures and local vacua. The former may cause stretching of the sheath and thus accentuate the vacua in subsequent cycles. The local vacua are weak spots because they ionize at low voltage, causing hot spots. Therefore, either the insulation thickness must be great enough to overcome this weakness, or means must be adopted to prevent the formation of voids.

In ordinary cables, the insulation is made thick enough to reduce the stresses to a point at which destructive ionization, in minute voids, does not occur. The elimination of voids may be accomplished in either of two ways, to be described below.

65. IONIZATION-FREE CABLES FOR HIGH VOLTAGES

PRESSURE CABLE. If the entire lead-sheathed cable be enclosed in a steel pipe and subjected to an external gas pressure of 12–15 atmospheres, the pressure will reach the interior of the cable and prevent the formation of voids. The insulation may then be of about one-half the ordinary thickness. (Hochstadter, *Royal Soc. Arts*, London, 1931.) Another type of pressure cable, the Oilostatic, uses a leadless paper cable in a pipe containing cable oil under similar pressure.

OIL-FILLED CABLE. The formation of voids may be prevented by the use of oil of low viscosity, not over 20 minutes Saybolt, and preferably much less. This permits the oil to flow radially through the insulation, and longitudinally through oil ducts furnished to carry the oil along the cable from reservoir-equipped joints. As with the *pressure cable*, the insulation thickness is about one-half the ordinary value, permitting the use of cables of practicable diameter for voltages as high as 250,000, three-phase.

Oil-filled Cable Approximate Formulas

The frictional resistance of a hollow core, to the flow of oil, may be calculated by the following formula, the factor b being that to be used in the formula for pressure drop given below.

Let Z = viscosity of oil, centipoises.
d = effective channel diameter.

$$b = \frac{0.0000283\ Z}{d^4}.$$

If the resistance is to be measured by forcing external oil through the hollow core, let

p = pressure, pounds per square inch.
q = flow of oil, cubic inches per second.
l = length of cable, feet.

$$b = 0.4\frac{p}{q^l}.$$

The usual order of value of b is about 0.05.

The maximum rate of oil demand of a cable may be approximated on the assumption that, at the beginning of heating or cooling, the entire heating or cooling depends on the thermal capacity of the copper and oil contained therein.

Let a = oil demand, cubic inches per feet per second.
α = coefficient of expansion of oil per degree centigrade, usually about 0.00074.
v = volume of oil in conductor (including hollow core), cubic inches per foot of cable.
W = watts per foot lost in cable.
$h = 1899\ (0.511\ W_0 + 0.101\ W_c)$.
W_0 = weight of oil in conductor, pounds per foot.
W_c = weight of copper, pounds per foot.

$$a = \frac{\alpha v W}{h}.$$

The usual order of value of a is about 50×10^{-6}.

The pressure drop in the hollow core, due to oil demand, may be calculated as follows:

Let p = pressure drop, pounds per square inch to distance x from oil-feeding point.
a = oil demand, defined above.
b = resistance factor, defined above.
l = total length of section, feet.

$$p = 2\,ab\left(lx - \frac{x^2}{2}\right)$$

At the end of the line, where $x = l$,

$$p = abl^2$$

It is usual to design the line so that p will not exceed 15 lb per sq in. at any point, nor fall below atmospheric pressure.

66. WIRE AND CABLE SPECIFICATIONS

Wires and cables constitute such a large proportion of electric systems that their quality is a matter of great importance, from the standpoint of safety, economy, and continuity of service. Practically all wires and cables are therefore purchased under standard specifications. The principal of these are as follows:

Subject	Standardizing Organization	Standard or Specification Number
Definitions, Methods of Test, etc.	A.I.E.E.	30
	A.S.A.	C–8–a
Bare Soft Annealed Copper Wire	A.S.T.M.	33
	A.I.E.E.	61
	A.S.A.	C–8–b–2
Tinned Soft Annealed Copper Wire	A.S.T.M.	B–33
	A.I.E.E.	60
	A.S.A.	C–8–b–1
Rubber-insulated House Wire and Cord	N.B.F.U.	Nat. Elec. Code
	A.S.A.	C–8–11
	N.E.M.A.	......
Rubber-insulated House Wire and Cord Intermediate Grade	N.E.M.A.	......

Rubber-insulated Wire, 30 per cent Hevea, Class A..	A.S.T.M. A.I.E.E. N.E.M.A.	393 63 ......
Rubber-insulated Wire, 30 per cent Hevea, Class AO	A.S.T.M. A.S.A.	D–27 C–8–d–1
Rubber-insulated Wire, Performance Type.........	A.S.T.M.	D–253
Rubber-insulated House Wire and Cord Performance Type..	N.E.M.A. A.S.T.M.	...... D–353
Impregnated-paper Cables (Including Oil-filled).....	A.E.I.C. I.P.C.E.A. A.S.A.	....
Varnished-cambric Wires and Cables..............	I.P.C.E.A.	......
Magnet Wire..................................	A.I.E.E. A.S.A.	69, 70, 71 C–8–J–1, 2, 3.
Cable Shipping Reels...........................	I.P.C.E.A. E.E.I.	....
Braid Colors for Control Cable....................	E.E.I. I.P.C.E.A.	....
Marine Wires and Cables.......................	A.I.E.E.	45

(a) The braces indicate that the specifications included by them are identical in substance.
(b) A.I.E.E. = American Institute of Electrical Engineers.
A.S.A. = American Standards Association.
A.S.T.M. = American Society for Testing Materials.
E.E.I. = Edison Electrical Institute.
I.P.C.E.A. = Insulated Power Cable Engineers Association.
N.B.F.U. = National Board of Fire Underwriters.
N.E.M.A. = National Electrical Manufacturers Association.
(c) A.S.T.M. and N.E.M.A. Specifications for Perfcrmance Type Rubber differ principally in that the former contains a low water absorption requirement which is absent from the latter.

67. INSTALLATION

For the installation of wires and cables in buildings see Wiring of Buildings. For the construction of the pole lines carrying the messenger wire see Arts. 25 and 26. For the construction of conduit systems see chapter on Underground Lines. Below is given a brief description of modern practice in installing insulated wires and cables on messenger wires and in underground conduit systems. See also the articles on Distribution Lines and Transmission Lines.

MESSENGER CONSTRUCTION. The messenger wire is erected in the same manner as an ordinary line wire; see Art. 30. A " leading-up " wire is stretched from the bottom of one pole to the messenger wire on the starting pole, forming an incline on which to pull up the cable. A pulling rope is then fastened to the end of the cable by means of a cable grip and carried alongside of the messenger to the point where the cable is to reach, thence through a snatch-block down to the terminal pole to a second block at the bottom and thence to a capstan, winch, locomotive. or whatever is to be used for pulling. Either temporary rollers should be provided on the poles over which the rope runs, or the rope should be suspended from the messenger by wire hooks. The cable is then slowly drawn up the inclined wire and along the messenger, attaching temporary carriers to the cable as it is paid out and hooking them over the messenger to carry the weight of the cable. Linemen must be stationed on each pole to pass these carriers around the messenger clamp or insulator. The final suspension of the cable may be accomplished in either of the following ways: (1) When the end of the cable arrives at the beginning of the last span, the lineman on each pole replaces the temporary carriers by permanent hangers, spacing them regularly along the cable, so that when the last span is pulled, all the hangers will be in place. (2) When the cable has been pulled all the way, a lineman rides along the messenger wire in a carriage replacing each temporary carrier by a hanger. This plan is preferable as the hangers may be attached more tightly to the messenger wire, and are less likely to slip on the cable.

INSTALLATION OF CABLES IN DUCTS. The conduit system having been constructed, it must be prepared for the reception of the cable by being cleaned out or rodded as described in the chapter on Underground Lines.

If several ducts are available, the choice of the particular duct to be used should be governed by the following considerations: (1) avoiding unnecessary crossings of cable in

the splicing chambers, substations, etc.; (2) avoiding the obstructing of empty ducts; (3) keeping the cables cool; and (4) keeping d-c cables away from others. The coolest and best heat-radiating ducts are those located at the lower corners of the system; next are those nearest to the outside of the system, and lastly the middle and top ducts which not only take up heat from the lower cables, but must also dissipate heat through adjoining ducts.

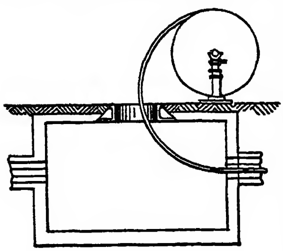

Fig. 5

The next step is to set the cable reel on the shaft of a pair of wheels of slightly greater diameter than the reel itself or on jacks and raise it slightly above the ground, taking care to locate it as shown in Fig. 5, so that the cable will unreel into the manhole without making a reverse bend.

The pulling rope having been left in the duct after rodding, the cable is unreeled sufficiently to bring its end close to the mouth of the latter and a wire pulling grip (Fig. 6) is drawn over its end. Several companies prefer to use pulling eyes soldered to the conductors and sheath of the cable. The end of the grip or pulling eye is hooked to the rope and the rope pulled from the other end. The pulling may be done by capstan, winch, motor truck, horse, or by hand, depending upon the size and amount of cable to be pulled and upon local conditions. The cable should be carefully guided into the duct so as to avoid sharp bends and abrasions, and a small quantity of grease, about 100 lb. per mile, may with advantage be spread over the cable as it enters the duct. It is also necessary to cover the edges of the duct with pieces of lead or other suitable material to prevent abrasion of the cable.

Fig. 6

PROTECTION OF CABLES IN SPLICING CHAMBERS. Wherever there are several large cables in a splicing chamber, there is always danger that a burn-out of one cable will involve some or all of the remainder. Hence it is usual to protect such cables by means of one or more of the following methods:

1. Cement coating with $^1/_4$-in. rope bond.
2. Asbestos tape saturated with silicate of soda.
3. Asbestos tape covered with soft steel-tape armor.
4. Asbestos rope.
5. Special trade-marked products designed for this purpose.

68. CABLE JOINTS

The problem of cable splicing may be resolved in the following elements:

(*a*) Joining the conductors to retain their full carrying capacity and requisite tensile strength.

(*b*) Insulating the joint to resist both the normal radial stresses and the tangential stresses caused by the termination of the sheaths.

(*c*) Reducing tangential stresses as far as practicable in high-tension joints.

(*d*) Keeping out air and moisture.

(*e*) In oil-filled cables, to provide (1) an oil barrier, (2) a continuous channel for the oil, (3) suitable oil passages for connecting the cable oil channels to an external reservoir.

Conductors

The joining of conductors is a standard procedure, involving the cleaning and "tinning" of the conductors with stearine flux and 50/50 solder. The conductor ends thus prepared are inserted into standard N.E.L.A. connectors of the dimensions shown in Table XXXVIII. Solder, 50/50, is then ladled over the connector until all interstices are filled, and then all surplus solder is wiped or filed off, so as to leave the connector and abutting conductors free of roughness or projections. In the case of sector conductors, it is usual to hammer the ends into cylindrical form and use standard connectors, of the next larger size in the table.

Insulation

The next step is to prepare the cable insulation surface to receive the joint insulation. Except in certain special designs, the insulation is penciled down from its full diameter to approximately the diameter of the connector, and the short spaces ($^1/_4$ to $^1/_2$ in.) between the penciled ends and the connector filled with insulating tape of the same material, but much narrower, as is used for the joint insulation. The length of the bared insulation

Tables XXXVIII. Nominal Dimensions Straight Tinned Copper Connectors

commonly used is shown in Fig. 7. The penciling is usually about 0.2 in. in length per 64ths inch of thickness. Some engineers prefer to have the insulation stepped, rather

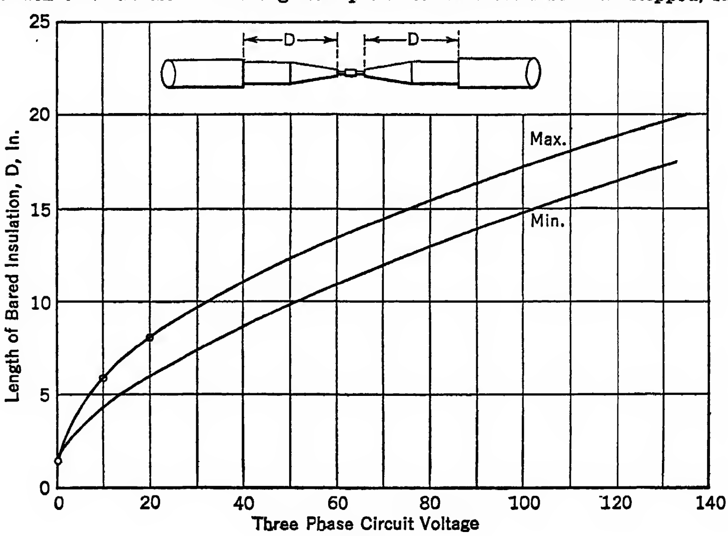

FIG. 7

than penciled gradually, in which case the slope may be somewhat steeper, as the unequal stretching of the tape does not have to be considered.

The main insulation of a joint consists of tape applied lapped, in cigar form, from beyond the ends of the penciling on one side, to a corresponding point on the other, with a maximum thickness over the connector. This maximum is usually about 40 per cent more than the thickness of cable insulation.

For rubber-insulated cables, rubber tape is used. Both for varnished cambric and impregnated paper, it is common to use bias-cut varnished-cambric tape. For high-voltage cables, say 11,000 volts and over, the varnished-cambric tape is generally of the low dielectric loss type. The usual thicknesses of varnished-cambric tape are 7, 10, or 12 mils. Rubber tape up to 25 mils thick is used. Care must be taken not to stretch the tape unduly, lest its dielectric strength be impaired.

Some power companies use impregnated-paper tape, usually 5 or 6 mils thick, and in a few instances, wide rolls of paper with converging sides are used, the purpose of the convergence being to make the paper roll up with conical ends.

The higher-voltage cables generally begin the slope of the tape at the end of the lead and the slope is covered with a flared metallic shield, usually of copper gauze tape.

Where the cable insulation is shielded, it is usual to carry the shield over the entire joint insulation. The proper slope of shield has much to do with the reduction of tangential stresses.

The design of joints from the standpoint of stress is based on the formula for the capacity between concentric cylinders and on the fact that the total voltage divides inversely as the capacities. By means of these relations the voltages at the various layers may be calculated and the axial potential drops calculated therefrom.

It is necessary to keep air and moisture out of a joint, and to this end, it is customary, with either varnished cambric or paper tape, to apply a liberal amount of oil or compound as each layer of tape is being applied. The insulation is finally " boiled out " by pouring hot compound over it.

Compound

When the joint is equipped with its sleeve, it is filled with compound of one or other of the following types in accordance with Table XXXIX.

A, insulating oils, that remain liquid over the operating temperature range encountered and which migrate into cable.

B, insulating greases and viscous compounds (not an asphaltic compound) having melting points within the operating temperature range and which migrate (more or less) into cable.

C, plastic and hard compounds having melting points above the maximum operating temperature encountered and which do not migrate into cable.

Table XXXIX. Recommended Types of Joint-filling Compounds Standard Walls of Insulation and Lead

	0–18 Kv	19–23 Kv	24–34.5 Kv (Note 3)	Above 34.5 Kv (Note 3)
Belted 3-conductor cable...	*C*	......	....	....
Shielded 3-conductor cable.	*C*	*C*	*A*, for underground *B*, for underground (Note 1) *C*, for submarine or aerial	*A*
Single conductor cable....	*C*	*C*	*A*, for underground *B*, for underground (Note 1) *C*, for submarine or aerial	*A*, for underground *C*, for submarine (Note 2)

Notes: For heavier walls of insulation than standard the limits of Class *C* compound may be raised 10 percent.

(1) With proper servicing.

(2) For submarine use, a full length of cable without joints is obviously first choice. Where piers for bringing ends out of water are feasible, oil-filled joints are recommended. Where this is not possible, solid filled joints (fully shielded) can be used.

(3) There has been limited experience in this country with joints filled with Class *C* compounds as follows:

Shielded, 3-conductor cable up to 34.5 kv.

Single conductor cable, up to 46 kv.

When further experience is available, a modification of this rule may be possible.

Coverings

Lead-sheathed cable joints are usually enclosed in lead sheaths, but very long joints sometimes have brass or copper sleeves. The sleeve diameter is generally based on a clearance of about $^1/_4$ to $^1/_2$ in. over the joint insulation.

The lead sleeve is slipped over the cable before the conductors are joined and is brought into position when the structure of insulation and shielding has been completed. The ends are beaten down to meet the cable sheath and joined thereto by wiping with 45 tin/55 lead solder.

Rubber cables with braid covering do not have lead sleeves on their splices but are finished either with "anhydrous tape" or friction tape, over which asphaltic compound is poured. Low-voltage rubber joints are often made without other compound, but high-voltage rubber-lead cables always have their sleeves filled with plastic compound.

Reservoirs

Experience has shown that insulating greases and viscous compounds *B* cannot be used satisfactorily as a filling medium without reservoirs or other means of maintaining pressure and supplying surplus compound. This type of filling material does not act as a definite seal and allows the entrance of moisture and air when accidental leakage occurs in the outer metallic casing. Also, these compounds have a tendency to migrate into the cable, causing vacuum and collapse of the joint casing. For these reasons, this filling material is not recommended unless accompanied by reservoir, or servicing, to maintain surplus supply and positive pressure. These reservoirs usually have about 1 to 1 $^3/_4$ gallons capacity of working oil.

Oil-filled Cables present special problems of their own, which are treated in *Trans. A.I.E.E.*, 1928, p. 200, and *Elec. World*, 1929, p. 97.

The success of joint making for high voltages depends on careful design with respect to potential distribution, mechanical features, and care in workmanship to avoid leaving dirt, air pockets, sheath leaks, and rough edges on conducting parts.

69. FAULT LOCATION

Faults may be classified as follows:

(*a*) Conductors not burned apart.

1. Solid ground on one or more conductors with one clear conductor.
2. Solid ground on all conductors.
3. Short or cross between two or more conductors with one clear conductor.
4. Short or cross between two conductors with one conductor grounded.
5. Short or cross between all conductors and ungrounded.

(*b*) One or more conductors burned apart.

1–5. Conditions 1–5 inclusive (see above) from either end of cable.

6. All conductors burned off and clear of grounds.

The general procedure followed in locating a fault varies somewhat with local conditions, but is typified by the following:

Failure
|
Sectionalization as far as possible
|
Test Analysis by above classification
|
Fault Reduction, as required

1	2	3	4	5
Inspection	Cut and Test until Localized	Tone Test	Loop Test	Capacity Test
		Final Cut and Test	Tone Test	Cut and Test for Approximate Location
			Final Cut and Test	Final Cut and Test

In short cables, the fault is usually located by inspection, i.e., looking for smoking manholes or listening for crackling sounds when the kenotron is applied to the faulty cable.

The final step in every fault hunt is a cut and try, although ordinarily the fault is found at the first cut.

The two major methods of locating circuit faults are the **tracing current** or **tone test method** and the **bridge method.** The former is more generally useful and certainly more accurate, although the latter is quite indispensable for long transmission lines.

TONE TEST METHOD. The tracing current method depends on the Lundin, or some similar, fault locator, which includes three main elements, the interrupter, the analyzer, and the pick-up or listening equipment.

The interrupter uses a 110-volt alternating current source of 50-amp capacity and applies current of suitable voltage to the cable and analyzer in characteristic periodic impulses, which may be picked up along the cable by the listening equipment.

The analyzer, with its reactive loading coils, indicating lamp, and step-up transformers, enables an experienced operator to obtain a description of the fault.

The procedure of analysis is as follows:

The inductance coils of the analyzer are connected in series with the conductor to be studied. If this conductor is open and clear of ground, the current, in passing through the inductive loading coils, will produce a voltage drop across the capacitative conductor, which is greater than the applied voltage. If, however, there is a high-resistance fault, the voltage may be equal to or less than the applied voltage. Where a solid ground exists, the circuit voltage is reduced nearly to zero. These voltage conditions are tested by means of a lamp which is bright, dim, or extinguished according to which of the conditions exists.

A partial ground is usually reduced by the application of sufficient voltage, in order to facilitate the locating process.

The locating depends upon an abrupt decrease or change in the signal at a certain point along the cable, to indicate that the fault has been passed. A pick-up coil with telephone receiver is used for detecting "grounds."

In the case of triplex cables, if the detector is moved circumferentially around the cable, it will sometimes be near and sometimes away from the conductor carrying the tracing current. The resultant variation in loudness, called the "hump effect," always indicates that the fault is farther on. Sheath current produces no hump effect. The change from humped to uniform sound around the cable gives the precise location of the trouble. If the trouble is in a duct, it is usual to check the location by "ringing" the lead at the near joint and checking again with the earphone and by trying for a spark across the cut.

Another device is a bar listening coil, which is used on the surface of the ground, and which, up to the fault, gives a louder sound with the bar vertical than when horizontal, and beyond the fault gives a louder sound with the bar horizontal than when vertical.

In some cases, a large listening coil is used on an automobile which is driven along the route of the cable until the sound changes.

In single-conductor cables, where there is no "hump effect," the stray sheath currents beyond the fault will make locations uncertain. In such cases a heavy copper strap is used to divert current from the sheath locally; the exploring coil being applied between the sheath and conductor current when the fault is beyond, the signal will be strengthened, and when it is behind, it will be weakened, as the shunt is applied.

The usual cable fault is at its lowest resistance when a current of 1 to 5 amp is flowing through it. Less current will allow the fault to cool, and more, to burn up, either tending to increase the resistance. If the pilot lamp flickers when starting to reduce the fault at 1100 or 2200 volts, it is probable that there is moisture at the break. In such cases it is usual to resort to the bridge method.

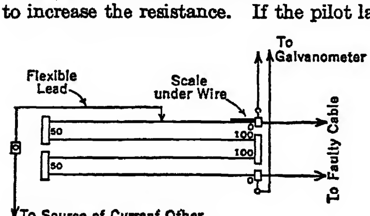

FIG. 8. Murray Loop

BRIDGE METHOD. The bridge method, moreover, is much used for transmission lines because the tracing current method is necessarily slow on long lines and because high-voltage cable faults are often hard to reduce to low enough resistance to be located by a tracing current.

The bridge uses the Murray loop as shown in Fig. 8. It consists essentially of a resistance wire graduated into two equal scales each reading from 0 to 100, the zero points being at the ends of the wire. A galvanometer is connected across the zero points, and a flexible lead connected to the positive terminal of a source of direct current is put

in sliding contact with the wire. The negative terminal of the d-c source is grounded. A protective gap is often placed across the galvanometer terminals to protect against surges which occur when a sudden change in fault resistance occurs. The usual source of d-c supply for a bridge test is a motor-generator set giving about 1500 volts.

Capacity tests for open-circuited conductors without ground are usually made by measuring the charging current with an a-c milliameter.

Trouble in buried series lighting cable is usually located by tests at the lamps. The section having been found in this way, the location in the section is found by a bridge test, using a return conductor above ground.

The usual time required to locate a service fault in a cable in a duct line is about 2 to 3 hours. Test failures may take about an hour longer.

LOCATION OF FAULTS IN NON-METALLIC SHEATH TYPE CABLES FOR SERIES LIGHTING. Such cables are usually buried back of the curb or under pavements, making inspection impossible.

Grounds can be located in a section between adjacent lights by noticing which lamps do not burn properly. After the ends of the faulty section of cable are exposed at the lamp posts, a loop test with portable battery energy can be used for approximate localization. It is necessary to lay a temporary return wire along the ground between the exposed cable ends. Then the cut and test method must be used for final localization. Faults can generally be found within 10 ft of loop test locations.

In the case of an open circuit, the cables being shielded by the ground, the electrostatic field will not extend outside the sheath. However, the lamp filaments, being unshielded, may still be used as sources of sound for a Lundin detector. By this means opens may be located between lamps. The exploring coil may occasionally be used to trace opens, but here, the entire current from the station being charging current, the signal dies out uniformly to the point where the open exists. Usually, the trouble hunter can get to within 200 ft of the open before the signal becomes inaudible.

In some of the recent types of series circuits with buried cables and buried insulating transformers at the base of the lighting standards, the electrostatic field does not extend to the secondaries and lamp filaments. In this case, however, the charging current of the cable up to the fault is transformed and circulated through the lamp filaments. For this condition, a special coil, vertically mounted, is attached to the end of a fish pole, and connected to the earphones or amplifier, which picks up the sound at the lamp. This satisfactorily locates the fault between two lamps. More precise location may sometimes be made with triangle and amplifier from the surface of the ground, if the fault is solid; otherwise digging will be necessary.

If the circuits do not enter the stations, it is necessary to move a portable set to the location to analyze and apply tracing current to the faulty circuit.

70. WEIGHTS OF INSULATED WIRES AND CABLES

So many variables enter into the weight of an insulated wire or cable, and so many forms are in use, that it is impossible to give comprehensive tables here. The weight of a cable may be calculated from its dimensions by finding the sum of the weights of the conductors and the weights of the insulation, braid, tape, sheath, etc. The weight of the conductor may be found in the wire tables under Bare Wires and Cables. The weight of the insulation, braid, tape, or sheath may be found by calculating the cross-section of each of these materials and multiplying by the length of the cable and a factor proportional to the density of the material; see Table XL.

The cross-section of a tube having an internal diameter d and thickness t is $\pi t(d + t)$. When the diameter and thickness are in inches and the specific gravity of the material forming the tube is δ, then the weight in pounds per 1000 feet of tube is

$$W = 1362\ \delta t(d + t)$$

The values of the specific gravity δ, the product 1362 δ, and the weight per cubic inch for the common materials used in the construction of cables are given in Table XL. From this relation the weight per 1000 ft of any tubular (circular cross-section) layer of insulation, braid, tape, or sheath may be readily calculated. The formula is, therefore, directly applicable to single-conductor tables.

The weight of duplex or triplex cables is calculated as for a group of single-conductor cables, except with regard to the fillers. The cross-section of the filling material is most readily calculated by subtracting from the cross-section of the entire cable the cross-sections of the individual conductors and the tubular insulation, sheath, etc. The diameter of the circle circumscribing three round insulated conductors of diameter d is 2.15 d.

The weight of separators in pounds per 1000 ft is usually between 5 and 10 times the mean diameter, expressed in inches, of the conductor and separator.

The weight of saturated braids per 1000 ft is from 12 to 30 times the diameter over the insulation, expressed in inches. The corresponding multiplier for 12-mil rubber-filled cotton tape with 1/4 lap is 24.

Table XL. Weights of Cable Insulation

Material	Specific Gravity, δ	Pounds per Cubic Inch, $0.03613\,\delta$	$1362\,\delta$
Rubber compound, 30 per cent para:			
Organic base	1.2	0.0434	1635
Mineral base	1.5 to 2.0	0.054 to 0.072	2043 to 2724
Varnished cloth	1.11	0.401	1515
Paper, impregnated	1.17	0.0423	1594
Lead	11.37	0.411	15,530
Braid, untreated	1.11	0.0402	1515
Braid, saturated	1.33	0.0480	1809
Tarred jute, in cable	0.63	0.0228	858
Dry jute, in cable	0.267	0.00965	364
Dry hemp, in cable	0.267	0.00965	364
Gutta-percha	1.0	0.0361	1362
Rubber-filled tape	1.0	0.0361	1362
Copper	8 89	0.3212	12,108

WIRING OF BUILDINGS

By George W. Zink

72. GENERAL REQUIREMENTS

Wires and fittings designed to conduct electricity in a building should be selected as to size and insulation and installed in such a manner that: (1) the attending fire risk and the possibility of an electric shock to the inhabitants shall be a minimum; (2) the electric power efficiency of the system shall be reasonable; (3) the voltage at the receiver shall approximate the rated voltage of the receivers and shall remain sensibly constant; (4) the mechanical arrangement of the system shall be simple and convenient for inspection and use; (5) the conductors shall be mechanically protected from external injury; (6) the service shall not be interrupted under normal load; (7) the cost of the materials, labor of installation, and replacement due to depreciation shall not be excessive, and (8) the entire wiring system shall conform to the rules and regulations of any authority having jurisdiction over the building in question.

73. SYSTEMS OF WIRING

For d-c and single-phase distribution the two-wire system and the three-wire system are employed. For two-phase distribution either three or four wires are used. For three-phase distribution three wires are usually employed, although a fourth or neutral wire is sometimes installed.

D-C AND SINGLE-PHASE DISTRIBUTION. In d-c or single-phase a-c circuits, the two-wire or the three-wire system is used. The two-wire system is used for the greater part of interior wiring, the three-wire system being used chiefly for feeders and mains. (See Arts. 1 and 11.) The neutral wire of a three-wire system is usually of the same size as either outside wire, the saving in copper over the two-wire system then being $^5/_8$ or 62.5 per cent. In some cases, buildings are wired with the three-wire system in which the neutral wire is made twice the size of either outside wire so that, if necessary, the system may be operated either as a two-wire or a three-wire system; in the former case the two outside wires are connected in parallel. Power may then be supplied to the building from a local two-wire source of supply (isolated plant in the building) or from an emergency three-wire street service.

In this case wires of such size would be used as would give normal efficiency and regulation when used as a two-wire system; the loss when used as a three-wire system would then be only half as great.

The first cost of a three-wire system may not be less than that of a two-wire system because of the increased cost of the fittings, insulation, and the labor of installation. The

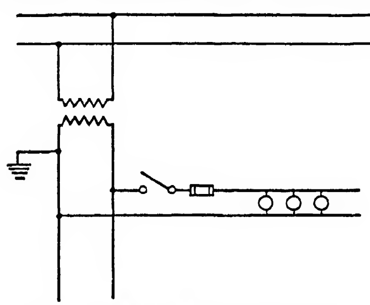

Fig. 1. Single-phase Two-wire System

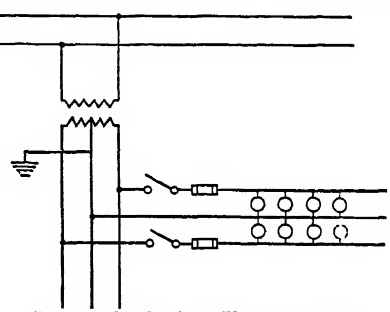

Fig. 2. Single-phase Three-wire System

three-wire system is not as simple as the two-wire system, and is subject to more disturbances unless the load is kept balanced. Some electric power companies limit the power which they will supply to a two-wire system, and in such cases in new installations buildings taking power above the two-wire limit must be wired with the three-wire system. The two-wire system is used for either lighting or power loads; the three-wire system, for either lighting or mixed lighting and power loads, motors in the latter case being connected between the outside wires. (See Figs. 1 and 2.)

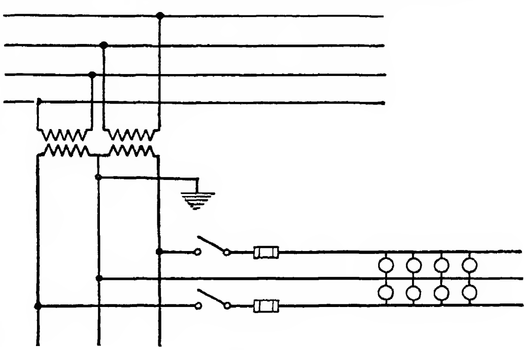

Fig. 3

TWO-PHASE DISTRIBUTION. For distributing two-phase alternating currents, either three or four wires are employed. A four-wire two-phase system may be treated as two separate two-wire systems, which cannot in any case be connected in parallel. A single wire 41 per cent larger than either of the wires it displaces may be substituted for any two of the wires of the four-wire two-phase system thus making a three-wire two-phase system. Either three or four wires may be used for two-phase lighting or power loads.

All the three or four wires are used for power loads, the motors being connected to

both phases. Lighting loads are connected to each phase, in the three-wire system, one wire being common to both phases. It is important that the phases are kept in balance by maintaining equal loads on each side of the circuit.

THREE-PHASE DISTRIBUTION. This system is the most usual one for power distribution and for mixed power and small lighting loads. Where power is the only load, a

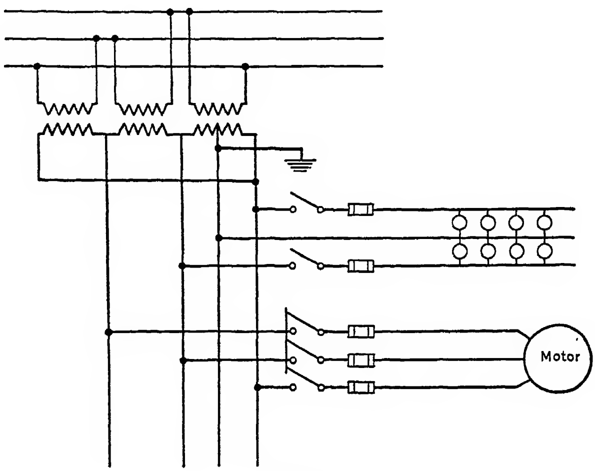

Fig. 4

three-wire system is used. If a small lighting load is required on a three-phase, 230-volt system, one phase may have a neutral tap and a three-wire lighting circuit obtained. This, however, will tend to throw the system out of balance and can be used only for small loads. (See Fig. 4.)

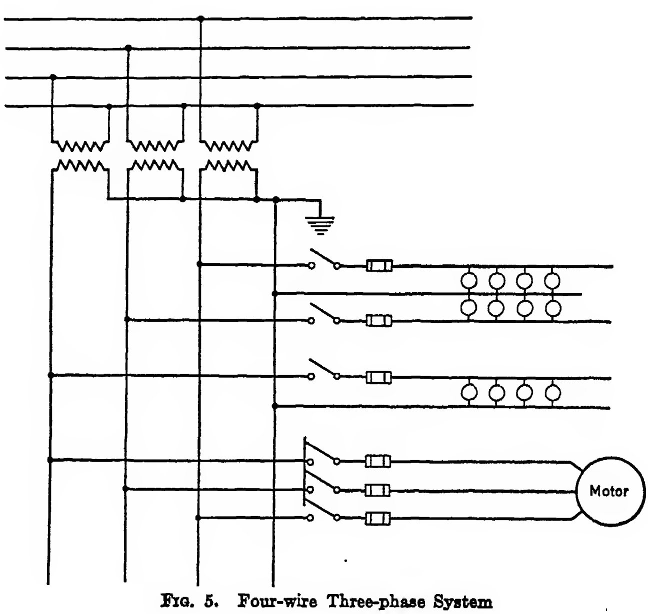

Fig. 5. Four-wire Three-phase System

Four-wire Three-phase System. This system is in general use where the power load is subordinate to the lighting load. In this case, the fourth wire is the neutral and usually grounded, and there should be no fuse in this wire in any part of the system. Branch lighting circuits may be run either two-wire, using one outside wire and the neutral; or three-wire, using two outside wires and the neutral. Care must be taken to distribute the lighting load so as to keep all phases of the system in balance. Power loads are connected to the three outside wires. This system is usually 120–208 volts, that is, 120 volts from any outside wire to neutral and 208 volts between the outside wires. (See Fig. 5.)

74. STANDARD VOLTAGES FOR LIGHTING AND POWER

The standard voltages used in connection with the wiring of buildings are usually 115–230–460–550 or 2300 volts. The National Electrical Code does not permit voltages above 7500 for general wiring of buildings. Higher voltages, however, are sometimes used for service connections from the power company's distributing lines to a transformer vault within the building. These cases are considered extensions of the street mains and not general wiring.

The usual lighting circuits are normally 115 volts, although in industrial plants 230 volts are sometimes used. Series lighting or constant-current systems use higher voltages, but this type of lighting is not permitted by the National Electrical Code for installations indoors except in a few restricted locations.

The voltage of power circuits is determined by the character of the load, distance from the center of distribution, and other local conditions. For plants with small and medium-sized motors, 230 volts are most frequent, and where large motors or other units of large capacity are required, as in steel mills, voltages of 2300 or higher are commonly used.

75. STANDARD FREQUENCIES

Throughout the United States, alternating current for light and power is usually supplied at a standard frequency of 60 cycles. Some isolated plants use other frequencies such as 25 or 40 cycles, and 50 cycles is a standard frequency abroad. Transformers, motors, and other equipment are regularly furnished for three-phase 60-cycle current in all the standard voltages; equipment for other frequencies is not readily available. For lighting circuits, frequencies less than 60 cycles are not satisfactory, as the lamps have a noticeable flicker.

76. AUTHORITIES GOVERNING THE INSTALLATION OF WIRING

Before proceeding with a wiring layout, it is necessary to become familiar with the laws and rules governing the installation of wiring and electrical equipment in the locality where the work is being done. In general, the authorities having jurisdiction are (1) the National Board of Fire Underwriters, (2) the local municipal authorities, and (3) the utility company supplying the current.

The National Electrical Code was originally issued in 1897 by a group of interested organizations in an effort to establish rules, governing the construction and installation of electrical equipment, which would reduce fire hazard to a reasonable minimum. The Code is now sponsored by the National Fire Protection Association, under the rules of procedure of the American Standards Association, and is published and distributed by the National Board of Fire Underwriters.

The Code is revised every two years by the Electrical Committee of the National Fire Protection Association and issued so as to become effective, usually, on November 1, of the odd years. If progress in the art or other considerations warrant it, interim revisions or additions may be made at any time.

The National Electrical Code rules are drawn up primarily in connection with fire insurance risk, but recently they have been giving consideration to accident risk as well. Accident risks, however, are more specifically covered by municipal regulations and various safety codes.

UNDERWRITERS' LABORATORIES, INC. It is to be noted that the Code does not specify test requirements for equipment, but refers to "approved" devices or apparatus. This means approved by the Underwriters' Laboratories, Inc., an organization established to examine and test materials and equipment to determine their fitness for use under the Code. Detailed specifications for the construction and performance under test

and in service of approved electrical fittings and material will be found in the Standards of the Underwriters' Laboratories.

The "List of Inspected Electrical Appliances" is published semiannually by the Underwriters' Laboratories, and all "listed" materials bear some evidence of their approval. Permission must be obtained to use unlisted material.

Copies of the National Electrical Code and the List of Inspected Electrical Appliances may be obtained from most local inspection bureaus or from either the National Board of Fire Underwriters, 85 John Street, New York, N. Y., or the Underwriters' Laboratories, 109 Leonard Street, New York, N. Y. (Chicago address: 207 East Ohio Street).

MUNICIPAL REGULATION. Most states and municipalities have laws concerning the installation of electric wiring, and these laws usually include the National Electrical Code with such modifications as considered advisable to suit local conditions. These modified rules are often more rigid than the Code in that they prohibit certain practices recognized by the Code. For example, concealed knob and tube wiring is one method of wiring recognized by the Code, but prohibited by most municipalities. Local regulations are often broader than the Code in that they cover accident risk, inspection, licensing of electricians, and penalties for violations. Municipal authorities should be consulted with regard to obtaining copies of local regulations.

REGULATIONS OF THE UTILITY COMPANIES. Most lighting and power companies have rules which must be observed by consumers obtaining service from their lines. These rules are made necessary by conditions pertaining to the operation of their particular systems and usually concern the location of meters, the type and location of service entrances, and, in the case of power loads, the type and size of motors, etc.

ENFORCEMENT AND INSPECTION. The National Electrical Code, as issued by the National Board of Fire Underwriters, has in itself no legal status. However, inasmuch as the Code rules form part of ordinances of most cities throughout the country, it has almost universal enforcement by the police power of such municipalities. Where not so enforced, insurance companies require the Code to be observed if the buildings in question are to be insured. In order to ensure the observance of the Code, the Fire Underwriters and most municipalities have inspectors to check the electrical work in buildings. These two inspection agencies may act independently, but often they cooperate and have one office handle both inspections. Before a new building is occupied, and when the occupancy of an old building is changed, it is advisable to be sure that proper inspection has been made.

77. METHODS OF WIRING

The National Electrical Code recognizes a number of methods of wiring, one or more of which must be selected for any wiring layout. Inasmuch as certain types of wiring recognized by the Code are not permitted in some municipalities, this should be checked before deciding upon any particular method. The methods listed by the 1935 Edition of the Code are as follows:

(1) Installed on insulators.
- (*a*) Open wiring.
- (*b*) Concealed knob and tube.

(2) The "pull-in and pull-out" systems.
- (*a*) Conduit work—rigid or flexible metallic conduit.
- (*b*) Electrical metallic tubing.
- (*c*) Wireways and busways.
- (*d*) Underfloor raceways.
- (*e*) Cast in place raceways.

(3) Cable assemblies.
- (*a*) Armored cable.
- (*b*) Non-metallic sheath cable.
- (*c*) "Non-metallic" wiring systems for use in wet places.

(4) Extension materials.
- (*a*) Surface metal raceways.
- (*b*) Surface wooden raceways.
- (*c*) Under plaster extensions.
- (*d*) Non-metallic surface extensions.

(5) Special feeders.
- (*a*) Bare bus-bars and risers.
- (*b*) Service entrance conductors.

OPEN WIRING. This method is used extensively where the appearance of exposed wiring is not objectionable, as in industrial buildings, and where not exposed to mechanical injury. It is a satisfactory method in buildings or rooms subject to moisture, corrosive vapors, or heat, such as paper mills, dye houses, or dry kilns. Its use is permitted for voltages up to 600 volts.

In installing, single-conductor wires are supported on knobs or cleats. Wires shall never be fastened with staples. For voltages not exceeding 300 volts, wires shall be separated 2 1/2 in. from each other and 1/2 in. from the surface wired over. For voltages from 301 to 600, the wires shall be separated 4 in. and at least 1 in. from the surface wired over. In damp places, 1-in. separation from the surface wired over must be maintained for all voltages. Wires must be supported at least every 4 1/2 ft, except that in buildings of mill construction wires No. 8 A.W.G. and larger may be separated 6 in. and run from timber to timber with supports on each timber.

Where exposed to mechanical injury, the wires must be protected by suitable guard strips—boxing or other means approved by the National Electrical Code. Wires passing through floors, walls, timbers, or partitions shall be protected by insulating tubes or bushings. Insulating tubes must be used over the wire where within 2 in. of piping or other conducting material. Open wiring must not be located in hoistways.

Wire suitable for dry locations are approved rubber-covered (Type R), slow-burning (Type SB), slow-burning weatherproof (Type SBW), varnished-cambric (Type VC), or asbestos-covered (Type A).

In damp places or buildings especially subject to moisture, rubber-covered wire must be used.

Wires subject to corrosive vapors must be rubber-covered, varnished cambric, or weatherproof.

Knobs must conform to the following minimum dimensions and have a body designed to maintain the wire at least 1 in. from the surface wired over.

Size Wire A.W.G.	Size of Base			Solid Knobs Groove, Inches		Thickness of Caps and Split Knobs inches from top of groove
	Diameter of Circular Knobs	Single Wire Cleats and Square Knobs		Depth	Diameter	
		Width	Length			
14–10	1 1/8	3/4	1 3/4	3/16	1/4	3/8
8–4	1 1/2	7/8	2	5/16	5/16	5/8
2–2/0	2	1	2 1/4	7/16	5/8	5/8
3/0–300,000 cir mils	2 1/2	1 1/8	2 3/4	7/16	25/32	7/8
400,000–1,000,000 cir mils	3	1 3/8	3 3/4	5/8	1 1/4	1

Multiple wire cleats for voltages up to 300 may be used if designed to maintain the separation of wires previously mentioned.

Approved tubes and bushings conform to the following minimum dimensions:

Diameter of Hole	External Diameter	Thickness of Wall	External Diameter of Head	Length of Head
5/16	9/16	1/8	13/16	1/2
3/8	11/16	5/32	15/16	1/2
1/2	13/16	5/32	1 3/16	1/2
5/8	15/16	5/32	1 5/16	1/2
3/4	1 3/16	7/32	1 11/16	5/8
1	1 7/16	7/32	1 15/16	5/8
1 1/4	1 13/16	9/32	2 5/16	5/8
1 1/2	2 3/16	11/32	2 11/16	3/4
1 3/4	2 9/16	13/32	3 1/16	3/4
2	2 15/16	15/32	3 7/16	3/4
2 1/4	3 5/16	17/32	3 13/16	1
2 1/2	3 11/16	19/32	4 3/16	1

CONCEALED KNOB AND TUBE. This type of wiring is used in buildings of frame construction where economical concealed wiring is desired. Most cities and towns prohibit this method of wiring, and its use therefore is restricted largely to isolated rural dwellings. It cannot be used for circuits of more than 300 volts between wires or 150 volts to ground.

The method of installing consists of running single insulated wires in the hollow spaces of walls and between floors. Where run parallel to timbers or floor, the wires are supported on single wire insulators or knobs and where passing through timbers or floors by insulating tubes. Wires must be separated at least 5 in., and where this spacing cannot be maintained, as in entering outlet boxes, it shall be encased in flexible tubing which shall extend from the last knob into and be secured to such boxes. The requirements as to supporting, clearances, etc., which are specified for open wiring, apply also to knob and tube.

Approved rubber-covered wire (Type R) is required.

CONDUIT WORK. The best and most extensively used type of wiring consists of wires enclosed in metallic conduit, either rigid or flexible. Rigid conduit is standard for general work; flexible conduit is frequently used for short runs such as from the end of a rigid conduit to a motor mounted on a machine frame. Conduit is employed in all types of buildings and may be run exposed or concealed and may be used for all voltages.

Rigid conduit is standard steel pipe, protected against corrosion by galvanizing, sherardizing, enameling, singly or combined—or pipe of non-corrosive metal may be used. It is regularly furnished in 10-ft lengths and cannot be used in sizes smaller than 1/2 in. The system must be installed complete from outlet to outlet and be securely fastened in place. The wires shall not be pulled in until all mechanical work on the building is completed.

Numerous designs of fittings are made for joining or terminating the conduit. These may be of the threaded or threadless type, and in either case must be installed to give adequate electrical continuity to the system, which must be grounded, as provided for by the Code.

A run of conduit between outlets or fittings must not contain more than four quarter bends, the radius of the curve of any field bend being not less than six times the internal diameter of the conduit.

Wires of different systems must not occupy the same conduit, outlet box, fitting, or cabinet. In a-c systems, all wires of the same circuit must be placed in one conduit; this practice should also be followed for d-c systems to provide for possible future change-over. For voltages above 600, wire must be installed as cable.

Wires in vertical conduits must be supported by means of suitable clamps or other approved means, such as deflecting the wires at 90 deg over insulating supports in junction boxes. The intervals of supports are as follows:

No. 14 A.W.G. to No. 1/0	not over 100 ft
No. 2/0 A.W.G. to No. 4/0	not over 80 ft
250,000 cir mils to 350,000 cir mils	not over 60 ft
350,001 cir mils to 500,000 cir mils	not over 50 ft
500,001 cir mils to 750,000 cir mils	not over 40 ft
Over 750,000 cir mils	not over 35 ft

Special vertical riser cables designed to be self-supporting may be used for feeders.

Wires in conduit should be rubber-covered (Type R) except as follows: Where the ambient temperature exceeds 120 deg fahr (49 deg cent), asbestos-covered (Type A) or slow-burning (Type SB) shall be used. Where permanently dry, and where the temperature of the insulation will not exceed 167 deg. fahr. (75 deg. cent) varnished-cambric (Type VC) may be used. With flexible conduit in damp locations, lead-covered wire (Type RL) must be used. With rigid conduit in permanently wet locations, underground, or in concrete slabs in contact with moist earth, lead-covered wire (Type RL) must be used.

The Tables I, II, III, and IV show the number and size wire permitted in various-sized conduits. Where other combinations are used, the combined cross-sectional areas of the several wires should not be more than the per cent of the interior cross-sectional area of the conduit shown in the following table.

	Per Cent of Internal Area of Conduit				
	Number of Conductors				
	1	2	3	4	over 4
Conductors not lead covered...	53	31	43	40	40
Conductors lead covered.......	55	30	40	38	35

Electrical Metallic Tubing. A form of rigid conduit having the same internal diameter as standard conduit, but with a much thinner wall and referred to as "electrical metallic tubing," may be used in the same manner as rigid conduit with certain restrictions imposed because of the lighter material. The tubing, unless of noncorrodible metal, must be protected with a rust-resisting coating. It is installed under the same rules as rigid conduit, except as noted below.

Table I. Standard Rigid Conduit
Made in 10-ft lengths

Standard Size of Pipe, in.	Internal Diameter, in.	External Diameter, in.	Nominal Weight per 100 ft, lb	Number of Threads per In. of Screw	Approximate Internal Cross-sectional Area, sq in.
1/2	0.62	0.84	85	14	0.30

It shall not be used for circuits over 600 volts or for conductors larger than No. 4 A.W.G. Threadless fittings must be used throughout. It shall not be used in sizes larger than 2 in. or less than 1/2 in. electrical trade size, except in under-plaster extensions where 3/8 in. may be used. It cannot be laid in cinder concrete or fill, or where subject to severe mechanical injury.

Bushings, Bends, etc., in Rigid Conduit. All parts of the conduit system including outlet or junction boxes must be mechanically secured in place and must be electrically connected and grounded. At outlets or junction boxes rigid conduits must be provided with bushings or nipples to protect the wires from abrasion.

The above sizes apply to straight runs or with nominal offsets equivalent to not more than two quarter-bends.

WIREWAYS AND BUSWAYS. In industrial plants where exposed work is not objectionable and a readily accessible low-voltage wiring system is desired, branch circuits are often run part of their length in wireways. These consist of sheet-metal troughs with hinged covers and made in convenient length so designed as to be securely fastened together. Convenient knockouts are provided in the sides and bottom so that extensions of conduit, tubing, armored cable, etc., may be run from any point. Rigid supports must be provided at least every 5 ft. Wireways may be used only in dry locations and for voltages not exceeding 600 volts.

The wires are placed, after the system is installed, by raising the cover and laying the wires in place. Not more than 30 wires may be placed in one wireway unless the excess are signal or control wires. No conductor larger than 500,000 cir mils shall be used, and the cross-sectional area of all cables shall not exceed 20 per cent of the area of the wireway.

Rubber-covered wire (Type R) and varnished-cambric (Type VC) are used, unless the ambient temperature exceeds 120 deg fahr (49 deg cent), in which case slow-burning or asbestos-covered wire (Types SB or A, respectively) shall be used.

Busways are similar in construction to wireways and governed by the same rules as to location and use. Instead of insulated wire, bare copper buses mounted on suitable insulators are used. Their chief application is for large feeders.

UNDERFLOOR RACEWAYS. In buildings of fire-resisting construction, metal or fiber raceways laid in concrete floors are extensively used for running branch circuits. This method is particularly adaptable to office buildings, where the location of partitions is frequently changed with a change of occupancy.

The use of this type of raceway is restricted to dry locations and to circuits where the voltage between wires or voltage to ground does not exceed 300 volts.

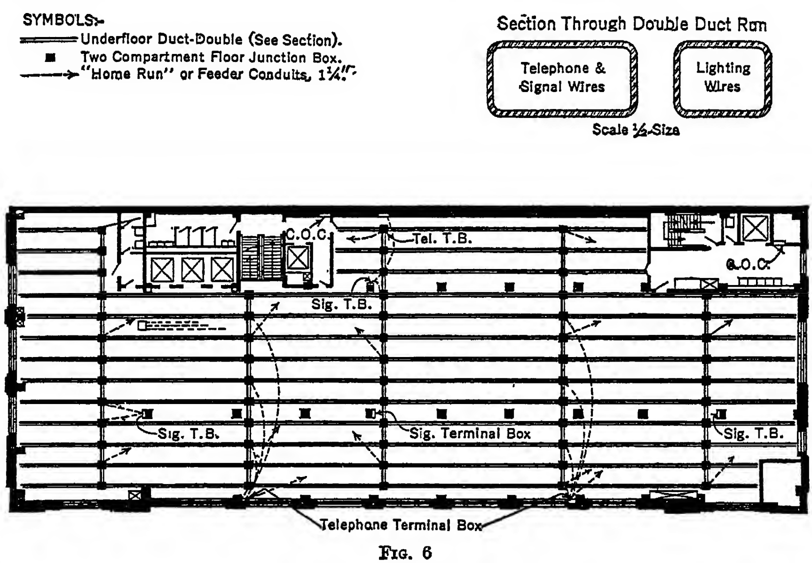

FIG. 6

Raceways are made in several styles, the metal ones usually being of rectangular section and the fiber ones of semicircular or oval section, and have conveniently spaced outlets formed in the duct. They are usually installed in the form of a grid covering an entire floor in such a manner that, no matter what the office layout may be, there will be an outlet convenient to any desk or other equipment.

The ducts are often run parallel in pairs, one for light and power wire and one for telephone or signal systems. Fig. 6 shows a typical floor layout of this kind.

Raceways may be placed in the concrete fill between the rough and finished floor, or in the slab, provided raceways of half-round section or of flat-top section not over 4 in. in width, shall have at least $^3/_4$ in. of concrete above the raceway, except that in office occupancies, metal flat-top raceways not over 2 in. in width may be laid flush with the concrete if covered with substantial linoleum or equivalent floor covering.

It shall not be used for circuits over 600 volts or for conductors larger than No. 4 A.W.G. Threadless fittings must be used throughout. It shall not be used in sizes larger than 2 in. or less than 1/2 in. electrical trade size, except in under-plaster extensions where 3/8 in. may be used. It cannot be laid in cinder concrete or fill, or where subject to severe mechanical injury.

Bushings, Bends, etc., in Rigid Conduit. All parts of the conduit system including outlet or junction boxes must be mechanically secured in place and must be electrically connected and grounded. At outlets or junction boxes rigid conduits must be provided with bushings or nipples to protect the wires from abrasion.

2,000,000	3 1/2	6	6	......	......	......	......	......	......	......	......	......

The above sizes apply to straight runs or with nominal offsets equivalent to not more than two quarter-bends.

WIREWAYS AND BUSWAYS. In industrial plants where exposed work is not objectionable and a readily accessible low-voltage wiring system is desired, branch circuits are often run part of their length in wireways. These consist of sheet-metal troughs with hinged covers and made in convenient length so designed as to be securely fastened together. Convenient knockouts are provided in the sides and bottom so that extensions of conduit, tubing, armored cable, etc., may be run from any point. Rigid supports must be provided at least every 5 ft. Wireways may be used only in dry locations and for voltages not exceeding 600 volts.

The wires are placed, after the system is installed, by raising the cover and laying the wires in place. Not more than 30 wires may be placed in one wireway unless the excess are signal or control wires. No conductor larger than 500,000 cir mils shall be used, and the cross-sectional area of all cables shall not exceed 20 per cent of the area of the wireway.

Rubber-covered wire (Type R) and varnished-cambric (Type VC) are used, unless the ambient temperature exceeds 120 deg fahr (49 deg cent), in which case slow-burning or asbestos-covered wire (Types SB or A, respectively) shall be used.

Busways are similar in construction to wireways and governed by the same rules as to location and use. Instead of insulated wire, bare copper buses mounted on suitable insulators are used. Their chief application is for large feeders.

UNDERFLOOR RACEWAYS. In buildings of fire-resisting construction, metal or fiber raceways laid in concrete floors are extensively used for running branch circuits. This method is particularly adaptable to office buildings, where the location of partitions is frequently changed with a change of occupancy.

The use of this type of raceway is restricted to dry locations and to circuits where the voltage between wires or voltage to ground does not exceed 300 volts.

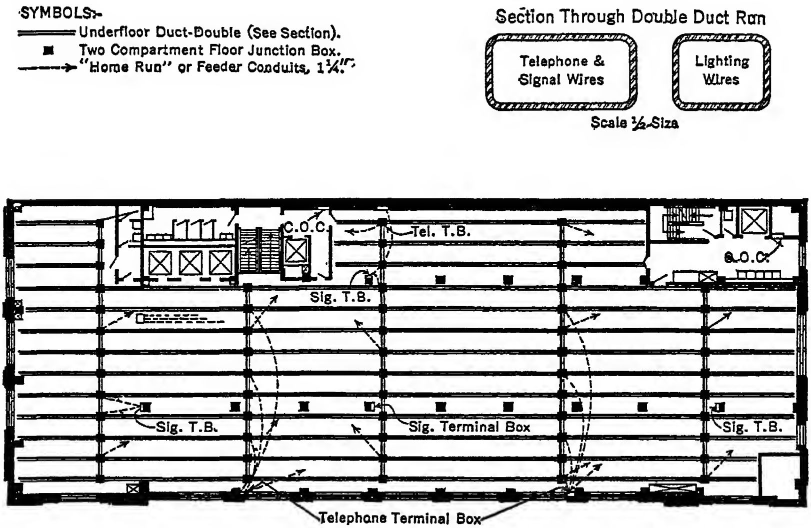

Fig. 6

Raceways are made in several styles, the metal ones usually being of rectangular section and the fiber ones of semicircular or oval section, and have conveniently spaced outlets formed in the duct. They are usually installed in the form of a grid covering an entire floor in such a manner that, no matter what the office layout may be, there will be an outlet convenient to any desk or other equipment.

The ducts are often run parallel in pairs, one for light and power wire and one for telephone or signal systems. Fig. 6 shows a typical floor layout of this kind.

Raceways may be placed in the concrete fill between the rough and finished floor, or in the slab, provided raceways of half-round section or of flat-top section not over 4 in. in width, shall have at least $^3/_4$ in. of concrete above the raceway, except that in office occupancies, metal flat-top raceways not over 2 in. in width may be laid flush with the concrete if covered with substantial linoleum or equivalent floor covering.

Open-bottom raceways must be laid on a smooth concrete pad at least 1 in. thick, extending 1 in. on either side of the raceway, and the joint must be filled with waterproof cement.

Where metal raceways are used, they must be continuous, both electrically and mechanically, be properly grounded, and conform in general to the rules for rigid conduit.

Not more than 10 wires may be used in any one raceway, and no wire larger than No. 8 shall be used. Individual circuits shall not be fused for more than 30 amp, nor shall the combined cross-sectional area of all conductors exceed 40 per cent of the cross-sectional area of the raceway.

" Duplex " or " flat twin " rubber-covered wire (Type RD), armored cable or non-metallic sheath cable must be used in open-bottom raceways. In closed-bottom raceways, rubber-covered wire (Type R) may be used.

CAST-IN-PLACE RACEWAYS. In fire-resisting buildings, raceways may be cast in place in concrete floor slabs, walls, or ceilings, provided they do not interfere with the strength or fire-resistive value of the unit. Such raceways are in effect non-metallic rigid conduit. Fiber or tile ducts imbedded in concrete would also come under this classification, although, at present, they are not referred to in the National Electrical Code.

Cast-in-place raceways are formed by pouring concrete around rubber cores, similar to a heavy rubber hose, which is pulled out as soon as the concrete is sufficiently hard. Such raceways are terminated in special fittings designed for the purpose. The practice regarding the number of wires, their support in vertical runs, the type of wires and other features, is the same as for rigid metallic conduit.

ARMORED CABLE. Armored cable, sometimes known as BX or ABC cable, is employed almost universally in residence wiring and is also a satisfactory method of installing concealed wiring in old buildings. It is frequently used for branch circuits in installations where the feeders are run in conduit. It is permitted for all voltage up to 600 volts and where the ambient temperature does not exceed 120 deg fahr (49 deg cent).

The cable consists of one or more rubber-insulated conductors, protected by an interlocking metal strip, usually galvanized steel, wound helically to form a tube similar to flexible conduit. Where of more than one conductor, the insulated conductors are cabled together and enclosed in a braided or impregnated fiber or paper covering before the armor is applied.

Armored cable may be installed exposed or concealed, may be run in the hollow spaces of walls or between floors, or may be " fished " through such spaces in completed buildings.

Special fittings or outlet boxes are available to fit cables of various sizes. All cable must be continuous from outlet to outlet and be connected both electrically and mechanically thereto, and the armor shall be properly grounded.

Where exposed to weather, continuous moisture, or imbedded in masonry or otherwise exposed to materials likely to affect the rubber insulation, a type of cable having a lead covering under the armor shall be used.

NON-METALLIC SHEATHED CABLE. This material is used in a manner similar to armored cable but requires more protection where exposed to mechanical injury. It is prohibited by the Code for certain types of buildings. It may be used for voltages up to 600 volts.

The cable consists of rubber-insulated conductors in two- and three-wire assemblies, protected by paper wrappings and cotton braids thoroughly impregnated with moisture-resisting compounds and the outer covering treated to make it fire-resisting. It is furnished with or without a bare ground wire in the assembly.

It may be installed exposed or concealed in dry locations where the ambient temperature does not exceed 120 deg fahr (49 deg cent). It is not permitted in sizes larger than No. 4 B.W.G.

NON-METALLIC WIRING FOR USE IN WET PLACES. In ice plants, breweries and other wet locations, rubber sheathed multiple-conductor cable may be used as the wiring material. When so used the individual conductors shall not be smaller than No. 12 A.W.G. and the cable shall be supported on insulators spaced at intervals not exceeding 3 ft, except when passing through walls, where it shall be enclosed in conduit or insulating tubing.

Special fittings which provide a moisture-proof seal by means of a gasket must be used with this system of wiring.

SURFACE METAL RACEWAYS. Metal Raceways, sometimes called metal molding, is used for exposed surface wiring, usually in completed buildings for the extension of existing systems where a neat and inconspicuous metallic wire enclosure is desired and the voltages do not exceed 300 volts between wires or 150 volts to ground.

Raceways are made in various designs and sizes of substantially rectangular cross-section, with removable covers or backs. They are made in various sizes, together with the

necessary fittings, to accommodate from two to ten wires. The strips are fastened in place by screws or bolts so placed as not to interfere with the wire space.

The same rules regarding electrical and mechanical continuity between outlets or fittings and the same grounding rules apply as for rigid conduit.

Surface raceways are not permitted for wire sizes larger than No. 8 or circuits fused for more than 30 amp. They must not be used in damp locations or where exposed to corrosive fumes or where subject to severe mechanical injury.

Rubber-covered wire (Type R) is required except where the ambient temperature exceeds 120 deg fahr (49 deg cent), in which case asbestos wire (Type A) or slow-burning wire (Type SB) shall be used.

SURFACE WOODEN RACEWAYS. This method of wiring, although mentioned in the National Electrical Code, is practically obsolete and is prohibited in most localities. It is used in the same general manner as surface metal raceways. The raceways are made of waterproofed hard wood with a half-inch barrier between the wire grooves and a suitable wooden cap.

UNDER-PLASTER EXTENSIONS. Where the absence of hollow spaces in the walls and floors of finished buildings does not permit fishing between outlets, extensions may be made to existing systems by means of under-plaster extensions. This method is permitted in fire-resisting buildings only and used mostly in short runs. Such extensions must not extend beyond the limits of the floor where they originate.

The installation is made by channeling the plaster and fastening the raceway, cable, or conduit to the wall, then plastering over flush with the original finish.

Special small sizes of conduit, tubing, and raceways are permitted for these extensions, which are not permitted for other wiring, either open or concealed. "Ovalflex," a flat armored cable (National Electric Products Co.), is also made for this purpose. Standard "all metal" wiring systems are permitted for under-plaster extensions, but usually they are too large to be properly covered.

NON-METALLIC SURFACE EXTENSIONS. For short extensions from existing convenience outlets, a non-metallic surface extension material may be used for short runs not extending beyond the room in which they originate. The inclusion in the National Electrical Code of properly supervised material of this nature is intended to discourage the dangerous practice of using lamp cord for this purpose.

The material consists of two insulated conductors enclosed in a suitable fabric or other covering so designed that it may be tacked or otherwise fastened to walls or trim. It can be used only for 15-amp circuits up to 150 volts in residences or offices and is of value where the original wiring layout is inadequate.

BARE BUS-BARS AND RISERS. Conductors serving as main feeders in buildings of fire-resisting construction may be run without insulating coverings when suitable provisions are made in the design of the building. Such installations are treated as special cases and subject to review by the authority enforcing the Code in the locality where the installation is made.

Such installations may not be used for circuits in excess of 600 volts, and the conductors are supported on insulators in properly guarded shafts or channels, provided with fire cut-offs at each floor.

The conductors used may be bars of round or rectangular section or they may be of tubing. Copper tubing made in standard iron pipe sizes is frequently used. This gives a tubular section and has the advantage in the larger sizes on a-c systems of reducing the skin-effect losses which may be quite appreciable on conductors having an area above 500,000 cir mils.

In connection with the use of water pipe grounds, it should be noted that the American Waterworks Association at their May 1935 meeting passed a resolution stating that this Association does not approve of the practice of grounding electric light and power circuits to water pipes.

CONCENTRIC WIRING. This method of wiring at the present time (1936) is approved by the National Electrical Code only for service entrance cable and may not be used for interior wiring except that for range circuits only, an approved entrance cable with an uninsulated grounded conductor may be used provided the cable has a final non-metallic outer covering.

Several experimental installations of concentric wiring in interior wiring systems have been made, however, and the Electrical Committee of the National Fire Protection Association has approved certain provisions governing further trial installations. Also the Underwriters' Laboratories will "list" approved wire assemblies for such trial installations. When and if experience proves this type of wiring safe and otherwise satisfactory, it will be included in the Code.

A summary of the more important rules for trial installations and those which would

presumably be included later in the Code, are as follows: Limit to alternating current supply where voltage to ground does not exceed 150 volts. Must be grounded to an electrically continuous metallic underground water system. No fuses or switches in neutral conductor. Must be used for fixed wiring only and in new installations. May not be used for extensions to any other existing system.

The material consists of one insulated conductor and one bare conductor, in an assembly; the bare wire being the neutral conductor and, presumably, being at all times at ground potential, should require no insulation. Adequate grounding is essential to the safe use of such a system.

The usual construction consists of the neutral conductor being wound helically about the insulated conductor, either in the form of a conducting strip or a number of fine wires. This assembly usually has some overall protection, such as a weatherproof braid.

78. SERVICE ENTRANCE CABLE

This is a wire assembly or cable designed to be used as a feeder running from the service company's lines outside of the building to the service equipment within the building. It is used in place of conduit and is fastened to the side of the building in a similar manner. The most frequent application is for residence services, where it is less conspicuous than conduit. There are no restrictions, however, regarding its use for any type of service up to 600 volts.

Entrance cable is made in protected and unprotected types and may have a bare neutral wire. The protected type has a heavy armor over the assembly, and the unprotected type usually has the bare neutral, composed of several small wires, wound helically about the insulated conductors over which may be placed a metal or fiber tape and protecting braids. The unprotected type is approved only for use where not subject to mechanical injury.

Underground service entrance cables are also made in several types, with both metallic and non-metallic coverings. A typical non-metallic construction is shown in Fig. 7.

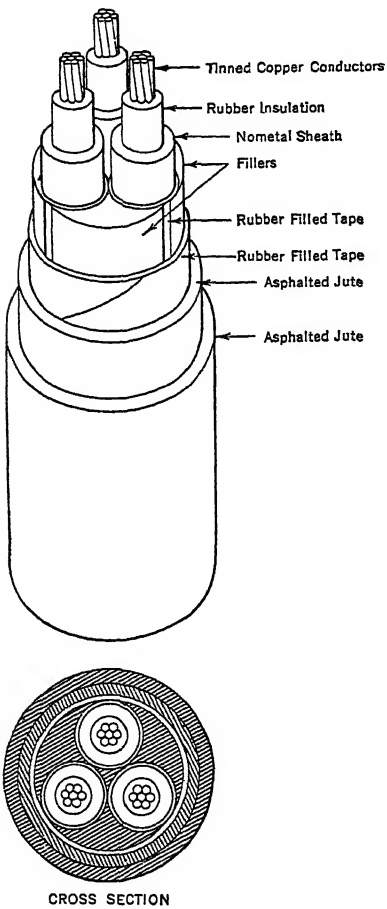

Fig. 7. Underground Non-metallic Sheath Service Entrance Cable

79. VERTICAL RISER CABLES

In tall buildings, it is common practice to locate the service transformers on a floor about half way up the building and distribute low-voltage current from this point. The service is then carried from the basement, as an extension of the street mains, up through the building to the transformer vault by means of a vertical riser cable. The voltage most frequently used is 13,200 volts.

Vertical riser cables are armored with steel wires wound helically about the insulated conductors and so designed that the entire cable may be suspended from its upper end by means of the armor wire. Inasmuch as long cables suspended from one end tend to untwist and cause damage to the insulation, the design of the complete cable must be such as to prevent untwisting.

The insulation may be rubber, varnished cambric, or paper, but is usually rubber or varnished cambric, so made as to prevent " bleeding " of the compound used between the tapes as a slipper.

80. WIRE AND WIRING ACCESSORIES

PANEL BOXES. Distributing panels mounted in metal boxes are available for any number of branch circuits and contain the switches, circuit breakers, or fuses necessary for controlling these circuits. For lighting branch circuits the switches are readily accessible for convenient operation, and the fuses and live parts are enclosed in such a manner as to be accessible only to authorized persons. Panels having automatic cut-outs or circuit breakers, in combination with the control switches, are frequently used, in which case the conventional type of fuse is not required for individual branches.

KNIFE SWITCHES. For the control of small motors, service entrances, and the like, enclosed knife switches may be used. Such switches are mounted, together with fuses, in a metal box so designed that the switch may be operated by means of a handle outside the box. The box can be opened for access to the fuses only when the switch is in the " off " position. For service entrances, the Code requires that enclosed switches be used, and it is common practice to provide meter connections and such facilities as the power company requires for meter testing in the same cabinet as the service switch.

SNAP SWITCHES. For the control of branch circuits up to 60 amp, 250 volts, either from panel boards or from isolated wall switches, single-pole snap switches are used. These devices are so designed as to give a quick break and reduce arcing when opened; they may be obtained for any type of mounting. The familiar push-button, toggle, and pull switches are of this type. For controlling circuits from more than one location, three- and four-way switches are made. (See Fig. 8.)

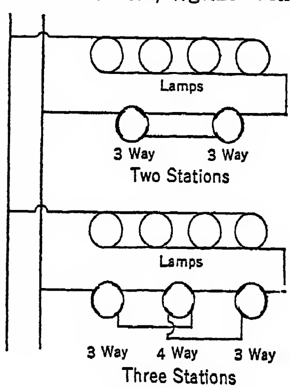

Fig. 8

Electrolier switches are used for controlling different groups of lights in the same fixture.

It should be noted that these are all classed as single-pole switches and must not be used in the neutral wire of any circuit. If for any reason a switch is placed in the neutral wire of a circuit, it must be so designed as to open all other wires of the circuit simultaneously.

OVERCURRENT PROTECTION DEVICES. To protect circuits from overloads, fuses, circuit breakers, or thermal cutouts are used, and all are designed to open the circuit when the current exceeds some predetermined value. Circuit breakers are magnetically operated, thermal cut-outs operate by means of a heating unit melting a fusible link, and fuses by the melting of short section of wire or strip.

Thermal cut-outs, not being designed to operate on short circuits but on small overloads of long duration, must be used in connection with fuses.

Fuses are the most common protective devices, and the enclosed types are completely standardized by the National Electrical Code as to rating and dimensions. The open link type of fuse is no longer permitted, except for a few special applications.

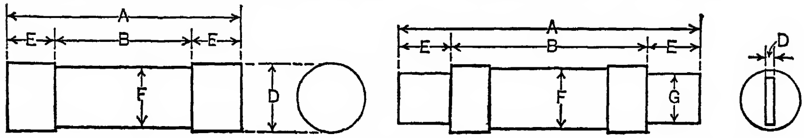
Plug fuses are designed with a screw base and are used in connection with a cut-out base having a screw socket similar to a lamp socket. They are made for the following ratings:

Non-tamperable type	Not over 250 volts	0–15 amp
Non-tamperable type	Not over 250 volts	16–25 amp
Standard screw shell type	Not over 250 volts	0–30 amp

Cartridge fuses have the fusible element enclosed in an insulating tube and are made in two styles, one having a ferrule contact and one a knife-blade contact. Renewable fuses are made to the same dimensions as cartridge fuses but differ from them in that the fusible element can be replaced in the case of a blown fuse and the fuse casing used over again.

Standard ratings and dimensions of fuses are shown in Table V.

Table V. Dimensions of National Electrical Code Standard Cartridge Fuses



Voltage	Capacity, Amp	A Length Overall	B Distance between Contacts	C Width of Contact	D Diameter of Ferrules or Thickness of Blade	E Minimum Length of Ferrule or Blade	F Diameter of Tube	G Width of Blade	
Not over 250	0– 30	2.0	1.0	0.5	0.5625	0.50	0.50	....	Ferrule type
	31– 60	3.0	1.75	0.625	0.8125	0.625	0.75	....	
	61–100	5.875	4.0	0.875	0.125	1.00	1.00	0.75	Knife-blade type
	101–200	7.125	4.5	1.25	0.1875	1.375	1.50	1.125	
	201–400	8.625	5.0	1.75	0.250	1.875	2.00	1.625	
	401–600	10.375	6.0	2.125	0.250	2.25	2.50	2.000	
Not over 600	0– 30	5.0	4.0	0.5	0.8125	0.50	0.75	....	Ferrule type
	31– 60	5.5	4.5	0.625	1.0625	0.625	1.00	....	
	61–100	7.875	6.0	0.875	0.125	1.00	1.25	0.75	Knife-blade type
	101–200	9.625	7.0	1.25	0.1875	1.375	1.75	1.125	
	201–400	11.625	8.0	1.75	0.250	1.875	2.50	1.625	
	401–600	13.375	9.0	2.125	0.250	2.250	3.00	2.000	

81. WIRES AND CABLES

The following is a brief description of wires and cables commonly used in connection with the various wiring systems. For details of construction, weights, dimensions, and carrying capacities, see chapter on Wires and Cables.

RUBBER-INSULATED WIRE (TYPE R) consists of rubber-insulated conductors protected by braids or tapes and braid. Sizes Nos. 6 A.W.G. and larger must have two braids or one tape and one braid; smaller sizes may have only one braid. Used in dry or moist locations.

RUBBER-INSULATED TWIN WIRE (TYPE RD) consists of two Type R wires laid parallel and protected with a braid or tape on each conductor and a braid overall. For use in dry or moist locations. Cannot be used for open wiring.

RUBBER-INSULATED AND LEAD-COVERED (TYPE RL) consists of Type R wires, single or multiple conductor, enclosed in a lead sheath. Used in permanently wet locations.

VARNISHED-CAMBRIC INSULATED WIRE (TYPE VC) consists of conductors insulated with layers of varnished-cloth tapes and protected with at least one braid. Can be used only in dry locations.

ASBESTOS-COVERED WIRE (TYPE A) consists of an asbestos-covered conductor saturated with some moisture-resisting compound. For use in dry, hot locations where other types of coverings would perish. Frequently used in switchboard wiring. A special type (Type AF) is designed for fixture wiring.

SLOW-BURNING (TYPE SB) consists of three braids impregnated with a flame-retarding compound and is used in a similar manner to Type A. A special type (Type CF) is used for fixing wiring.

SLOW-BURNING WEATHERPROOF (TYPE SBW) consists of one weatherproof and one flame-retarding braid. For use in open wiring in dry locations.

WEATHERPROOF WIRE (TYPE WP) consists of three braids, or the equivalent, saturated with a weatherproof compound. Used on insulators outdoors or where moisture is certain to be present.

FIXTURE WIRES. In addition to the flame-retarding types noted above, several types of rubber-insulated fixture wires are made for use in fixtures in moist locations. They are designated as Type RF for solid or stranded and Type FF for flexible. The

suffix 64 or 32 indicates the thickness of insulation. Fixture wires are permitted in sizes Nos. 18 and 16, whereas the smallest size permitted in other types is No. 14 A.W.G.

82. LAYOUT OF A WIRING SYSTEM

DEFINITIONS. The following definitions apply to the terminology commonly used in connection with Building Wire Circuits:

Appliance. Appliances are current-consuming equipment, fixed or portable, such as small heaters or motor-operated devices.

Approved. Acceptable to the authority enforcing the National Electrical Code.

Branch Circuit. That portion of a wiring system extending beyond the final automatic overcurrent protective device. **Lighting branch circuits** supply lighting outlets only. **Appliance branch circuits** supply either permanently wired appliances or attachment plug receptacles or a combination of the same with no permanently connected lighting fixtures.

Cabinet or Cut-out Box. An enclosure designed for surface mounting, having swinging doors or covers.

Demand Factor. Ratio of maximum demand to the total connected load.

Feeder. The conductors extending from the source of energy to a distribution center. This includes service conductors, mains, and subfeeders.

Service. A service includes the "service entrance" conductor and all "service equipment" required for bringing energy to the wiring system of a building.

Panelboard. A single or multiple unit, including buses and with or without switches and protective devices, used for the control of any type of circuit; designed to be placed in a cabinet and accessible only from the front. (This is distinct from a switchboard, which is generally accessible from the rear as well as the front.)

Adequate Wiring

In laying out a wiring system, in order to ensure its being adequate, safe, and efficient, consideration should be given certain general principles and accepted practices. The more important of these follow.

In designing new buildings, provision should be made for channeling and pocketing of buildings to accommodate the various wiring systems, keeping in mind that telephone, fire alarm, or other systems should be provided for but must be kept separate from light and power wiring.

Distribution centers should be centrally located in easily accessible places where switches and fuses for branch circuits can be grouped for convenient operation.

Branch circuit loads should be evenly distributed and complicated wiring avoided, so that the mechanical execution of the work will be as simple as possible.

With the increasing use of electrical devices, consideration should be given to possible future loads and provision made for ample capacity in branch circuits and mains. This applies particularly to residences and apartments. In addition to the desired lighting outlets, it is considered good practice to provide receptacle outlets so that no point on the walls shall be more than 10 ft from such outlet. Separate appliance branch circuits should be run to supply receptacle outlets in kitchen, dining room, and laundry. Such appliance branches are required to be of larger size wire than for lighting branch circuits, regardless of the immediate contemplated load.

Branch Circuits

The Code recognizes three types of branch circuits: a 15-amp branch circuit, an appliance branch, and a motor branch circuit.

A 15-amp branch circuit must not be smaller than No. 14 wire and must have overcurrent protection not exceeding 15 amp at 125 volts or 10 amp at 250 volts. Not more than 12 outlets shall be connected to such a circuit. Such circuits may supply lighting or receptacle outlets or permanently connected appliances except that no appliance so connected shall exceed a rating of 1320 watts.

It should be noted that 12 outlets does not imply 12 sockets, as a multiple light fixture may be connected to one outlet.

APPLIANCE BRANCH CIRCUITS. Wires smaller than No. 12 are not permitted for appliance branches, and overcurrent protection shall not exceed 25 amp. Such circuits shall supply only receptacle outlets or permanently connected appliances. No appliance connected to such a circuit shall be rated at more than 15 amp at 1650 watts. It should be noted that, if the 25-amp limit for fuses is adhered to, the wire size must be No. 10 as No.

12 cannot be fused for more than 20 amp, which is the maximum current-carrying capacity of No. 12 wire. (See Current-carrying Capacity of Wires and Cables.)

One side of all appliance branch circuits must be grounded, and the voltage to ground shall not exceed 150 volts.

INDIVIDUAL APPLIANCE BRANCH CIRCUITS must be used for all appliances rated over 15 amp or 1650 watts. That is, there shall be no receptacle outlets on such circuits.

MOTOR BRANCH CIRCUITS. Except for small motors used on appliance branch circuits, motor branch circuits are used. The conductors for supplying individual motors shall have a current-carrying capacity of 125 per cent of the full-load current of the motor. The overload protection requirements for such circuits are too involved to be given here but are fully covered by the National Electrical Code. In general, the motor is protected from continuous overload by means of some form of time delay device, and both the motor and conductor are protected from short circuit by means of fuses or circuit breakers, or both.

OVERCURRENT PROTECTION. Fuses or other overcurrent protection shall be located at the point where the size of a conductor changes and are so placed to protect the smaller conductor. Therefore, if fuses are used, they should not be rated higher than the current-carrying capacity of the conductor they protect. This does not apply when connection is to a grounded neutral, as no overcurrent device is permitted in conductors which are permanently grounded, unless it simultaneously opens all conductors of the circuit. This means that fuses can never be used in grounded conductors, as obviously they cannot open more than one conductor.

The overload protection of motors, and the use and location of circuit breakers in various types of circuits, are extensively covered in the National Electrical Code, Art. 8.

83. GROUNDING PRACTICE FOR INTERIOR WIRING SYSTEMS

Grounding in interior wiring systems is done primarily as a safety measure, and two classes of grounds are concerned:

In a **system ground,** one of the current-carrying conductors of a system is connected to ground.

An **equipment ground** is one where non-current-carrying parts are connected to ground. This covers such things as metallic conduit, cable armor, motor frames, switch boxes, and the like.

The purpose of equipment grounds is to keep all exposed metal parts at as near ground potential as possible by providing a low-resistance path to ground so that in case of a breakdown in the insulation, the non-current-carrying parts of the equipment cannot be raised above ground potential sufficiently to be dangerous to a person coming in contact therewith. In ungrounded equipment, it is also possible to have a high-resistance path to ground through some part of the building structure, such as metal lath, which would introduce a fire hazard as well as the accident risk, due to shock.

Equipment Grounds are required on exposed metal parts of practically all fixed equipment, including all metal duct and raceway systems. There are a few exceptions to this rule, the most important one being that grounding of conduit or armored cable runs under 25 ft is not required if free from metallic contact with the ground or grounded metal parts.

The exposed metal parts of portable equipment operating at more than 150 volts to ground must be grounded, and when possible, other portable equipment should be grounded. The attachment cords for grounded portable equipment are made with an extra conductor for this purpose.

The sizes of grounding conductors for equipment grounds are determined by class of equipment being grounded and by the size of the overcurrent device limiting the current.

System Grounds on interior wiring systems protect the low-voltage wiring in case of accidental contact with higher-voltage lines. Where the neutrals of both systems are grounded, a low-resistance path to ground is provided through the neutral of the low-voltage system, and in the event of a cross between the two systems a fuse should blow and isolate that part of the system where the trouble occurred.

If such a cross occurs with an ungrounded system, the low-voltage system will be brought up to the potential above ground of the high-voltage line. Under these conditions, there is danger of shock to persons coming in contact with the low-voltage system, as well as probable damage to the insulation of the low-voltage system and the equipment connected to it.

In order to be effective, a ground connection must be of low resistance. Therefore,

the grounding electrode must make good contact with moist earth. Continuous water piping systems afford the most convenient and best grounds. Where such a ground is not available, the metal frame of a building, a gas piping system, or a properly constructed "artificial ground" consisting of a buried plate or drain pipe may be used. Artificial grounds must not have a resistance of over 25 ohms and should be less. Water pipe grounds are of the order of 3 ohms or less.

Interior wiring systems require grounding as described in Art. 94.

The size of a grounding conductor for a system ground for a d-c system shall not be less than the largest conductor supplied by the system and in no case less than No. 8 A.W.G. copper.

The grounding conductor for an a-c system shall have a current-carrying capacity not less than one-fifth that of the conductor to which it is attached and in no case less than No. 8 A.W.G. copper.

84. RESIDENCE WIRING

SERVICE ENTRANCE AND EQUIPMENT. The service entrance must first be located with reference to the type of dwelling and position of the power company's lines. In general, the power company will supervise this part of the work and quite frequently install the complete service through the meter and service switch, up to the point where the branch circuits are connected. Service conductors are brought in overhead or underground, usually through conduit or by means of service entrance cables, as previously described. Two types of overhead entrances are shown in Fig. 9.

The service equipment located within the building should be easy of access, and provision should be made on the panel for extra branch circuits in order to take care of circuits that may be added in the future.

A master service switch, when installed, must open all wires simultaneously unless a ground terminal block within the cabinet provides means for disconnecting the grounded wire, in which case the switch may open only the current-carrying conductors.

Under certain conditions (specified in Art. 405 of the National Electrical Code) the master switch may be omitted in residence wiring.

In residence wiring, the limitation of 12 outlets on 15-amp branch circuits, as mentioned above, may be varied, provided at least one branch circuit is installed for every 500 sq ft of floor area in the building. These circuits are to be in addition to any appliance branch circuits which may be installed.

The branch circuits should be so distributed that the blowing of a fuse in one circuit will not leave an entire floor without light.

Basement, stair, and hall lights should be so wired as to operate from more than one location, and it is desirable to have several conveniently located lights operated from a switch at the main entrance.

Care should be taken in locating wall switches, to have them near the most-used entrance to the room, on the latch side of the door.

Electric ranges, water heaters, or other appliances having a rating of more than 1650 watts must be served by a separate branch circuit and, unless equipped with a plug-type connection, must have a disconnecting switch of the indicating type.

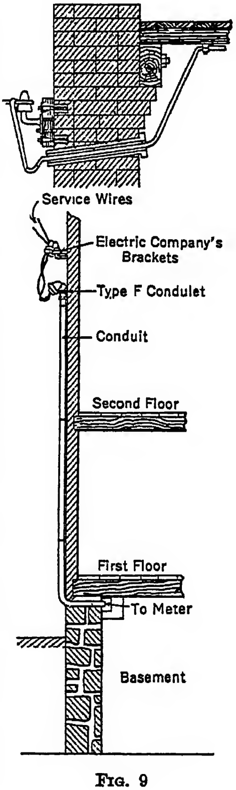


FIG. 9

In calculating wire sizes for ranges or heaters, care should be taken not only to see that the conductors are large enough to carry the rated current, but also, unless the feeders are short, to be sure that the voltage drop is not great enough to impair the efficiency of the appliance.

85. WIRING OF LARGE BUILDINGS

The first step in laying out a wiring system for buildings other than residences is to locate on a floor plan the lighting and appliance outlets and, if possible, the probable location and capacity of power equipment. Panelboard locations should then be determined in such a manner that the branch circuits serviced from them shall be of as nearly the same length as possible and preferably no longer than 100 ft.

In multistory buildings, the distributing boxes, from which mains run to the various panelboards, should be placed in the same locations on each floor. It is customary to provide pockets or closets in the building structure for such boxes and channels for the feeders to them.

The load for each panel should be calculated for use in determining the capacity of feeders. (See Wiring Calculations in this section.)

In laying out appliance branch circuits, a certain amount of judgment is required to determine the proper number of circuits. The probable load which may be applied is estimated by assuming the capacity of the devices most likely to be used.

Table VI gives the current drawn by some commonly used appliances:

Table VI. Watts Taken by Appliances

Device	Watts	Device	Watts
Flatirons	350–1200	Office machines	150
Immersion heater	300– 500	Curling iron	25
Water heaters	600–5000	Vibrators	50
Chafing dishes	420	Vacuum cleaner	150
Grill	660	Stove	5000–7500
Coffee percolators	420	Bake oven	5000–80,000
Toasters	500	Dish washer	200
Heating pads	60	Washing machine	600
Cigar lighters	70	Ironing machine	2500–6000
Glue pots	70–880	Hot plates (2)	2300
Luminous radiators	750–1500	Hot plates (3)	3100
Reflection heater	500–1000	Laboratory plate	860–4300
Air heater	500–5000	Industrial disc heater	1000–1800
Sewing machine	50	Soldering iron	100–500
Sun lamps	100–1500	Office fans	30–60
Refrigerators	100–350	Household stoves	4000–7500

The Number of Feeders depends upon the occupancy of the building and also upon (1) the power taken by the receiving devices, (2) the degree of control required at the main distributing center or switchboard, (3) the character of the receiving devices, and (4) the uniformity of voltage required.

In multiple-family dwellings one feeder is required for each apartment, the main distributing center being a metering panelboard where the meters for the entire building, or a large section of it, are grouped.

In other buildings if it is not required to control each floor separately; one set of feeders may be used for the entire building or a large section thereof.

It is advisable to sectionalize public buildings, or buildings occupied by a large number of people, in such a manner that not all the lights will fail in the event of an open circuit on any one set of feeders. It is not good practice to supply lighting loads and large fluctuating loads from the same feeders, as the voltage will vary with the load and cause undesirable flickering of the lamps. This means that power and lighting loads should not be supplied from the same feeders.

The maximum size of feeders should not exceed 1,000,000 cir mils, as it is not practicable to run larger conductors. Where larger capacity is required, several conductors having the necessary combined carrying capacity should be used. Large conductors on a-c systems are also undesirable because of loss due to skin effect.

86. DESIGNS AND PLANS

WIRING DIAGRAM. When the location of outlets, panelboards, and distributing centers, and the number of feeders, have been determined, a wiring diagram should be made showing the location and length of all feeders and branch circuits. The size of conductors for all feeders and mains should be indicated. A typical wiring diagram for an office building is shown in Figs. 10 and 11, and a list of standard symbols for electrical equipment in Fig. 12.

SPECIFICATIONS. A complete set of specifications should be prepared, giving the details of the installation. Typical specifications prepared by various committees and associations are readily obtainable.

WIRING CALCULATIONS. The size of conductor required for any circuit is determined by the current-carrying capacity and the allowable potential drop. The current-carrying capacity for building wires is fixed by the National Electrical Code. (See table of current-carrying capacities in section on Wires and Cables.) The allowable potential drop depends upon the character of the device being served. In lighting circuits, 3 per cent is considered satisfactory, and in power circuits 5 to 10 per cent.

CURRENT TO BE CARRIED BY FEEDERS. The amount of current carried by any feeder is related to the connected load but is seldom equal to the total connected load, inasmuch as not all devices provided for will be in use at the same time. The maximum demand on any feeder, therefore, will be some percentage of the connected load, and it varies with the type of occupancy of the building.

The probable maximum loads for lighting and appliance circuits in the more usual occupancies has been determined by experience and demand factors have been established for standard loads. The National Electrical Code gives such demand factors as a means of determining feeder capacities. These factors give the minimum capacity required and do not include heavy current-consuming loads such as ranges and motors, which are usually run on separate feeders distinct from the lighting and appliance load and treated separately.

For convenience, the factors as given in Section 2011 of the 1933 Code are condensed and tabulated below:

Class of Occupancy	Watts per Sq Ft Standard Load	Area Limits for Standard Loads *	Demand Factor, per cent
Single-family dwellings	1.0	First 2000 sq ft or less Excess over 2000 sq ft (Add 1000 watts for appliances)	100 60
Multi-family dwellings	1.0	First 2000 sq ft or less	100
Apartments and apartment hotels (See Note below)	1.0	Excess over 2000 sq ft 1–10 apartments 11–40 apartments 41 or over (Add 1000 watts for each apartment for appliances)	 70 60 50
Hotels with no provision for electric cooking in rooms, exclusive of ballrooms	1.0	First 10,000 sq ft 10,000–50,000 sq ft Excess over 50,000 sq ft	100 80 70
Stores, exclusive of show windows	2.0	Total area (Add 25 watts per lin ft for counter cases and 50 watts per lin ft for standing cases)	100
Show windows	...	200 watts per lin ft	100
Office buildings	2.0	First 10,000 sq ft or less Excess over 10,000 sq ft	100 70
Commercial or loft buildings occupied by more than one tenant	1.0	Total area	100
Garages	0.5	Total area	100
Hospitals, exclusive of operating and x-ray rooms	0.75	First 25,000 sq ft or less Excess over 25,000 sq ft	100 60
Schools	1.5	First 10,000 sq ft or less Excess over 10,000 sq ft	100 50
Storage warehouses	0.25	First 50,000 sq ft or less Excess over 50,000 sq ft	100 50

NOTE: Demand factors must not be applied to appliance loads in computing subfeeders to individual apartments, but may be applied in computing combined lighting and appliance loads for other feeders.

* Information in parentheses refers to special loads.

Where a common neutral is used for several feeders additional demand factors may be applied to neutral conductors, as follows:

Type of System	Current Load in Outside Conductors after Applying Demand	Further Demand for Neutral Conductors, per cent
3-wire, d-c or 1-phase, and 4-wire, 3-phase	0 to 200 amperes	100
3-wire, d-c or 1-phase, and 4-wire, 3-phase	above 200 amperes	70
5-wire, 2-phase	0 to 200 amperes	140
5-wire, 2-phase	above 200 amperes	100

For factories, theaters, libraries, and other buildings for special purposes, the feeders shall be designed for the specific load which they are to serve.

Electric-heated cooking appliances rated above 1650 watts shall have feeders computed on the following basis:

No. of Ranges	Demand Factor	No. of Ranges	Demand Factor	No. of Ranges	Demand Factor	No. of Ranges	Demand Factor
1	80	7	56	13	43	20	35
2	75	8	53	14	41	21	34
3	70	9	51	15	40	22	33
4	66	10	49	16	39	23	32
5	62	11	47	17	38	24	31
6	59	12	45	18	37	25	30
				19	36	Over 25	30

Example. A single-family residence 40 by 50 ft having two floors and finished basement, unfinished attic.

Area occupied $40 \times 50 \times 3 = 6000$ sq ft.

Watts load on feeders:

2000 sq ft at 1 watt per sq ft at 100% demand	= 2000 watts
4000 sq ft at 1 watt per sq ft at 60% demand	= 2400 watts
Allowance for appliances	1000 watts
Total	5400 watts

Current for 110 volt, 2-wire system

$5400 \div 110 = 49$ amp

Size conductor neglecting voltage drop = No. 6

Current for 110–220 volt, 3-wire system

$5400 \div 2 \times 110 = 24.5$ amp per wire

Size conductor neglecting voltage drop = No. 10

Example. An apartment house, with total area of 48,000 sq ft, having 60 apartments divided into three groups of 20 each, with meter banks in the basement.

Area of each apartment = 800 sq ft.

(1) Feeder for each apartment: 800 sq ft $\times$ 1 watt per sq ft = 800 watts

Appliance load 1000 watts

Total 1800 watts

Being less than 2000 sq ft, there is 100% demand.

Current for 110 volt, 2-wire = $1800 \div 110 = 16.4$ amp

Minimum wire size = No. 12

Current for 110–220 volt, three-wire system = $1800 \div 220 = 8.2$ amp

Minimum wire size = No. 14

(2) Feeder to each meter bank:

Total area supplied by each bank $20 \times 800 = 16{,}000$ sq ft. In this case the demand factor for groups between 11 and 40 apartments is 60 per cent after the deduction of the first 2000 sq ft at 1 watt per sq ft, or 2000 watts. We then have

16,000 sq ft at 1 watt per sq ft	= 16,000 watts
Allowed for appliances 20 × 100	= 20,000 watts
Computed load	= 36,000 watts
of which we have 2000 watts at 100%	= 2,000 watts
and 34,000 watts at 60%	= 20,400 watts
Maximum demand	= 22,400 watts

For 2-wire, 110 volts, the current = 22,400/110 = 203.6 amp
Minimum wire size = No. 1/0 (for rubber-insulated wire)

(3) Service feeders for the entire building, there being over 40 apartments, the demand after the first 2000 volts will be 50%. We then have

48,000 sq ft × 1 watt per sq ft	= 48,000 watts
Allowed for appliances 60 × 100	= 60,000 watts
Computed load	= 108,000 watts
2000 watts at 100%	= 2,000 watts
106,000 watts at 50%	= 53,000 watts
	55,000 watts

For 2-wire, 110 volts, the current will be 55,000/110 = 250 amp
Minimum size of feeder = 250,000 cir mils.

Feeders for Motor Loads

Feeders for individual motors must have a capacity of 125 per cent of the full load current of the motor.

Feeders supplying a group of two or more motors shall have a current-carrying capacity not less than 125 per cent of the full-load current of the largest motor plus the sum of full-load ratings of all the motors in the group.

Where two or more motors of the same horsepower are on the same feeder, it is assumed that one of these motors is larger for the purpose of calculating.

Certain exceptions are made to the above where the operation of motors is not continuous.

The current required by the various types of motors is given in Tables VII, VIII, IX, and X and the wire and fuse size for branch circuits in Table XI.

For industrial applications of motors, see Section 16.

Table VII. Full-load Motor Currents

Direct-current Motors

Amperes

Horsepower	115 Volts	230 Volts	550 Volts	Horsepower	115 Volts	230 Volts	550 Volts

200	....	415	208	166	43	....	182	145	37

* Values of current in common wire of two-phase three-wire system will be 1.41 times value given.

† For 90 and 80 per cent power factor the above figures should be multiplied by 1.1 and 1.25, respectively.

POTENTIAL DROP. In most installations the potential drop *per conductor* between service entrance or switchboard and the farthest receiver is taken as approximately 3 per cent of the *voltage to neutral* at the service entrance or switchboard. This is equivalent to a *total drop* (both wires) of 3 per cent of the *voltage between* wires in a two-wire d-c or single-phase system. In three-wire systems the two outside wires are to be regarded as the feeders.

In d-c or single-phase a-c systems the maximum potential drop *per conductor* will then be $0.015 \times 110 = 1.65$ volts for a 110-volt system, 3.3 volts for a 220-volt system, etc. In three-phase systems the potential drop *per conductor* will be $0.03 \times \frac{110}{\sqrt{3}} = 1.91$ volts for a 110-volt system, 3.82 volts for a 220-volt system, etc. In feeders and branch circuits the drop in the feeders is usually made two-thirds and the drop in the branch circuits one-third of the total drop.

125	....	310	155	124	32	264	132	106	26
150	....	360	180	144	36	....	158	127	32
200	....	480	240	195	49	....	210	168	42

For full-load currents of 208- and 200-volt motors, increase the corresponding 220-volt motor full-load current by 6 and 10 per cent, respectively.

* For 90 and 80 per cent power factor the above figures should be multiplied by 1.1 and 1.25, respectively.

Note that in the case of a lamp load the allowable drop of 3 per cent is based on the current corresponding to the *total connected load*, i.e., this is the maximum drop when *all* lamps are burning. In ordinary buildings the actual maximum load is seldom more than one-third the connected load; consequently when the wiring is designed on this basis the voltage at the lamps will seldom be more than 1 per cent lower than the voltage at the service connection.

CALCULATION OF SIZE OF WIRE. Let

I = current per conductor in amperes.
v = allowable potential drop *per conductor* in volts.
l = length of the conductor in feet.†

Then the required cross-section of a copper wire in circular mils is

$$A = \frac{KlI}{v} \tag{1}$$

where K is a factor depending upon the specific resistance of the wire, the size and spacing of the wires, the frequency and the power factor of the receiver. The factor K for a-c circuits is therefore not a constant, but for *preliminary* calculations its values for the sizes of wires and spacings (1 to 6 in.) ordinarily used for interior wiring is approximately as given in Table XII. The a-c values apply to single-phase, 2-phase 4-wire, and 3-phase 3-wire systems at any frequency from 25 to 60 cycles per second. For a d-c or single-phase 3-wire system proceed as for a 2-wire system, neglecting the presence of the neutral wire; the neutral wire should then be made the same size as each outside wire as thus calculated.

† Note that l is the length of *each conductor*; the total length of wire for a two-wire line is $2l$, for a three-wire line $3l$, etc.

* This value is practically exact, the others are approximate only.

Commercial sizes of wire differ successively by about 25 per cent in the larger sizes and 60 per cent in the smaller sizes; the odd-numbered sizes smaller than No. 1 are not generally manufactured, although Nos. 3, 5, and 9 are sometimes made. From Table XIII* select the size of wire corresponding to the calculated area. Unless the calculated area in circular mils agrees very closely with the area of one of the conductors given in the table, the next larger size of wire should be selected.

Table XIII. 600-volt Rubber-insulated Copper Wire *

* More extended wire tables will be found in the chapter on Bare Wires and Cables.
† Two insulated wires side by side, the insulation of the two wires in contact.
‡ Measured from insulation to insulation, equals distance between centers minus twice the thickness of insulation on either wire.

CHECK ON CALCULATION OF SIZE OF WIRE. CALCULATION OF ACTUAL POTENTIAL DROP. From the table, corresponding to the size of wire selected, take

r = the resistance per 1000 ft of conductor.
x = the reactance per 1000 ft of conductor.

and put

l = length of each conductor in feet.
I = amperes per conductor.
V = volts to neutral at receiver.*
$\cos\phi$ = power factor of receiver.

$$R = \frac{rl}{1000} = \text{total resistance per conductor.}$$

$$X = \frac{xl}{1000} = \text{total reactance per conductor.}$$

Then the actual volts drop *per conductor* is

$$v = \sqrt{(V\cos\phi + RI)^2 + (V\sin\phi + XI)^2} - V \qquad (2)$$

To a very close approximation in all ordinary cases this is equal to

$$v = RI\cos\phi\left(1 + \frac{X}{R}\tan\phi\right) \qquad (3)$$

If the drop as calculated does not check within a reasonable value with the drop assumed in calculating the size of the wire, select another size of wire and recalculate, etc. This refinement will be found necessary, only with low power factors and when the size of wire as calculated is either exceptionally large or exceptionally small, in which case the values given for the factor K in the formula for A, eq (1), may be in error by a large amount (in limiting cases 50 per cent or more).

In addition to making sure that the drop will be within a reasonable amount, one should also note whether the conductor selected is large enough mechanically and has the proper current-carrying capacity (see above), remembering also that the National Electrical Code requires that conductors through which power is supplied to a motor shall have a current-carrying capacity equal to 125 per cent of the full-load current taken by the motor.

Example of Calculation for a D-c or Single-phase System. Incandescent lamps taking 0.5 amp each are supplied with power from a 115-volt 60-cycle service through a set of feeders 200 ft in length which terminate at a cut-out cabinet as shown in Fig. 13. The lamps are grouped in sets of 10 lamps each (only one set is shown) and each set is connected to the cut-out cabinet by branch circuit conductors averaging 25 ft in length. Assuming a total potential drop of 3 volts, the drop per conductor will be 1.5 volts. The drop per conductor in the branch circuit should then be one-third of 1.5 or 0.5 volt, and the drop per conductor in the feeder circuit should be two-thirds of 1.5 or 1 volt. The respective calculations of the areas of the conductors in the feeder and branch circuits may then be carried on independently. In the branch circuit, referring to eq (1), $I = 10 \times 0.5 = 5$, $l = 25$ and $v = 0.5$, whence for copper wire

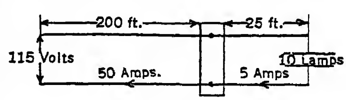

FIG. 13

$$A = \frac{11 \times 5 \times 25}{0.5} = 2750 \text{ cir mils}$$

From the wire table it is found that the next larger commercial size is No. 14 A.W.G., which has a resistance of 2.58 ohms per 1000 ft, and a reactance (assuming a 2.5-in. spacing) of 0.106 ohms per 1000 ft.

Referring to eq. (3), $V = 57.5$, $\cos\phi = 1$, $\tan\phi = 0$, $R = 2.58 \times 25/1000 = 0.0645$, $X = 0.106 \times 25/1000 = 0.00265$, whence

$$v = 0.0645 \times 5 = 0.323$$

Eq (2) gives the same value. This voltage is 35.4 per cent less than the assumed voltage of 0.5 volt, but since No. 13 wire is not a commercial size a closer realization of the assumed voltage is impracticable.

In the same manner, the required area of the conductors used in the feeder circuit is

* For d-c or a-c single-phase or a-c 2-phase, 2-wire systems $V = 1/2 \times$ (volts between wires); for a 3-phase system $V = \frac{1}{\sqrt{3}} \times$ (volts between wires); for a 2-phase 3-wire system $V = 1/2 \times$ (volts between either outside wire and middle wire). In calculating the normal drop in a single-phase 3-wire system pay no attention to the middle wire, i.e., assume a balanced load.

determined by substituting the following values in eq (1): $I = 100 \times 0.5 = 50$ amperes, $l = 200$ ft, and $v = 1$ volt. Hence

$$A = \frac{11 \times 50 \times 200}{1} = 110{,}000 \text{ cir mils}$$

From the wire table it is found that a No. 00 A.W.G. wire must be used.

The above calculations although made for a lighting load apply equally well to a motor load, except that in the final selection a wire must be chosen which will carry 125 per cent of the full-load current of the motor.

Example of Calculation for a Three-phase System. Power is to be supplied by three feeders each 400 ft in length to a three-phase, 60-cycle, a-c motor (power factor 80 per cent), the voltage between any two line wires at the service entrance being 550 volts. At full load the current taken by the motor is 50 amp. The voltage to neutral at the service entrance is $\frac{550}{\sqrt{3}}$ or 318 volts. The wires are to be spaced 6 in. apart.

Allowing a drop in each conductor of 3 per cent of the voltage to neutral, the drop will be 3 per cent of 318 or 10 volts approximately. The following values should then be substituted in eq. (1): $K = 17$, $I = 50$ amp, $l = 400$ ft and $v = 10$ volts, giving

$$A = \frac{17 \times 50 \times 400}{10} = 34{,}000 \text{ cir mils}$$

From the wire table it is found that a No. 5 A.W.G. wire might be used considering the potential drop alone but since the carrying capacity of the conductor must be 1.25×50 or 62.5 amp, it would be necessary to use a No. 4 wire.

Adopting a No. 4 wire and referring to eq. (3), $V = 318$, $\cos\phi = 0.8$, $\tan\phi = 0.75$, $R = 0.253 \times 400/1000 = 0.101$, $X = 0.101 \times 400/1000 = 0.040$, whence

$$v = 0.101 \times 50 \times 0.8 \left(1 + \frac{0.04 \times 0.75}{0.101}\right) = 5.3 \text{ volts}$$

87. WIRING OF BUILDINGS FOR MISCELLANEOUS DEVICES

In addition to the wires designed to conduct electrical energy to lamps, motors and heating devices in a building, wires may be installed in connection with telephone, telegraph, district messenger and call-bell circuits, fire and burglar alarms, door-opening devices, watchman's clocks, and electric clocks. Since all these devices are operated at low voltage, it is unnecessary to use the same care in selecting and installing the wires as in the higher-voltage systems, except that in all low-voltage systems care must be exercised that the conductors shall not become crossed with light and power circuits.

PROTECTION OF LOW-VOLTAGE WIRING. When the conductors of any low-voltage system are brought into a building from the outside, an approved protective device must be located as near as possible to the entrance of the wires to the building. With the exception of instrument circuits of telegraph systems, where cut-outs only are required, protective devices must contain a lightning arrester with a ground connection and a cut-out or heat-coil (see Pender & McIlwain). The conductors beyond the protective device in low-voltage systems need be insulated only sufficiently to prevent short circuits and the consequent interruption of service. When bunched together in vertical runs the wires must be inclosed in a fire-resisting covering to prevent the wires carrying fire from floor to floor. Low-voltage circuits may be run in the same shaft with light and power circuits, provided the two classes of wires are separated by at least 2 in. or one of the classes is run in a non-combustible tubing. Low-voltage wires may not be run in any case in the same conduit or raceway with lighting or power wires.

BELL WIRING. In its simplest form a bell-wiring system consists of a battery (or a bell ringing transformer connected to the lighting circuit), a bell-push, a bell or buzzer, and the connecting wire. Paraffin-impregnated double-cotton covered wires, or rubber-covered fixture wire in damp locations, ranging in size from No. 16 to No. 22 A.W.G. gage, are usually employed, either singly or in the form of twin wires. The wires may be fished, concealed in molding, or run exposed along the finish of the room. When a large number of bell-wires must be run together through a building, as in a hotel annunciator system, the wires are frequently inclosed in a cotton braid or lead sheath. In many buildings supplied with an a-c source of power a small step-down transformer is used in place of the batteries, thus effecting a saving in the cost of the installation and eliminating the possibility of run-down batteries. In Fig. 14 are shown several systems of bell wiring; these figures are self-explanatory.

BURGLAR ALARMS. In place of the bell-push used in bell-wiring systems, the bell circuit may be closed by some circuit-closing device attached to windows, doors, etc.,

so that the opening of any window or door in the building will be made known by the ringing of a bell. As such a system has the objection that it will not operate if the battery is run down or if the wires are cut, a closed-circuit system is preferable, in which the opening of a window or door opens the circuit and a relay in turn closes the bell circuit. In Fig. 15 is shown a typical open-circuit and in Fig. 16 a typical closed-circuit system. In Fig. 17 are shown a door spring A and a window spring B. Photoelectric cells are also used for actuating alarms.

FIG. 16

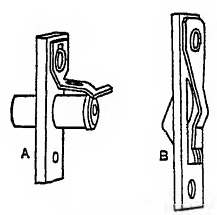

FIG. 17

FIRE ALARMS. In the manually operated system glass disks are placed at convenient points throughout the building, and with each disk is provided a hammer, with which the disk may be broken in case of fire. The breaking of the disk opens or closes an electric circuit by means of which electric gongs are rung throughout the building. In the automatic system the expansion or fusion by heat of elements in circuit-closing or -opening devices, usually placed on ceilings, causes gongs to ring throughout the building or in the watchman's office.

DOOR-OPENING DEVICES AND ELECTRIC CLOCKS. Doors may be opened by pressing a button at some distant point and thereby closing a circuit, through which current flows, energizing a magnet, which releases the nosing in the door frame. In the same manner, a moving disk on a master clock may periodically close a circuit, through which a magnet is energized which operates a pawl attached to the hands of another clock.

WATCHMAN'S CLOCK. Circuit-closing devices are placed at different points throughout a building so that a watchman on his rounds may close the circuit by means of a handle or special key. The closing of the circuit at any station makes a record on a dial in the watchman's clock indicating the time at which the circuit was closed at each particular station, the stations being designated by numbers. To obviate the possibility of run-down batteries, magneto systems are often installed, a small magneto being placed at each station.

GROUNDING OF ELECTRIC CIRCUITS AND ACCESSORIES

By R. F. Abele

89. PURPOSES OF GROUNDING

Some electric circuits are operated insulated, that is, with no intentional electrical connection from any point of the circuit to the ground; others are grounded by one or more conductors provided for the purpose.

Among the considerations influencing the decision of this point are: (1) danger of shock to persons touching the circuit; (2) danger of fire from escaping current, spark, or arc; (3) elimination of electrical oscillations set up in a circuit by the sudden changes in current resulting from the making and breaking of an arc, usually to ground, usually referred to as an " arcing ground "; such grounds may give abnormal voltages particularly on a-c circuits where the arc forms and is extinguished twice every cycle; (4) decreased strain on circuit insulation in case of accidental ground; (5) improvement of relaying, i.e., circuit protection by operation of relays; (6) the utilization of the ground and conductors on or in the ground for carrying return currents; (7) the danger of electrolysis and disturbance of telegraph, telephone, and radio systems by currents escaping to the ground.

In general, high-tension systems are grounded to protect apparatus and service and to aid relaying, whereas low-tension systems are grounded to protect life and guard against fire hazards.

Enclosures, frames, supports, etc., which may become energized owing to breakdown of electrical insulation are usually grounded, especially where others than trained employes are exposed.

90. ELECTRIC SHOCK FROM GROUNDED AND UNGROUNDED CIRCUITS

Of the various considerations affecting the desirability of grounding a circuit, that of shock is perhaps the most important. A person touching a circuit at any two points between which there is a difference of potential will receive a shock. The danger or severity of shock from touching simultaneously two line wires of a circuit is not affected by grounding the circuit, but the danger or severity of shock from touching simultaneously either wire and the ground does depend upon whether the circuit is grounded or not.

It should be noted that the sensitiveness of different people to shock varies a great deal and that the severity of a shock depends as much on the surface resistance of the skin (whether dry or wet), and on the parts and organs of the body through which the current passes, as on the voltage. It is therefore impossible to say that any voltage used in practice is so low that under no condition can it give a dangerous shock. However, considering ordinary conditions and the result of a majority of the shocks, circuits of voltages up to and including 150 volts from conductor to ground may be considered as not likely to cause a serious shock, whether grounded or ungrounded.

VOLTAGE TO GROUND OF GROUNDED CIRCUIT. When a circuit is intentionally grounded, the voltage of the grounded point is made permanently that of the earth, and the potential of every other point of the circuit becomes fixed with respect to the ground and may be readily calculated. Each conductor then carries a definite, predetermined risk, instead of an indefinite risk, which may be nothing or may be very great.

CURRENT THROUGH GROUND CONNECTION. In case of a ground, either intentional or accidental, the grounded point of the circuit is brought to ground potential, and the resultant charge on the earth is no longer zero. This charge must come by conduction from the circuit and must therefore enter the earth through the ground connection. As long as there is a change in voltage of the wires of the circuit due to the ground connection a current will flow through the ground connection. Such a current is only momentary in the case of a d-c circuit, but flows as long as the ground continues with alternating currents.

The number of amperes which flows through such a ground connection is roughly proportional to the voltage of the system and its electrostatic capacity to ground. In addition to current due to the capacity to ground there may be a leakage current due to imperfect insulation.

SHOCK FROM SINGLE CONTACT WITH HIGH-VOLTAGE CIRCUITS. Circuits having a normal line voltage of 11,000 volts or above are generally of sufficient extent (and therefore have sufficient electrostatic capacity) so that a fatal shock may be received from wire to ground, due to the current passing to ground through the body, even though the circuit be otherwise perfectly insulated from ground.

SHOCK FROM INTERMEDIATE VOLTAGE CIRCUITS. In general the power available for shock in the current escaping from an insulated circuit to ground is small compared to that in case of contact with the two wires of the circuit. Consequently, there is a class of circuits whose voltages are high enough to give serious or fatal shocks where contact is made with two points of the circuit, but not high enough to give serious (or sometimes even appreciable) shocks from wire to ground when the circuit is ungrounded. These circuits are intermediate between the low-voltage (220-volt) and high-voltage (11,000-volt) circuits above mentioned. This class includes 440- and 550-volt power circuits and *sometimes* 1100- and 2200-volt primary circuits, if leakage is small.

91. FIRE HAZARD

The ground current should be limited in amount or duration so that an arc cannot form and the ground conductor cannot burn off.

The National Electrical Code is the authority on the subject of grounding from the standpoint of fire hazard. These rules, given in the National Electrical Code (1935 edition), are abstracted in Table I.

92. ARCING GROUNDS

In normally ungrounded high-voltage circuits the current to ground is sometimes sufficient to maintain an arc between one of the wires and a grounded conductor near it but not quite in contact with it, producing a so-called " arcing " ground. Such grounds have been found to produce destructive voltages on the circuit, sometimes as great as six times the normal voltage. By metallically grounding the neutral or one wire of the circuit the rise of voltage is reduced.

LIMITING SHORT-CIRCUIT CURRENT BY RESISTANCE. In a grounded circuit every accidental ground becomes a short circuit. As such short circuits may be destructive to generating machinery, the current is sometimes limited by a resistance or reactance in the ground connection (usually made at the neutral). The amount of resistance required depends on the percentage of short-circuit current which is permissible. The resistance has, however, the disadvantage that it increases the strain on the insulation, so that, although the short-circuit current is reduced, the benefit to the insulation is also reduced. Where the circuit is grounded as a remedy for arcing grounds and no increased factor of safety on the insulator for normal condition of operation is desired, the use of resistance in the ground connection is allowable.

A system may be regarded as effectively grounded when its neutral is grounded in such a way that any arcing grounds which may occur cannot build up dangerous voltages.

Such a system may be either (*a*) directly or solidly grounded, (*b*) resistance grounded, (*c*) reactance grounded.

(*a*) A system is said to be **directly or solidly grounded** when its neutral is grounded in such a way that only the impedance in the ground leads and that of the ground itself are included and are of relatively small value. Under such conditions there can be no overvoltages due to arcing grounds.

(*b*) A system is said to be **resistance grounded** if resistance of an appreciable value is introduced in the neutral ground or ground leads. Such a system is effectively grounded if the resistance does not exceed the critical value above which maximum voltage to ground exceeds normal voltage between phases at normal frequency.

(*c*) A system is said to be **reactance grounded** if reactance of appreciable value is introduced into the neutral ground or ground leads, either in the form of reactance coils or of grounding transformers. Such a system is effectively grounded if the neutral shift under short-circuit conditions does not exceed 40 per cent of the line to neutral voltage, as under such conditions dangerous overvoltages cannot occur from arcing grounds.

LIMITING INSULATION STRAIN. In high-voltage circuits the cost of insulators is an important element. In an ungrounded circuit each insulator must be large enough to stand full line voltage (between wires), for any phase may become grounded accidentally. Where the neutral of the circuit is grounded the maximum voltage on any insulator can never exceed the voltage to ground. The voltages to neutral of a single- or two-phase system is 50 per cent of the voltage between lines, and the voltage to neu-

tral of a three-phase system is 58 per cent of the voltage between lines. A circuit with grounded neutral therefore requires insulators of from 50 to 58 per cent of those for same circuit with insulated neutral, or for the same size insulator the line voltage can be from 73 to 100 per cent higher with grounded neutral than without. These figures neglect the fact that the maximum strain is constant for grounded neutral, and occurs only for a short time at irregular intervals with insulated neutral.

93. RELAYING

Grounding is of assistance in facilitating operation of relays, especially on transmission lines. There are circuits, however, where it is better practice to operate without a system ground, in order to prevent operation of relays. For example, it is desired to keep the system alive, even if one side of the circuit should become grounded, in some types of primary distribution networks.

See Section 12, Art. 12.

94. SYSTEM GROUNDING

The practice of different companies is not consistent with respect to insulating or grounding of various classes of circuits, but the following rules cover the usual practice.

1. **TRANSMISSION SYSTEMS** do not involve questions of hazard, as far as circuit grounding is concerned, as they necessarily are dangerous. Neutrals are usually grounded to reduce insulation stresses and arcing grounds, and facilitate automatic tripping of the line. Where this last feature is not desired, grounding is, of course, a disadvantage.

2. **PRIMARY DISTRIBUTION SYSTEMS** usually have grounded neutral, not necessarily because of inherent advantages, but often because many such systems are of the 4000 volt 4-wire Y-type, converted from an older 2300-volt delta system. Ungrounded delta systems are likely to show better continuity of service.

3. **SECONDARY DISTRIBUTION SYSTEMS** are grounded as a protection to life and against fire, particularly in view of the possibility of crosses with the primary lines.

4. **D-C SYSTEMS, EXCEPT THREE-WIRE SYSTEMS,** are generally considered safer ungrounded. Neutrals of three-wire circuits are grounded if grounding will limit the voltage of the outside wires, to ground, to 150 volts or less. Where d-c circuits can come in contact with high-tension a-c lines, it is better to ground. Railway circuits are invariably grounded, in order to enable track rails to be used for returns.

TRANSMISSION LINES. The various methods used in grounding transmission circuits are as follows:

A. Solid ground—a low-resistance connection.

B. Resistance ground—connection through a resistor.

C. Reactance ground—air core or iron core reactor.

The Report of the A.I.E.E. Committee on Grounding, 1931, shows that systems of 110 kv and above are nearly always classified as solidly grounded. However, there appears to be a tendency in high-voltage systems to limit the ground current by some kind of impedance, resistance, reactance, or partial grounding of the total transformer capacity. On systems of 66 kv and below, the solid grounding practice is less pronounced. In this range, answers to a questionnaire sent out by A.I.E.E. show 51 per cent solidly grounded, 9 per cent grounded through resistance, 8 per cent grounded through reactors or grounding transformers, and 32 per cent with free neutrals.

There are three conditions to be considered in relation to grounding of neutrals:

A. Neutral anchored to ground potential and system provided with prompt disconnection in event of one leg being grounded.

B. Neutral potential not anchored, but system provided with prompt disconnection in event of one leg being grounded.

C. Neutral potential not anchored and system capable of operating for long period with one leg grounded, i.e., while repairs on grounded leg are being made.

PRIMARY DISTRIBUTION LINES. Not all grounds on a grounded system necessarily trip the circuit because such grounds are likely to have high resistance. The actual difference between grounded and ungrounded systems, as regards service protection, is not as great as might be expected. With regard to life hazard from fallen wires, grounding, for the same reason, is not a perfect protection.

The **Hood system,** or common neutral ground, in which the same ground wire is used for primary and secondary circuits, tends to give a low impedance for line-to-ground faults.

A-C SECONDARY SYSTEMS. Table I shows the National Electrical Code requirements. In addition to the service grounds, some companies ground the neutrals at the supply transformers. See also Art. 83.

Table I

Type of Current	Type of Circuit	Point of Attachment of Ground
D-c	Two wire—not to exceed 300 volts	At the supply station only. Recommended that ground be eliminated if voltage to ground of either conductor is over 300 volts after grounding.
	Three wire	Neutral, at one or more supply stations, but not at individual services.
A-c	Two wire or three wire	At every service end, provided voltage to ground does not exceed 150 volts. Recommended for over 150 volts but not over 300 volts. Additional grounds optional at transformer or one or more points of system.

95. STATION GROUNDING

GROUND MASS. The ground mass of a station consists of the ground electrodes buried in the earth to provide earth connection for the station. It is usual to provide a low-impedance bus network, with numerous connections to the station ground mass, to which equipment to be grounded is connected. The building steel is usually tied to this network, as is also the water piping if big enough to carry the current that may flow in it. See Arts. 83 and 98.

NEUTRALS. It is usual to connect the neutral of generators and transformers to the protective ground system. Lightning arresters may also be tied to the station ground mass.

FRAMES AND CASES. Machine frames, meter cases, cable sheaths, etc., are connected to the ground mass if they contain conductors which are or may be at 150 volts or more above ground. Instrument transformer grounds should be made in a way to avoid errors due to " sneak currents " in parallel paths. Suitable board frames are usually not grounded if they support bare conductors operating at 150 volts or more.

OUTDOOR SUBSTATIONS. In the case of outdoor substations, it is usual to provide fences with special grounds and not connect to the ground mass.

96. POLE LINE GROUNDING

Steel towers should be grounded so that power arcs will not create dangerous potential gradients at and near their bases.

OVERHEAD GROUND WIRE. Where an overhead ground wire is used, it should be designed so as not to flash over to the line insulators, i.e., its surge impedance, together with that of the tower or ground lead, should be greater than that of the system earth connection itself.

COUNTERPOISE GROUND. If the soil is of high resistivity, where steel towers are used, a counterpoise ground may be used, consisting of a wire or network of wires laid in the earth at a considerable distance from the tower and connected to it.

WOODEN POLES. The value of a ground wire on a wooden pole line is questionable, as without it the pole adds so much to the insulation. The pole has a flashover strength of about 160 kv per foot of length.

The grounding of transformer cases, on poles, is not universal practice, and there are advantages in not grounding.

97. CABLE SHEATH GROUNDING

Cable sheaths are grounded to prevent their attaining voltages dangerous to workers, when faults occur. Single-conductor high-tension a-c cable sheaths are likely to have induced high voltages under normal conditions, unless they are grounded. Sheaths should be grounded at station ends, at connections to overhead lines, and at manholes, where practicable.

98. GROUND CONNECTIONS

TYPES. Good ground connections require contact with permanent earth moisture and should extend below the frost line. Most of the resistance of a ground connection is in the shell of earth immediately surrounding it.

Water pipes make an ideal ground connection for alternating currents but cannot be used for direct current because of electrolysis.

The next best ground is a pipe, or group of pipes, driven into the ground. Plate grounds are now virtually obsolete.

GROUNDING TO CONDUCTORS USED FOR OTHER PURPOSES. Where an extensive system of water pipes buried in the earth is available, a satisfactory ground connection can be made directly to the pipes. This practice, however, is now opposed by the American Waterworks Assn., 1935. Gas pipes are not suitable for ground connections, as in case of broken joints the resulting arc might ignite the escaping gas. Steam heat pipes are heat insulated (and therefore partially electrically insulated) from the earth. Where there are two ground connections, one to an electric railway track and the other to a water pipe, there is danger that railway current may thereby be introduced into the water piping system and produce electrolysis. Sheaths of cables are not good ground as the cables might be injured by the currents in their sheaths, either from electrolysis or unforeseen heating. In fact, cable sheaths, like other buried conductors, have a tendency to collect stray currents from electric railways, and special ground connections sometimes have to be made to permit these currents to escape without producing electrolysis. Steel frames of buildings present only a limited surface to ground at the foundations and are therefore good only when the current to be discharged will be proportionally small.

CONNECTIONS TO PIPING SYSTEM. The National Electrical Code (1935) contains the following requirements:

Size of Ground Wires. The grounding conductor for a d-c supply system shall have a current-carrying capacity not less than that of the largest conductor supplied by the system and in no case smaller than No. 8 A.W.G. The grounding conductor for an a-c supply system shall have a current-carrying capacity not less than one-fifth that of the conductor to which it is attached except that in no case shall it be smaller than No. 8.

Method of Making Ground Connections. The grounding conductor shall be attached to circuits, cabinets, equipment and the like, which are to be grounded, by means of suitable lugs, clamps, blocks, or other approved means.

The grounding conductor shall be attached to the pipe or rod (1) by means of an approved bolted clamp to which the conductor is soldered or otherwise connected in an approved manner or (2) by means of a pipe fitting, a plug, or approved device screwed into the pipe or into the fitting, or (3) by other approved means.

Where a non-conductive protecting coating such as paint or enamel is used to protect the equipment, conduit, couplings, and fittings, such coating shall be completely removed from threads and other surfaces in order to ensure a good contact between ground clamp and equipment. Pipes and rods used as ground electrodes shall have clean metal surfaces, and shall not be covered with paint, enamel, or other poorly conducting materials.

GROUNDING TO SPECIAL PIPES, PLATES, ETC. When suitable buried conductors are not already available, direct connection to the ground may be made (1) by driving a pipe or rod vertically into the earth, (2) by burying a wire or ribbon in the earth, or (3) by burying a plate in the earth. The pipe or rod form of ground connection is now generally accepted as the best.

FACTORS AFFECTING THE IMPEDANCE OF GROUND CONNECTIONS. The impedance offered to a flow of current into the ground depends almost entirely on the nature of the soil. To obtain low ground impedance, it is necessary to have electrolytic moisture in contact with the earth connection, or to have a very large area of earth cross-section for the current. Table II shows a typical case of the influence of moisture on soil resistivity. Other factors affecting the impedance are (1) the extent of metal surface in contact with the earth, (2) the thoroughness of this contact, (3) the wetness of the earth, (4) the distance between this ground connection and the ground connections (if any) at which the current leaves the earth.

The effect of the distance upon the impedance between a pair of ground electrodes, such as ground pipe and a test electrode, is frequently overlooked. If the electrodes are close together, the impedance will be low on account of the shortness of the current path. If the distance between electrodes be increased, the impedance will be increased until a certain distance, usually about 25 ft, is reached, after which it will steadily decrease on account of the increase in the cross-sectional area of the earth path (Fig. 1).

The potential drop in the soil near a ground connection is surprisingly high, as shown by a typical case in Table IX.

DEFINITION OF THE RESISTANCE AND IMPEDANCE OF A SINGLE GROUND CONNECTION. If the distance between a pair of ground connections be fixed and the drop of potential from one of them G_1 and a point P between them be plotted against the distance of P from G_1 a curve such as $G_1\,DA$, Fig. 2, will be obtained, if the two ground connections G_1 and G_2 are similar. If, on the other hand, the ground connection G_1 has very much more perfect and extensive contact with the earth, the curve of

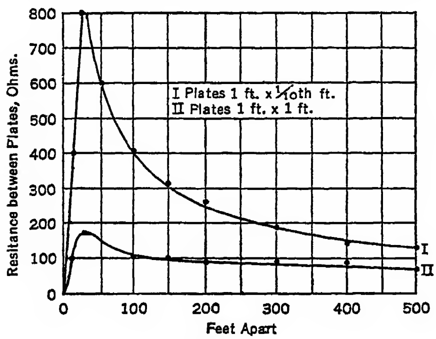

FIG. 1

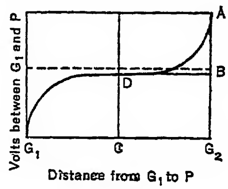

FIG. 2

potential drop will have the shape $G_1\,DB$. Both curves have the peculiarity of being steep near the restricted electrodes and of becoming relatively flat between them, indicating that the greater part of the resistance occurs near the electrodes, where the current is restricted to a limit area, practically no drop occurring where the current spreads out.

Table II. Effect of Moisture Content of Red Clay Soil on Resistance

Per Cent Moisture in Terms of Dry Earth	Resistance, ohms per cc	Per Cent Moisture in Terms of Dry Earth	Resistance, ohms per cc
12	170,000	20	9000
14	65,000	30	5000
16	17,000	60	5000
18	10,000		

The impedance of the ground connection G_1 is then defined as the ratio of the potential drop CD, to the current entering the ground at G_1, and similarly for the ground connection G_2. The resistance may be approximated by measuring the impedance at different frequencies, and by extrapolation, finding the impedance at zero frequency. A more accurate way, however, is to use a special bridge which will give a phase balance as well as a resistance balance. See Bureau of Standards Technological Paper 108; also Section 5, Art. 9 and Section 6, Art. 8.

RESISTANCE OF SOME TYPICAL GROUND CONNECTIONS. The resistance of ground connections varies so greatly with the condition and nature of the soil that data on resistance have only local application. The data in Table III are presented merely to give a general idea of the results which are obtained in practice.

Table III

Authority	Time of Year	Description of Soil	Type of Ground Connection	Dimensions	Depth, feet	Ohms
Hoxie.......	Feb.-June	Surface loam	Plate	1 ft × 1 ft	..	1940
	Feb.-June	Moist black loam	Plate	6 ft × 2 ft 3 in.	6	113
	Feb.-June	River bottom	Plate	1 ft × 1 ft	..	132
	Feb.-June	Gravelly soil	Pipe	1 1/4 in.	5	630
	Feb.-June	Gravelly soil	30 Pipes	1 1/4 in each	5	13
	Feb.-June	Swampy soil	7 Pipes	1 1/4 in each	5	15
Del Mar....	Summer	Rock and loam fill	Plate	15 in. × 15 in.	6	155
Hayden.....	Aug.-Sept.	Clay loam	Pipe	2 1/2 in.	3 3/4	26.1
Hayden.....	Feb.-March	Clay loam	Pipe	2 1/2 in.	3 3/4	120
Hayden.....	June-July	Clay loam	Pipe	2 1/2 in.	3.1	35.4
	March-April	Clay loam	Pipe	2 1/2 in.	3.1	240

The Bureau of Standards (T–108) gives the following comparative table of ground pipe resistances in various kinds of soil:

Number of Grounds Tested	Soil	Resistance Ohms		
		Average	Minimum	Maximum
24	Fills and ground containing more or less refuse as ashes, cinders, and brine waste.	14	3.5	41
205	Clay, shale, adobe, gumbo, loam, and slightly loam with no stones or gravel.	24	2.0	98
237	Clay, adobe, gumbo, and loam mixed with varying proportions of sand, gravel, and stone.	93	6.0	800
72	Gravel, sand, or stones with little or no clay or loam.	554	35	2700

The Bureau of Standards has made measurements of resistance of a ground connection using a driven pipe. The pipe was $^3/_4$ in. galvanized and driven in rather stony clay ($\rho = 7420$). The figures in Table IV give the results obtained with accuracy within 2 to 3 per cent.

Table IV

Number of Specimens	Depth, feet	Average Measured Resistance, ohms	Number of Specimens	Depth, feet	Average Measured Resistance, ohms
8	1	167	1	6	42.5
8	2	76.3	3	7	31.0
8	3	47.2	1	8	22.5
8	4	37.5	1	9	23.5
8	5	49.5	8	10	36.5

The irregularity of the soil produces the variance in figures. The lower depths were found to be of boulders, 2 to 5 in. in diameter, which have high resistance. These resistances were obtained by the ammeter-voltmeter method, using 60-cycle current.

Design of Ground Connections

It is as a rule impracticable to install a ground connection of sufficiently low conductivity to allow the passage of the maximum current it may have to carry without producing a considerable rise of voltage. The conductivity which a ground connection should have is therefore largely a matter of experience and judgment rather than of exact calculation. Cheapness and durability generally determine the material, usually iron or copper, and the thickness.

COPPER PLATES. Formerly the most common form of ground connection consisted of a copper plate imbedded in charcoal or coke in moist earth. Coke, so often recommended for earth connections, is not a good conductor in itself. It attracts and holds moisture, but since that moisture does not contain an electrolyte in solution, it may leave the earth connection with high resistance. Furthermore the sulfur in the coke is likely to corrode the copper plate and thus increase its resistance. Some engineers are of the opinion that neither charcoal nor coke is of any particular use in connection with a ground plate. The corrosion of copper ground plates is greatly reduced by coating with tin. As the conductance of a ground connection is not proportional to the area of the metal plate, the use of a single large plate is an uneconomical method of obtaining a low resistance.

COPPER WIRE OR RIBBON. Wire or ribbon has the advantage of a lower resistance than a plate for the same area and is useful where bedrock is near the surface. The wire has the further advantage that no special material or connection is required. The wire may be laid out in a straight line or coiled with turns wide apart into a plane spiral. The latter form is sometimes made by wrapping a number of turns of wire around the butt of a pole before setting it.

PIPES DRIVEN INTO THE GROUND. On the basis of the first cost, and of inspection, resistance measurement, etc., the driven pipe or rod is probably the best of all

forms of direct ground connections. Iron is the cheapest available metal and has proved its serviceability even when imbedded in salty marshes.

The pipe is often galvanized, sherardized, or copper covered, from $^3/_4$ in. to 2 in. in nominal size, driven 6 ft or more into the moistest ground available. The effect of depth on resistance is shown in Table V. The diameter of a pipe has little effect upon its earth resistance, as shown by Table VI. To facilitate driving, the pipe is sometimes provided with a pointed casting at the lower end and cap at the upper end. The pipe has the advantage that it is cheap to install, as no hole is dug, and being driven vertically, it can tap any conducting stratum of the earth which is practically accessible. It is highly efficient as regards conductivity per square foot of surface exposed to the earth, and while the resistance of a single pipe will exceed that of a large plate, a higher and more permanent conductivity can be obtained from several pipes driven at some distance apart and connected in multiple, than from an equal expenditure in money on a single large ground plate. See Tables VII and VIII. Ground pipes or plates in multiple should be not less than 6 ft, and preferably 10 ft, apart, in order to avoid superimposing two zones of high current density.

Table V. Effect of Depth upon Resistance of Pipe in Fairly Wet Soil

Depth in the Fairly Wet Soil, ft	Resistance, ohms	Depth in the Fairly Wet Soil, ft	Resistance, ohms
1	152	6	37
2	90	7	32
3	66	8	29
4	52	9	26
5	42	10	24

Table VI. Effect of Pipe Diameter upon Resistance (Pipe buried 10 ft)

Overall Diameter of Pipe, cm	Resistance, ohms	Overall Diameter of Pipe, cm	Resistance, ohms
1	37	5	28 1/2
2	33	6	27 1/2
3	31	7	26 1/2
4	29 1/2	8	26

Table VII. Effect of Number on Parallel Ground Pipes on Resistance, Pipes Being 10 Ft Deep and 10 Ft Apart

Number of Pipes	Per Cent of Resistance of One Pipe	Number of Pipes	Per Cent of Resistance of One Pipe
1	100	5	19
2	57	6	12
3	38	7	9
4	27	8	8

Table VIII. Effect on Resistance of Separation of Pipes, 5 Ft Deep

Distance Apart, ft	Per Cent of Resistance with No Separation	Distance Apart, ft	Per Cent of Resistance with No Separation
0	100	3	61
1	72	4	58
2	65		

Table IX. Voltage Drop at Various Distances from a Pipe Ground

Distance from Ground Pipe, ft	Per Cent of Total Voltage Drop	Distance from Ground Pipe, ft	Per Cent of Total Voltage Drop
0	0	6	76
1	34	10	88
2	48	Infinite	100
4	65		

If the ground available is naturally dry the conductivity may be improved as much as 50 per cent by cupping out the soil around the pipe at the surface and adding salt and

water. A concentration of 1/2 per cent calculated on the soil moisture accomplishes nearly 90 per cent of the highest concentration and may be used as a basis for calculations of amount of salt required. A neat form of earth unit is shown in Fig. 3. A cylinder of metal or earthenware of any available diameter is set around the pipe at the surface of the ground and covered by a lid. This receptacle will hold the salt. Its advantages lie in the easy construction of the connection and protection of surrounding vegetation from the saline water.

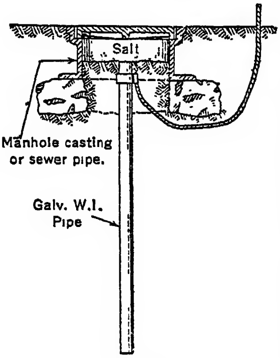

FIG. 3

PIPE GROUNDS FOR LIGHTNING ARRESTERS. A number of grounds is desirable at each installation. These numerous ground connections are joined together by a copper connection. It sometimes happens that a good ground cannot be conveniently made near the arrester, or that a better one can be made at a more distant point. In this case it is recommended that the principal ground be made at the more distant point, but that a ground of some sort, the best possible under the conditions, be made directly underneath the arrester.

CONNECTIONS TO GROUND PLATES AND PIPES. The wire connecting the apparatus to be grounded to the buried conductor should lead directly to the latter with as few bends as possible; this is particularly important in grounding lightning arresters, in which case a flat strip is also better than a round wire. All exposed joints and those buried in the ground should be made in such a way that they will not rust off. The buried connection from a ground plate to the surface should be so protected that it will not rust off or be cut off when excavations are made for other purposes. It is also necessary that the connections be protected from mechanical injury and theft, from the surface of the ground to above the level at which it can be reached. To insure reliability, connections should as far as possible be made so that their continuity can be determined by inspection.

W. W. Lewis' formula gives the circular mils A to carry the maximum current of I amperes for S seconds:

$$A = 10.6\,IS$$

This is based on clamped, bolted, or soldered connections and 250 deg cent final temperature. For brazed joints and a final temperature of 450 deg cent the numerical factor is 8.7. The carrying capacity of ground electrodes is treated theoretically and experimentally by H. G. Taylor, *Jour. I.E.E.* (London), 1935, vol. 77, pp. 542–560.

Tests of Ground Connections

Ground connections should be frequently tested to determine their continuity and occasionally to determine their impedance. Alternating current should be used, in order to avoid the effects of polarization. In order to pass a current through a ground connection it is necessary to have a second connection in order to complete the circuit. Where a large water-piping system is available for the return connection, an approximate measure of the resistance can be obtained by passing a current from the ground connection to an accessible part of the piping, say a hydrant, and computing the resistance by dividing the volts by the amperes. The resistance thus obtained includes both the resistance to be measured and that of the connection through the piping system. As the latter is probably much the smaller and may be insignificant, the result gives an approximate idea of the resistance and locates a discontinuity as an infinite resistance, that is, no current flowing. Where there are two similar grounds, current may be passed from one to another and the sum of the two resistances, or the average resistance, obtained.

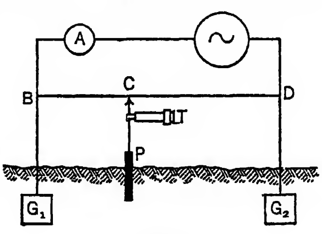

FIG. 4

When a more accurate determination of the individual resistances of two or more ground connections is desired, the connections shown in Fig. 4 may be employed and a curve obtained by test, similar to that shown in Fig. 2. The apparatus required comprises a source of alternating current, a rod P which may be driven into the earth, a high-resistance wire BD stretched between the two ground connections G_1 and G_2, an ammeter A, and a telephone receiver T. The

contact C is slid along the resistance wire until the telephone receiver is silent. The drop of potential between G_1 and the rod is then the same as between G_1 and the contact C. The drop between G_1 and P is therefore equal to

$$\frac{(\text{Length of wire } BC)}{(\text{Length of wire } BD)} \times (\text{Total drop from } G_1 \text{ to } G_2)$$

By taking a series of observations with P driven into the ground at various points the curve of potential drop is readily plotted and the resistance of each ground connection, as defined above, obtained. Bureau of Standards Technological Paper No. 108 describes an improved Kohlrausch bridge, for the same purpose.

On grounded services, a very simple way of determining whether or not a satisfactory ground has been obtained is as follows: (1) On a 220–110 volt secondary system connect the underground leg through a 5-amp fuse to an available point on the water-piping system. If sufficient current flows to blow the fuse, the ground connection may be considered satisfactory. (2) On a 440–220 volt system, the current should be sufficient to blow a 10-amp fuse.

Under some conditions it is of advantage to have a disconnecting clamp in the ground circuit. It decreases the hazard to men working on the circuit and also affords a means of disconnecting the ground for test purposes.

Care of Ground Plates and Pipes

The greatest trouble with ground plates and pipes arises from electrolysis, and periodic resistance measurements should be made as described above. When a ground connection shows an abnormally high resistance, it is usual to supplement it with a new ground connection, as it seldom pays to remove the old ones. Ground connections deteriorate rapidly if equipped with salt boxes; but even under the worst conditions they are likely to last many years. J. L. R. Hayden cites the case of some pipe grounds which maintained the same average resistance for three years.

SPECIFICATIONS FOR GROUND PIPES AND PLATES. In the case of ground plates, the following data should be specified: material of plate; size of plate, area, and thickness; depth at which the plate shall be buried; amount of charcoal below and above it; method of connecting the plate to its cable or wire (usually soldered and bolted); whether the plate shall also be connected to the track rails and if so, how.

In the case of pipe ground connections, the following data should be specified: diameter of pipe; whether galvanized, sherardized, etc.; depth to which the pipe shall be driven; method of finishing the top of the pipe; height the pipe shall project above the ground.

ELECTROLYSIS OF UNDERGROUND STRUCTURES

By W. A. Del Mar

100. STRAY CURRENTS

The following discussion will be limited to the electrolysis of underground structures, that is, to the corrosion of metal work in the earth, due to the action of stray currents from the grounded rails of electric railroads.

The track rails of electric railways practically always form part of the electric circuit feeding the cars. As these rails are laid either in the ground or on ballast on the ground, and as the ground is a partial conductor, some of the current will leave the rails and flow in the ground. If pipes, lead-sheathed cables, or structural foundations happen to be in the ground near the railway, part of the stray current from the rails will enter these under-

ground structures and flow along them, leaving them at some other point to return to the station bus. If the current is direct, the underground structure from which current leaves to enter the earth becomes the anode of an electrolytic cell, the earth containing the electrolyte. This anode corrodes as the result of the liberation of acids from the salts contained in the earth. Occasionally the cathode, or underground structure into which current enters from the earth, is liable to corrosion by secondary causes. In the case of railways using alternating current for distribution, the stray currents are usually a large proportion of the total current, but the electrolytic effects are negligible. (See J. L. R. Hayden, *Trans. A.I.E.E.*, Vol. 26, p. 221.)

In d-c railways, it is therefore desirable to confine the current to the track rails as far as practicable. This may be done by maintaining the rail bonds in a high degree of efficiency and by keeping down the voltage drop in the rails by means of insulated negative feeders, attached thereto at suitable intervals.

While such means will assist materially in mitigating electrolysis troubles, it is often necessary to take special steps to protect underground structures without relying upon the railway companies to confine their currents to the rails.

MINIMUM VOLTAGE TO PRODUCE ELECTROLYSIS. The conduction of current through moist ground is almost entirely electrolytic, ordinary conduction being almost negligible. Electrolytic corrosion occurs whenever current flows from metal into the ground, regardless of whatever difference of potential may exist between different parts of the circuit. In order that current may flow, however, it is in general necessary that the difference of potential between anode and cathode exceeds the algebraic sum of the emf's of combination and separation of the compounds involved in the electrolytic process. An iron anode in a soil containing iron salts in solution will be attacked when the emf is infinitesimal.

101. CORROSION EFFICIENCY AND PASSIVITY

When an electric current is passed through an electrolyte, the mass of the anode dissolved may be calculated theoretically by Faraday's law (see Sec. 6). In practice this amount may be exceeded, or the reverse. The term " coefficient of corrosion " or " corrosion efficiency " is used to designate the ratio of the actual to the theoretical mass of the anode dissolved. The corrosion efficiency is usually less than 100 per cent, owing to the occurrence of secondary reactions. Thus the corrosion of iron, which primarily occurs by the formation of ferrous salts, should theoretically occur at the rate of 1.045 grams per ampere-hour, but in practice the rate may be anywhere from zero to 40 per cent more than the theoretical value. In the case of iron in soil, without protection, the corrosion efficiency is practically independent of the temperature over a range from 0 to 40 deg cent. It is also independent of the kind of iron, whether wrought iron, steel, or machined cast iron. The efficiency is greater the lower the current density, varying from 20 to 140 per cent for a range of current densities between 5.0 and 0.05 milliamperes per square centimeter. It is greater with increasing moisture content up to saturation of the soil. Data on steel encased in concrete are given below, under Protection of Steel by Concrete.

102. DISTRIBUTION OF EARTH CURRENTS

The distribution of stray currents in the earth depends not only upon the resistance of the earth but also upon the resistance and distribution of the conducting structures in the earth.

EARTH RESISTANCE. As the earth conducts electrolytically, its specific resistance can be calculated from the concentration of the salt solutions it contains. Such calculations are, generally useless, however, as, even with moderate specific conductance, the extent of the current path in the earth is so great that its resistance is very low, except near the electrodes. The effect of the electrodes is to concentrate the current streams into limited areas, thereby increasing the effective resistance of the earth. It is obvious, therefore, that the resistance of the earth depends more upon the electrode area, and the dampness of the soil around the electrodes, than anything else.

The resistance of the earth is low when the electrodes consist of considerable lengths of track rails. This is particularly noticeable in single-phase lines, owing to the skin effect and inductance of the rails. Thus J. Dalziel and J. Sayers (Inst. Civil Engineers, London, 1909) found that, on the Midland Railway, most of the current did not continue along the rails for any considerable length, but within a few hundred yards of the car sank gradually into the earth to re-enter the ballast at a very short distance from the power station. H. F. Parshall found that on a line eight miles long, the earth-return current

was 60 per cent of the total. Probably the most exact data of this kind are those due to A. W. Copley (*Trans. A.I.E.E.*, Vol. 27, p. 1171, 1908) who stated that on the New York, New Haven & Hartford Railroad, before the adoption of the three-wire system, the percentage of current in the earth was 25 per cent on the four-track sections and 60 per cent on the single-track sections.

ELECTROLYTIC ZONE. When a drop of potential occurs in a track rail, the current spreads out from it into the soil in much the same way that the leakage lines of magnetic force from a long electromagnet spread out into the air; that is, almost the entire leakage current is confined to a limited zone of the earth, the extent of this zone depending upon the potential gradient and the length of the line. The stream lines of the current will tend to crowd into a pipe or cable sheath (on account of its low resistance) if such conductor is within this zone, but this tendency rapidly diminishes as the distance between the conductor and the rails increases. Conductors at a comparatively short distance from the rails are, therefore, not liable to electrolysis unless the difference of potential between them and the rails is large or the leakage path of the current from the rails to the conductors is of low resistance. Thus in England, where the permissible drop in the grounded return is limited to a total of 7 volts, Messrs. Cunliffe found experimentally that the electrolytic zone is confined to within 3 ft of the track. The voltage drop under this rule is taken as the mean between the average and the momentary maximum values during a 15 to 30 min period of a schedule run, at the time of maximum traffic, exclusive of exceptional occasions.

103. STRUCTURES AFFECTED BY CORROSION

Stray currents can set up corrosion of the rails, rail spikes, cross-bonds, steel columns, etc., through which they escape into the earth, and they can set up corrosion of gas and water pipes, cable sheaths, building structures, etc., which they may enter and leave in their course through the earth. The protection of the former class of materials is entirely the concern of the railroad company which originates the earth currents; not so with the latter class, which is often of great concern to the municipalities or public-service corporations which own them. Electrolytic surveys should, therefore, be made with a clear understanding of which class of property is under suspicion of danger. As a rule, electrolysis is most destructive to the grounded metal of the railroads; foreign pipes, cable sheaths, etc., being affected in comparatively rare instances. Of all properties foreign to the railroads, the thin sheaths of telephone cables are most susceptible to electrolytic corrosion.

DESTRUCTION OF CONCRETE BY ELECTROLYSIS. Where iron imbedded in concrete becomes an anode, not only is the iron corroded but the concrete also is cracked. This action is due to the internal stress set up by the increase of volume which the iron suffers when it changes to an oxide or salt. The current has no direct effect upon the concrete at the anode even when sufficiently strong to liberate chlorine from the brine used to impregnate it. (C. E. Magnusson, *Trans. A.I.E.F.*, June, 1911.) At the cathode, however, the concrete becomes softened and loses its bond with the electrode. See papers by E. B. Rosa, B. McCallum, and A. S. Peters, Nat. Assn. of Cement Users, 1912, and abstracted in *Eng. News*, Vol. 68, p. 1162, 1912. No action, however, occurs on concrete through which current flows, except at the electrodes.

104. ELECTROLYTIC SURVEYS

An electrolytic survey is an investigation made to determine the condition of grounded metallic structures and the soil in which they are imbedded and of their electrical conditions with the view of ascertaining what conditions tending to produce damage may exist.

POTENTIAL READINGS. Random readings between rails and pipes give no quantitative information about electrolytic conditions. As a matter of fact, a difference of potential between a pipe and rail at any point is often greater the less the stray currents at that point. To illustrate this, we may assume a pipe to be outside the electrolytic zone and, therefore, safe from electrolytic corrosion. If, at any point, the rail is at the same potential as the pipe, the potential of the rail at every other point will differ from the pipe. Also, if the part of the rail which is at the potential of the pipe happens to be at some distance from the power station, the pipe will be positive to the rail at all points between the equipotential point and the power station. Hence the fact that the pipe is positive to the rail does not indicate that it is subject to electrolysis. A more important illustration is a pipe carrying little current itself but connected to some distant pipe which is carrying considerable current. In such a case, a pipe may be highly electropositive to the rails and yet be quite innocent of electrolytic tendencies. These illustrations are merely specific

instances of the general principle that potential readings are useless unless taken with reference to the resistance of the earth between rails and conductors, which in turn depends upon the direction and distribution of the current stream lines. The potential difference between the structure tested and earth affords more complete information than can be secured from any other practicable class of observations. For this purpose, it is necessary to use a non-polarizable electrode such as that shown in Fig. 1, which is known as the **Haber electrode.** The zinc sulfate paste shown therein is made by adding saturated zinc sulfate solution to fine zinc sulfate crystals until the mixture has attained a semi-fluid condition.

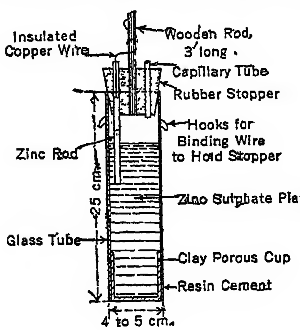

Fig. 1

MEASUREMENT OF LEAKAGE CURRENT IN GROUNDED RETURN SYSTEM. The columns and foundations of elevated structures and subways, rail spikes, bare negative cables, and bonds are the parts most likely to be attacked electrolytically.

In the elevated railways of New York City, after about nine years' operation with the steel structure a part of the return system, it was found necessary to remove all metallic connections in the Borough of Manhattan between the track rails and structure and to install negative feeder cables to compensate for the conductivity thereby sacrificed.

The corrosion of rail spikes, though happily rare, is a matter of such grave concern to the railroads and public that it should be carefully watched for. It occurs when ties are old and water-logged or when improperly treated with preservative. Timber is ordinarily classed with the non-conductors, because, when dry and well-seasoned, it has considerable dielectric strength and resistance. When green or moist, however, it becomes an electric conductor of comparatively low resistance. The resistance along the grain is much less than across it, and porous woods, such as oak, are better conductors than the non-porous woods such as pine. The conductivity of wood is due primarily to the presence in its pores of electrolytes formed from the salts found in natural timber, from preservatives and from salts originating from coal fumes or ashes. The flow of current, from the rails and spikes into the ties, fills the pores of the wood with iron salts, which add to the electrolytic conductivity and permit the leakage of more current. The effect is, therefore, cumulative, the leakage current increasing until the pores of the wood are completely saturated with electrolyte. Cases have been known where spikes were pitted more than half way through and where the rail flanges were badly corroded. Creosote has but little effect upon conductivity. A mixture of creosote and gas-oil, however, is a preservative which greatly reduces conduction. Red oak treated with zinc chloride is a bad tie from the electrolytic point of view.

Columns of elevated railroads, subways, passenger stations, etc., are best tested for electrolytic trouble by means of a sensitive galvanometer used in the following way. Iron clamps with pointed tips are fastened to the column at points 4 or 5 ft apart, care being taken that the points penetrate the paint and make metallic contact with the steel. Wires are run from these clamps to a galvanometer and the deflection noted. The galvanometer having been calibrated, this gives the drop of potential in the column. The cross-sectional area of the column being known, its resistance may be calculated from the known resistivity of structural steel (usually 11 times that of copper). The potential drop, divided by the resistance, gives the flow of current in the column. The direction of flow, its amount, and the efficiency of corrosion being known, the actual damage being done by electrolysis may be calculated as a definite weight of metal per annum. This method has been used in the Grand Central Terminal, New York, the galvanometer employed being a Queen & Co.'s E-8010 with tube E-8011, a calibration resistance, and a tripod. A deflection of one scale division is equivalent to about 0.000003 volt. Considering an average column with a resistance of 0.000,004 ohm for a 4-ft length, a deflection of one scale division corresponds to three-fourths of an ampere. Where the columns are to be encased in concrete, permanent testing terminals should be provided, preferably in the form of small iron pipes screwed into the steel and ending flush with the concrete.

MEASUREMENT OF LEAKAGE CURRENT IN PIPES, CABLE SHEATHS, ETC. It is not uncommon to find potential readings taken between different systems of pipes, without regard to the location of the connections, the results being recorded as differences of potential between those systems of pipes. The potential of a pipe system, however, may vary from point to point, and consequently such readings have no significance unless the points between which the potential difference is measured are specified. The signifi-

cance of potential readings between specific points is that they afford an indication of the potential gradient normal to the tracks and thereby help to determine the electrolytic zone.

Making use of all possible connections to the pipe, the potential difference between these points and the anode end of the grounded system should be determined as described below and the limits of the " electrolytic zone " ascertained by noting where the potential gradient in the pipe becomes negligible. For this purpose, water hydrants and water pipes constitute the best connection points.

Potential readings between points on the same pipe line or cable sheath are sometimes made the basis of potential curves showing the drop in the pipe or sheath. Such potential curves may be very significant when taken from cable sheaths, but are of little use for pipes on account of the variable joint resistance of the latter. Thus in a cable sheath of uniform resistance along the entire length tested, where the potential curve is flat, the sheath carries no current; when it is a straight sloping line, the sheath carries current without giving current to or taking current from the earth; where it changes its slope, current is either entering or leaving the sheath.

Hering's Method. The current in a pipe may also be measured by the following method. (C. Hering, *Trans. A.I.E.E.*, June, 1912.) The fundamental principle is as follows. Let *P*, Fig. 2, be a part of an underground pipe which has been uncovered and through which an unknown current *I* is flowing. Let *D* be a sensitive galvanometer, millivoltmeter, or any other suitable form of detector; there should preferably be no variable resistance like an unbonded pipe joint between the two contact points. Let *A* be an ammeter, *B* a few battery cells, and *R* an adjustable resistance; the shunt circuit containing them is connected as shown, anywhere outside of the points of application of the voltage detector, the farther away the better; they may even be on the other side of a joint.

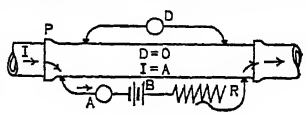

FIG. 2

To find the current flowing in the pipe adjust the resistance *R* until *D* reads zero; then the current due to the battery *B* will be exactly equal and opposite to the current in the pipe. Hence the reading of the ammeter *A* gives the current in the pipe.

If *D* is a galvanometer with proportionate deflections, instead of a mere detector, then by taking a deflection immediately after the shunt circuit has been opened a reading proportionate to the drop of voltage for that current will be obtained. The instrument *D* is thereby calibrated to read the pipe currents directly and can be used for this purpose thereafter; the test with the battery current is therefore merely of the nature of a preliminary calibration, and need be carried out only once for each station.

Instead of attempting to adjust the current in the shunt to bring the voltage *D* to zero, it is often more convenient to use a regular measuring instrument for *D* instead of a mere zero detector, and to pass a definite current through the shunt, say 10, 50, or 100 amp. reading the two deflections of *D* when this current is on and when it is off; this had best be repeated several times. The difference between these two readings then corresponds to the current in the pipe. The best current to use is that which will reduce the original deflection as much as possible. By thus using the difference between a large and a small deflection the errors due to a loose zero, which are so common with highly sensitive instruments, are reduced.

Methods for overcoming fluctuating currents are given by Hering in the paper cited above.

Having thus calibrated the voltmeter *V* at each of two neighboring stations, the currents which enter or leave the pipe between them may be determined, with the fluctuating currents, by taking the readings of the two instruments simultaneously by means of visual or telephonic signals, preferably at times when the currents are momentarily steady.

Measurement of Current Leaving Pipe at Any Point. The strength of the current at the point where it is leaving the sheath may be determined by the following test, which involves the use of a temporary bond in the form of a stout copper cable, electrically connected through an ammeter with both sheath and rail. Let

V = total drop of potential in the rails from *their* anodic center to the point where the temporary bond is connected.

By " anodic center of the rails " is meant the center of gravity of the leakage current *leaving* the rails.

v = difference of potential between the sheath and rail at the bonding point prior to the insertion of the bond.

v_1 = same, after the insertion of a bond which carries I amperes. The current in the bond is read from the ammeter.

Then the earth current, i, after the insertion of the bond will be

$$i = I \cdot \frac{k}{1 - k}$$

where
$$k = \frac{v_1}{v} \cdot \frac{V - v}{V - v_1}$$

The earth current from the pipe, without bonding, would be

$$\frac{V - v}{V - v_1}(I + i)$$

For example, suppose the drop in the rails from the anodic center to the bond to be 100 volts, and the differences of potential between the pipe and the rails at the bonding point to be 5 volts before the bond is inserted and 1 volt after. Suppose the current in the bond is found to be 50 amp.

Then $\quad V = 100, \quad v = 5, \quad v_1 = 1, \quad I = 50$

$$k = \frac{1}{5} \cdot \frac{100 - 5}{100 - 1} = 0.19$$

$$i = 50 \cdot \frac{0.19}{1 - 0.19} = 12 \text{ amp, approximately}$$

Without bonding, the current would be

$$= \frac{100 - 5}{100 - 1}(50 + 12) = 59 \text{ amp, approximately}$$

The above formula is based upon the following assumptions:

(1) That the drop in the rails V is not affected by the insertion of the bond.

(2) That the area over which the current from the pipe or sheath enters the earth is short. For proof of formula, see *Elec. World*, 1910, Vol. 35, p. 407.

105. MITIGATION OF ELECTROLYSIS

Where stray currents are unavoidable, electrolysis may be mitigated by the use of drainage bonds, insulation, electric shielding, boosters, or cathode maintaining generators.

PROTECTION FROM ELECTROLYSIS BY DRAINAGE BONDS. Bonds are not only useful for testing purposes; they may be applied permanently to reduce the earth currents. Certain effects, however, may render their use inadvisable.

1. If one piping system is connected to the rails or bus, a difference of potential will be established between it and all other underground metallic structures and it will, therefore, attract current from the latter and expose them to electrolytic danger. A bonded piping system thus becomes a part of the trolley return circuit, and the owner may become a party to whatever damage may occur in the other structures.

2. A considerable current in a gas pipe is a serious fire hazard and in a lead cable sheath is a menace to continuity of service.

3. Electrolysis is promoted at all imperfect joints and connections.

4. In power cables, the sheath currents may be great enough to add unduly to the heating of the cables.

In spite of these objections bonds are very largely used to protect cable sheaths from corrosion. To be most effective, the sheath should be connected to the negative bus by an insulated cable and the bus itself should be connected to the track rails by insulated cables only.

PROTECTION OF STEEL BY CONCRETE. The conductivity of concrete depends upon its porosity and wetness. Tests have shown that when concrete is wet its specific resistance may be as low as 20 or 30 ohms per yard cube, and when dry, as great as 2000 ohms. When the potential gradient in the concrete around an anode exceeds about 2 volts per centimeter, the temperature rises and the corrosion of iron is usually so rapid as to cause the concrete to crack open. At ordinary temperatures, the efficiency of corrosion of iron in concrete is low, but if the temperature is high, owing either to the high current density or external causes, the efficiency of corrosion may become quite high, as shown by Table I compiled from Tech. Paper 18 of the Bureau of Standards. For any fixed temperature the amount of corrosion for a given number of ampere-hours is independent of the current strength.

Passivity at ordinary temperatures is due principally to the drying of the film of anode rust by endosmose (see Section VI, Art. 15) and to a less extent to the concentration of calcium hydrate near the cathode, where it becomes converted into chalk, which fills the pores

of the concrete. Both these actions have the effect of increasing the resistance from anode to cathode, but the effect of the former action, which is the principal one while the current flows, does not last long after the stoppage of current (W. A. Del Mar and D. C. Woodbury, *Elec. World*, 1917, Vol. 70, p. 916).

Table I. Corrosion Efficiency and Temperature

Temperature, degrees, centigrade	Corrosion Efficiency, per cent	Temperature, degrees, centigrade	Corrosion Efficiency, per cent
10	2.0	70	22.5
20	2.5	80	37.5
30	3.0	90	44.5
40	3.5	100	47.0
50	5.0		
60	11.5		

Briefly stated, concrete affords good protection to steel work if the current density is not high enough to heat the concrete excessively.

Salt should never be used in concrete if there is the slightest probability of action by electric currents, since the addition of even a fraction of a per cent of chlorine is sufficient to increase the rate of corrosion a hundred fold.

PROTECTION OF STEEL BY PAINT. Unpainted steel imbedded in concrete can be electrolytically corroded at the anode, but a good insulating paint applied to the steel prevents such corrosion. Acid-proof paints with tar or asphalt base such as are commonly used to protect steel imbedded in concrete are usually effective. A typical paint of this kind has the following composition: 16 parts coal-tar paint, 4 parts Portland cement, 3 parts kerosene. When the voltage between cathode and ground does not exceed 5 volts the corrosive efficiency of an anode, so protected, is usually less than 1 per cent.

PROTECTION OF CABLE SHEATHS. No entirely satisfactory protection is available which is both inexpensive, flexible and able to resist heat and electrolytes. Asphalted hessian or duck tapes have been fairly successful but tend to loosen from the lead in time. Special rubber compounds are now being tried with some promise of success.

PROTECTION BY INSULATED JOINTS. In a number of installations, flow of stray current on metallic pipe lines has been prevented by the use of a sufficient number of insulating joints. It is found that, where a pipe line is laid with every joint insulated, the line has such a high electrical resistance that no measurable current flows, although considerable potential gradient may exist in the earth parallel to the pipe line. Insulating joints in cable sheaths are not found to afford an effective means of preventing electrolysis.

PROTECTION BY SHIELDING. Underground structures have been protected from electrolysis by connecting to the structure an auxiliary metallic conductor located so as to cause the current to flow to earth from the auxiliary conductor. The shielding conductor must be so placed as to prevent the current from leaving the structure to be protected, or at least, to cause its magnitude to be greatly reduced.

PROTECTION BY BOOSTER. It is often proposed to render grounded metal work electronegative to the rail return by means of a booster, but such proposals are seldom carried into execution on account of the expense they involve.

PROTECTION BY CATHODE (MAINTAINING) GENERATOR. The following system is used for protection of oil pipes against electrolysis and natural corrosion. At places where there is danger, electrodes are placed in the earth in the neighborhood of the pipes and these electrodes are connected to the positive pole of a low-voltage generator while the pipe to be protected is itself connected with the negative pole. In this way electric current is forced to enter the pipe from the earth so that anodic destruction of the pipe is impossible.

The same system is used to prevent the pitting of condenser tubes, especially where salt water is used for cooling.

106. BIBLIOGRAPHY

A very complete bibliography of the subject up to 1908 is given in a paper by W. H. Gee, Electrolytic corrosion, *J.I.E.E.*, 1908, Vol. 41, p. 425. In addition to these references and those given in the text, the following papers should be consulted:

Report of the American Committee on Electrolysis, 1921. (This contains a great deal of valuable information on the subject, including a description of European practice and protective legislation. It also contains a bibliography of contributions which are regarded by the Committee as having permanent value.)

Bureau of Standards Technologic Papers, 15, 18, 25, 26, 27, 28, 32, 52, 54, 55, 62, 63, 72, and 75. (These papers cover almost every phase of the subject.)

LIGHTING

By F. C. Caldwell

1. ILLUMINATION AND LIGHT

Units, Definitions, and Laws

I.E.S. Illuminating Engineering Nomenclature and Photometric Standards

For the purpose of illuminating engineering, light is radiant energy, evaluated according to its capacity to produce visual sensation. (See also Sec. 9 of *Fundamentals of Engineering* for Theory of Radiation, and Sec. 5, Art. 21, for Photometry.) The units associated with the applications of light are based upon the "international candle."

LUMINOUS FLUX. (Also called light flux.) The rate of flow of light, as defined above, from a luminous body. Generally only a small portion of the emitted radiation is thus effective, and the effectiveness of that portion varies as indicated by a visibility factor, shown in Fig. 14. The luminous flux is the integral of luminous intensity, I, that is, $F = \int_0^\omega I\,d\omega$, where F is the flux and ω is a solid angle.

LUMEN. The unit of luminous flux. It is the flux emitted from a uniform point source of 1 candle through 1 unit of solid angle, or 1 steradian. On a sphere of 1-ft radius this unit angle subtends 1 sq ft. There are, therefore, a total of 4π or 12.6 (12.5664) lumens emitted by a source of 1 mean spherical candle, or, if I_s = mean spherical candles, $F = 12.6\,I_s$; and for any zonal solid angle, ω, $F_\omega = \omega I_{s\omega}$.

LUMINOUS INTENSITY. The uminous intensity of a point source, in any direction, is the luminous flux per unit solid angle, emitted by that source, in that direction. If the distance at which the intensity is measured is large relative to the dimensions of the source (about 10 times) this source may be taken as a point. The light-giving body, though often a prime light source, may also be a surface which reflects light. Luminous intensity is also called candlepower. It may be applied to certain average or mean values, thus:

Mean spherical intensity $-I_s$; mean lower hemispherical intensity $-I_{mlh}$; mean upper hemispherical intensity $-I_{muh}$; mean horizontal intensity $-I_h$.

INTERNATIONAL CANDLE. The arbitrary unit of luminous intensity established in 1909 for the United States, Great Britain, and France. It is usually called a "candle"; its value is maintained by groups of standardized lamps at the U. S. Bureau of Standards and other national laboratories. The Hefner unit, German standard = 0.9 candle. (See also Sec. 5, Photometry.)

ILLUMINATION. The effect produced at any surface by flux falling upon or passing through it. The term is used both qualitatively and quantitatively. Quantitatively, illumination is measured by the density of the luminous flux at the point in question. Illumination is, therefore, independent of the character or color of the surface at which it is measured. Illumination, as the most usual application of light, is the most important phenomenon connected with it, and the unit of illumination is the most important unit.

FOOT-CANDLE. The unit of illumination used by English-speaking peoples. It is the illumination produced by luminous flux having a density of 1 lumen per square foot. As explained under *lumen*, 1 lumen per square foot is received at a distance of 1 ft from a light source of 1 candle. Thus, a foot-candle illumination is produced by 1 candle falling on a surface at 1 ft normal distance, from 1 candle.

LUX, PHOT. (Metric units.) These are given by 1 lumen per square meter and per square centimeter, respectively. They are also the illumination values produced by a standard candle on a surface at 1 meter and 1 cm normal distance, respectively. One foot-candle = 10.76 lux (10.76 sq ft in a square meter). One lux = 0.093 ft-c. The phot = 10,000 lux.

LUMEN-HOUR. This is the unit of radiant energy, referred to its effective value for vision. It is, for instance, used in measuring the total output of an incandescent lamp during its life.

BRIGHTNESS. This is the luminous intensity of a surface, per unit area, as projected on a plane normal to the line of sight. Using s = area and θ = angle of surface with normal, brightness = $dI/ds \cos\theta$. The brightness of a surface depends upon the relative directions of the incident light and the line of sight, to the plane of the surface. Brightness is proportional to the product: illumination times reflection factor.

THE CANDLES PER SQUARE INCH (projected area) is the most-used unit of brightness, based on the English system of units. The *candle per square foot* is also used for low brightness-values of reflecting surfaces.

LAMBERT (metric unit) is the brightness of any perfectly diffusing surface, emitting or reflecting 1 lumen per square centimeter. It is also the average brightness of any surface which emits or reflects 1 lumen per square centimeter. **Millilambert,** 0.001 lambert, is more generally used; because of its smaller value it is better suited to most cases. To reduce candles per square centimeter to lamberts, multiply by π. To reduce candles per square inch to lamberts, multiply by 0.487 ($\pi/6.45$, approximately $^1/_2$).

The foot-lambert is the average brightness of any surface emitting or reflecting 1 lumen per square foot. One foot-lambert = 1.076 millilamberts.

POINT-SOURCE, OR EXTENDED SURFACE. From a point-source the light rays spread out in the form of a cone. Thus the areas intercepted by planes at distances d_1 and d_2 are proportional to $(d_1/d_2)^2$, and the illumination, being inversely proportional to the areas over which the flux is spread, will be inversely proportional to the squares of the distance from the source. This is the inverse-square law; it is true only if the source is a point, but it is essentially true if the diameter of the source is not greater than $^1/_{10}$ the distance to the illuminated surface. On the other hand, if the light rays are effectively parallel, owing either to large area of light source or to great distance (sunlight), the illumination is independent of the distance. Illumination of interiors, due to reflection from light colored ceilings, generally lies between these extremes. The inverse-square law may be applied for artificial illumination of interiors with dark ceilings and walls and for many cases of exterior lighting, but effectively parallel illumination is never met with, even in searchlight beams. Sunlight is an example of parallel radiation.

THE COSINE LAW. If the surface upon which a given beam of light is falling normally be tilted through an angle θ, the area of the illuminated surface is increased in the ratio $1/\cos\theta$; the illumination is thus decreased in the ratio $\cos\theta/1$. The angle θ is also the angle made by the light rays with a line normal to the surface, which is the "angle of incidence of the light," as in Fig. 1. Thus illumination varies as the cosine of the angle of incidence.

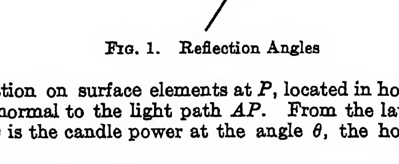

FIG. 1. Reflection Angles

CALCULATION OF ILLUMINATION, POINT-BY-POINT METHOD. In Fig. 1 let A be the location of an illuminant and P a point at which the illumination from A is to be determined. The three most important cases of this problem refer respectively to the illumination on surface elements at P, located in horizontal and vertical planes, and in a plane normal to the light path AP. From the laws of inverse squares and of cosines, and if I_θ is the candle power at the angle θ, the horizontal illumination at P is

$$E_h = \frac{I_\theta \cos\theta}{d^2} = \frac{I_\theta \cos^3\theta}{v^2}.$$

The vertical illumination at P is $E_v = \dfrac{I_\theta \sin\theta}{d^2} = \dfrac{I_\theta \sin^3\theta}{h^2} = \dfrac{I_\theta \cos^2\theta \sin\theta}{v^2}$.

The normal illumination at P is $E_n = \dfrac{I_\theta}{d^2} = \dfrac{I_\theta \cos^2\theta}{v^2} = \dfrac{I_\theta \sin^2\theta}{h^2}$.

Also, $E_h = \dfrac{I_\theta \cos\theta}{h^2 + v^2} = \dfrac{I_\theta v}{(h^2 + v^2)^{3/2}}$.

If v is small compared to h, then approximately, $E_h = \dfrac{I_\theta v}{h^3}$.

Also, under these conditions, approximately, $\sin^2\theta = \sin^3\theta = 1$, hence $E_v = E_n = I_\theta/h^2$ (1 per cent error for $h = 7v$).

For other methods of point-by-point calculation and useful tables see Benford, *Trans. I.E.S.*, 1912, Vol. 7, p. 695.

REFLECTION, TRANSMISSION, AND ABSORPTION. When light falls upon the surface of an object, these three phenomena occur. Depending upon which predominates, the object (*a*) has a high reflection factor, is a good reflector; (*b*) has high transmission, is transparent or translucent; (*c*) has high absorption, is opaque.

Reflection Factor. Is defined as the ratio of luminous flux reflected to that incident upon a surface. It is thus a percentage of the incident flux. Some typical values are given in Table I. Reflection is specular, as from a mirror, or diffuse, as from blotting

Table I. Reflection Factors for Typical Materials

(Poller and Meaker, *Trans. I.E.S.*, 1931, Vol. 26, p. 1029)

Material	Reflection per cent
Paint:	
Flat white	75–85
Gloss white	75–80
Vitreous porcelain enamel on steel:	
Matte white	60–83
Glazed white	65–77

Alabaster ($CaSO_4$):	
Veined	49–67
Colored	27–29
Matte-finished metal:	
Oxidized or etched aluminum	70–89
Aluminum paint	60–65
Polished metal:	
Silver	90–92
Chromium	63–66
Aluminum *	62
Monel metal	49–55
Chromium-nickel (stainless) steel	55

* After electrolytic treatment 83 per cent. Dickerson, *Trans. I.E.S.*, 1934, p. 358.

paper, or a combination of both. In specular reflection the angle of reflection is equal to the angle of incidence as in Fig. 2(*a*). Fig. 2(*b*) shows perfect diffusion with equal

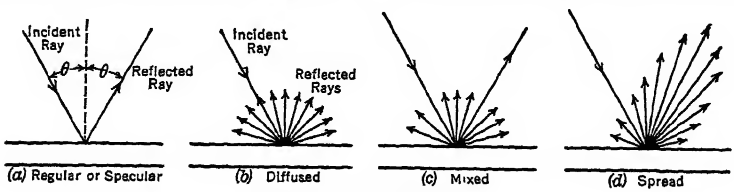

Fig. 2. Types of Reflection

candlepower radiated in all directions. Fig. 2(*c*) shows mixed reflection, as from an enameled surface. Fig. 2(*d*) shows imperfect diffusion or spread reflection. Reflection is generally selective as to wavelength, thus resulting in the appearance of color. This is treated in Art. 4 under Color. **Transmission factor,** or **transmission,** is also given as a percentage of the incident luminous flux. It varies from nearly 100 per cent, as in clear glass, to almost zero. Some light is transmitted through or into even the most dense substances, as witness a greenish glow through thin gold leaf. Transmission depends upon the thickness of the object, being roughly inversely proportional to the thickness. Some values are given in Table II. In considering the transmission through thin glass sheets, the reflection from the two surfaces, which will amount to about 8 per cent or more, must be taken into account, that is, only about 90 per cent of the incident light will come through the clearest glass, with normal incidence. If this angle of incidence is large the reflection is much greater. **Absorption factor,** or **absorption,** is equal

to 100 per cent less the sum of the reflection and transmission factors. It represents that part of the light radiation which is converted into invisible heat energy in the object or material under test. It is approximately proportional to thickness.

REFRACTION. The phenomenon which accounts for the bending of a light ray when it passes from one substance to another of different density is important because of its use in redirecting light rays in prismatic globes. (See Art. 5.)

Table II. Transmission, Reflection, and Absorption Factors for Typical Translucent Materials

(Poller and Meaker, *Trans. I.E.S.*, 1934, Vol. 26, p. 1031)

Type	Thickness, in.	Transmission, per cent	Reflection, per cent
Configurated,* obscure clear glass	0.12–0.23	57–90	7–24
Clear glass, satin finish:	0.075	85–89	6–8
Alabaster glass	0.125–0.19	60–70	20–30
Flashed opal glass	0.08 –0.13	27–66	31–67
Composition, white diffusing	0.010–0.025	0–41	32–75
Solid opal glass	0.06 –0.14	12–51	40–78

CANDLEPOWER DISTRIBUTION CURVES. The performance of any light source as to candles emitted in different directions is shown in a candle power "distribution curve." On this curve each point is determined by the length of the radius in the appropriate direction, as in Fig. 3. Most light sources, though varying greatly as to distribution in a vertical plane, through the axis, are practically constant as to distribution in horizontal planes at right angles to the axis. The principal exceptions are asymmetric refractors, designed for street lighting (Art. 9). In such cases the distribution may be more or less completely defined by the curves for several vertical planes. Another method of representation useful for asymmetric light sources (Benford, *Gen. Elec. Rev.*, 1925, p. 271; *Trans. I.E.S.*, 1926, p. 129) uses the curve sheet shown in Fig. 4. Isocandle curves for the light source are drawn upon this sheet, and thus the performance of the source can be easily seen. In this curve sheet the vertical space per degree is constant and is equal to the horizontal space at the equator. The horizontal spaces in any zone are proportional to sin θ, where θ is the midzone vertical angle; sin θ measures the relative area of this zone on a sphere. This set of isocandle curves, besides giving the graphical presentation of the candlepower distribution of the light source, is useful for the determination of light flux.

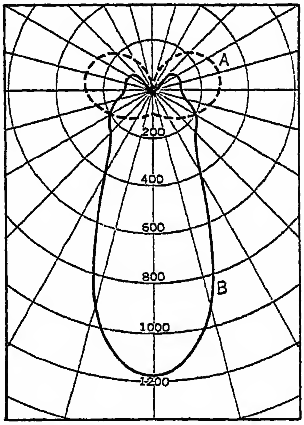

FIG. 3. Distribution Curve

CALCULATION OF LIGHT FLUX AND MEAN INTENSITIES FROM POINT SOURCES. Because of the variation of solid angle (and subtended area) of zones, which have equal vertical angles, the area of the vertical distribution curve is not a measure of the total flux. This is shown in Fig. 3, which represents the distribution curve for a bare incandescent lamp, A, and for the same lamp with a concentrating prismatic reflector, B. Curve A, of course, shows a greater flux than curve B. Various methods of calculation of flux from the vertical distribution curve have been used, of which two will be given. The fact that light flux is usually measured by the spherical photometer (see Sec. 5, Art. 21), rather than calculated, decreases the importances of such methods.

Let I_θ be the mean intensity of a light source at an angle θ from the equatorial plane at right angles to the axis. The flux within an elementary zone at this angle of inclination is then

$$dF = I_\theta \, d\omega = 2\pi I_\theta \cos\theta \, d\theta; \quad F = \sum_{-\pi/2}^{+\pi/2} 2\pi \cos\theta \times I_\theta \, \Delta\theta$$

If the 180 deg from $-\pi/2$ to $+\pi/2$ be divided into n equal angles, then $\Delta\theta = \pi/n$, and F' for one zone $= \left(\dfrac{2\pi^2 \cos\theta}{n}\right) I_\theta$, and the total flux is the sum of these zone-fluxes

corresponding to the n midzone values of I_θ. These values of I_θ are read from the distribution curve for the light source. For 18 zones of 10 deg each the constant by which each value of I_θ must be multiplied is given in Table III.

Table III. Constants for Flux Calculation

Midzone Angle from Equator—θ	$\frac{2\pi^2}{n}\cos\theta$ K_θ	Midzone Angle Measured from the Perpendicular	
5	1.091	85	95
15	1.058	75	105
25	0.992	65	115
35	0.897	55	125
45	0.774	45	135
55	0.628	35	145
65	0.463	25	155
75	0.283	15	165
85	0.095	5	175

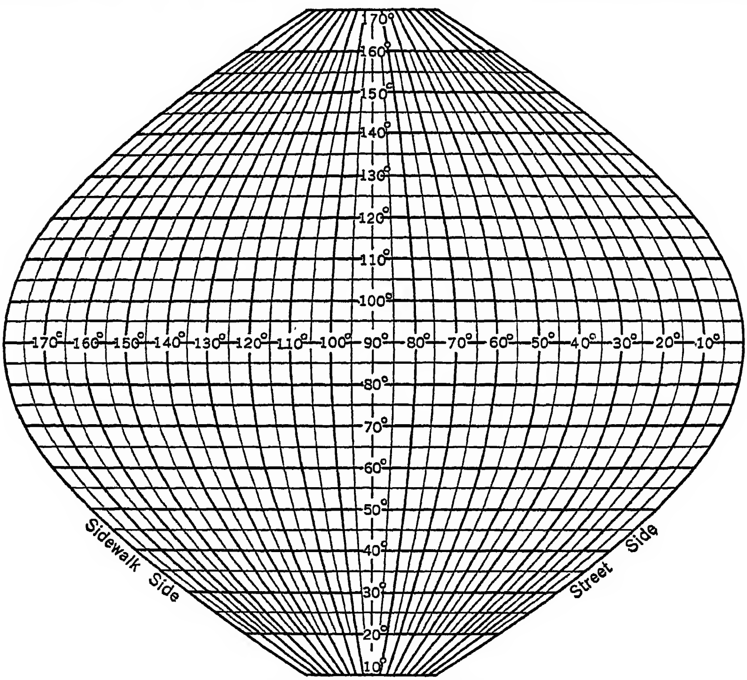

FIG. 4. Benford Isocandle Web

The total flux is the sum of the products of $K_\theta \times I_\theta$ for the eighteen 10-deg zones. A larger number of zones would give more exact values of flux. The flux for the lower hemisphere, or for any zone, as for instance for 20 deg below the horizontal, may be easily determined by this method. (Kennelly, *Elec. World,* 1908, p. 645; Caldwell, Modern Lighting, p. 92.)

PROTRACTOR METHOD. This method is adapted to quick approximations of flux output. The method assumes a sphere of light distribution divided into zones of equal solid angular content, i.e., of equal altitude. A direct average of the mean candlepower of the several zones gives the general mean for all the zones included, since each component zone bears equal weight. For convenience it may be assumed generally that the mean candlepower in any zone agrees closely with that at the angle which bisects the area of the zone. Fig. 5 shows a convenient subdivision of the sphere based on this assump-

tion. To obtain the mean spherical candlepower, the intensities at all the angles indicated by radial lines are averaged. This result multiplied by 12.6 gives the total flux from the source. For convenience in practice a transparent protractor may be prepared with the reference angles marked by lines. This protractor may be placed over the polar distribution curve and the values for averaging read off directly.

For asymmetrical light sources, as street lighting refractors, the Benford isocandle curves (Fig. 4) are useful, since in these curves the areas of isocandle bands are actually proportional to the flux. If a uniform source of I candles were placed within the sphere represented by the Benford web, I candles would be recorded at all points and the flux would be $12.6\,I$. An area of 10 deg × 10 deg at the equator is 0.00243 of the total area of the sphere, and I candles will give, for this equatorial 10-deg square area, $0.00243 \times 12.6\,I$, or $0.0305\,I$ lumens. This figure, 0.0305, then becomes the constant by which the candle value for each 10-deg square at the equator must be multiplied to convert candles into lumens. At any other vertical angle $-\theta$, measured from the nadir, the area of a 10-deg square is proportional to $\sin\theta$, and the lumens become $0.0305 \sin\theta\, I_\theta$.

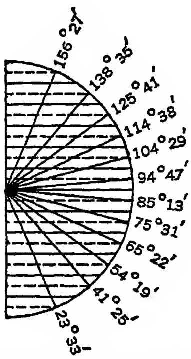

FIG. 5. Equal Area Zones for Flux Calculation

To obtain the total flux, therefore, the number of 10-deg squares covered by an isocandle band in the zone with mid-angle θ will be multiplied by $0.0305 \sin\theta$; the same operation will be performed for each other candle value in the θ-deg zone, the boundaries of the bands being lines midway between the isocandle lines. This operation will be repeated for all other isocandle bands in each of the other zones. The sum of all such products will be the total flux. For any angular area h degrees wide by v degrees high, with a mean angle of elevation θ, the lumens equal $0.000305\, hv\, I_\theta \sin\theta$. To obtain the flux falling upon any rectangular area, great circles which cut the boundaries of the area being studied will be drawn on the web, and the flux within the area on the web so delineated will be determined. (Benford, *Trans. I.E.S.*, 1926, Vol. 21, p. 129.)

MEASUREMENT OF ILLUMINATION. From the point of view of the user of illumination, the measurement of existing installations is of great importance. Instruments and methods are described in Sec. 5, Art. 21, under Photometry. The Weston photronic illumination meter (Goodwin, *Trans. I.E.S.*, 1932, Vol. 27, p. 828) and the foot-candle meter are calibrated directly in foot-candles. The former requires only the reading of a pointer on a calibrated scale and calls for little expert skill on the part of the observer. This instrument is made in a variety of forms, suited to the use of non-technical persons, and is largely superseding the foot-candle meter which does call for some skill and experience in order to obtain satisfactory results. These instruments in the forms known as *sightmeters* and *lightmeters*, are inexpensive and should be in the hands of persons who are responsible for the design or maintenance of lighting. The Macbeth and similar instruments, which depend upon the inverse-square law, require considerable photometric skill.

2. LIGHT SOURCES

Although flames were the only lamps for many thousand years, and are even now perhaps the most numerous, space permits the consideration here of only present-day electric light.

Incandescent Lamps

SOLID FILAMENT TYPE. The temperature to which an electrically heated conductor, as a lamp filament, rises, is such that the heat dissipated is equal to I^2R. When the vaporization temperature of a solid substance is approached, disintegration becomes rapid, which limits the permissible operating temperature of a lamp. Based on these facts, and the laws of the electric circuit (see Sec. 3), the following general statements with regard to incandescent lamps may be made.

(*a*) The higher the lamp voltage, the less the current and the thinner the filament (watts constant); the resistance must vary as the square of the voltage. Hence the limit of practicable voltage, in the United States generally to about 115 (250 volts is common in Europe), also higher permissible temperatures, and hence higher efficiencies for low-voltage lamps. (*b*) To obtain high efficiency a lamp is operated near to its vaporization temperature; thus a small increase in voltage greatly shortens the lamp life through disintegration

of the filament. (See Table IV.) (c) With increase in voltage, and thus of temperature, the watts-input increases, but not so rapidly as the lumen-output, and hence the efficiency increases. The effect of voltage variation on life, watts, lumens, and lumens-per-watt for tungsten lamps is shown in Fig. 8. These data are all based upon rated voltage as 100 per cent and hold for only a limited range of voltage.

SELECTIVE LUMINOUS RADIATION. Bodies which radiate owing to temperature are either selective or non-selective (the latter also called **black bodies**; see Sec. 2, Art. 21). As the result of a selectivity, which causes a relative increase in the visible radiation, the efficiency of some filament substances is considerably increased. This raises the efficiency of a tungsten lamp about 25 to 30 per cent. (E. P. Hyde, Lectures on Illuminating Engineering, p. 57.) Carbon, on the other hand, is practically non-selective. The ratio of visible to invisible radiation, and hence the luminous efficiency, increases rapidly with temperature as seen in Figs. 15 and 16.

FILAMENT MATERIAL. A material for lamp filaments should have, in large measure, the following characteristics: (a) Highest practicable vaporization temperature. (b) Melting temperature high enough to prevent softening and deformation of filament. Example: though carbon has a higher melting temperature than tungsten, its vaporization temperature is lower. (c) Favorable selectivity. (d) High mechanical strength, which is not seriously affected by temperatures experienced during the operation of the lamp. (e) High resistivity to give thicker filaments. (f) A high positive temperature coefficient to counteract voltage variation. (g) Ductility, to permit formation into a suitable filament. (h) Moderate cost. Carbon and tungsten alone, up to the present time, have been extensively used for filaments. Tantalum was the first metal used, but was soon superseded.

BLACKENING OF THE BULBS. The particles of filament material which are thrown off from the filament by the disintegration at high temperature are largely deposited on the bulb. This results in a progressively increasing absorption of light, and is a considerable factor in the loss of lumen-output of the lamp during its life. In large lamps, where blackening is particularly serious, granulated metal is enclosed in the bulb. By sliding this around the blackening is largely removed.

CARBON-FILAMENT LAMP. This was the first and for over 20 years the only incandescent lamp. Carbon melts at about 4300 deg K, but vaporizes at about 3800 deg K. These lamps are made only in small sizes and give about 3.3 lumens per watt. This efficiency is so low that their use, except for special purposes, cannot be economically justified.

TUNGSTEN, ITS PROPERTIES. This metal is obtained from a tungstate of iron and manganese called wolframite, a tungstate of calcium called scheelite, and certain other ores. Its properties are much affected by previous treatment. Melting point 3380 deg cent; boiling point 5560 deg cent. A very heavy metal with an atomic weight of 184 and a specific gravity of 19 (gold 19, lead 11). Tensile strength very high, $^1/_2$ lb per sq mil, about 10 per cent higher for very fine wire (high-grade steel, $^1/_4$ lb). Resistivity, ohms per mil-foot at 25 deg cent, hard-drawn 37, soft-drawn 31. Temperature coefficient 0.0045 per degree at 20 deg cent, 0.0057 at 500 deg, 0.0089 at 1000 deg (Somerville). Ratio of resistance at operating temperature to cold resistance for vacuum-type lamps, 12 to 14; for gas-filled lamps, 15 to 17. Ductile tungsten suitable for drawing into a wire is made by sintering powdered metal into a bar in an electrically heated and hydrogen-filled furnace. Because of its great hardness the tungsten wire is drawn through dies made from diamonds.

TUNGSTEN FILAMENT LAMPS. These are either of the vacuum type or are filled with a mixture of approximately 86 per cent argon and 14 per cent nitrogen. The nitrogen is added to increase dielectric strength. Argon is characterized by low heat conductivity and a high degree of inertness. It is a rare gas found in the earth's atmosphere. The gas is used at about atmospheric pressure. By reason of this gas pressure of about 15 lb per sq in. on the filament, vaporization of the tungsten is decreased, so that the operating temperature may be higher and the efficiency increased. See Table IV.

Another important function of the gas is the carrying, by convection currents, of the vaporized tungsten to the top of the bulb, where it is least effective in reducing the useful light. The larger sizes of gas-filled lamps have an elongated bulb, the upper portion of which serves as a cooling chamber. The walls of this chamber receive the black deposit from the filament. The larger sizes of gas-filled lamps are standard for operation in a pendent position (within 45 deg) only.

The presence of gas in the lamp bulb also promotes heat convection. This effect decreases with increased diameter of filament. This leads to higher efficiency in three classes of lamps: large lamps of the 115-volt type, low-voltage constant-potential lamps, and constant-current street lamps, which also operate at low voltage. See Table V. If a

filament is coiled into a spiral whose diameter is several times that of the wire, it acts, from the point of view of convection, like a wire of the diameter of the spiral. Most lamps now use spiral filaments. Concentration of the light-giving area, which is essential for projection lamps, and for other applications where definite modification of the light distribution

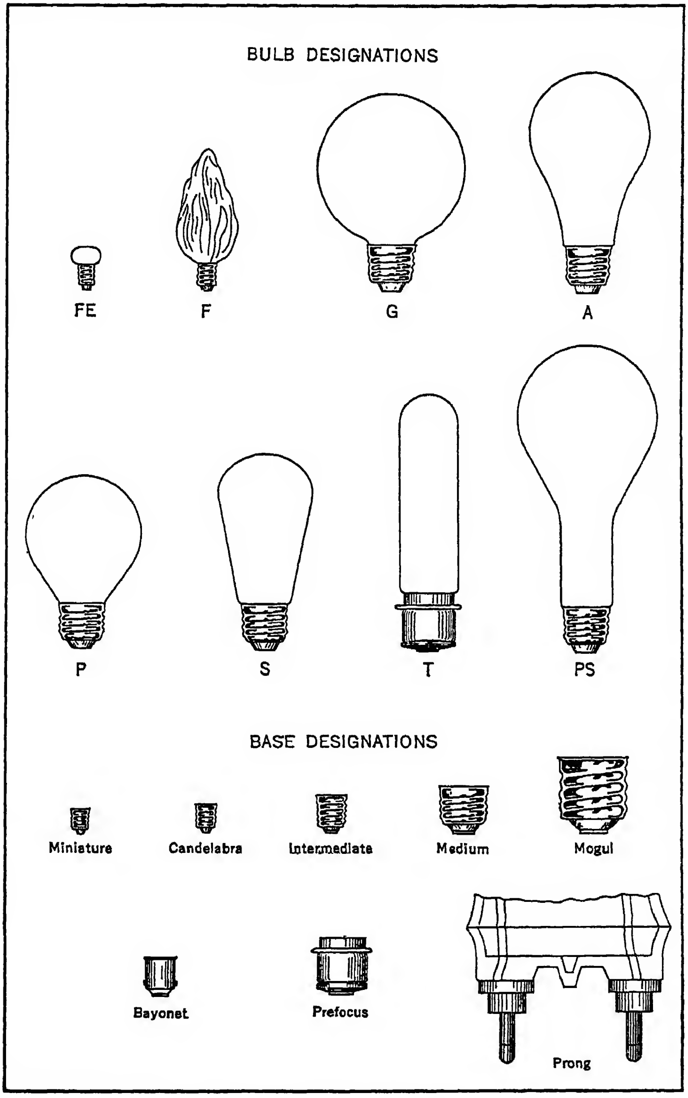

Fig. 6. Standard Types of Bulbs and Bases

by prisms or lenses is involved, is promoted by coiling the filament. Also, breakage due to blows is decreased by the spiral spring effect produced. The tensile strength of tungsten is high before use, but it is greatly reduced after long operation, so that the filament is easily broken.

BULBS, BASES, AND FILAMENTS. The more common forms of bulbs and bases are illustrated in Fig. 6. In the bulb designation, such as S–19, the letter indicates the type of bulb, and the number the diameter of the bulb in eighths of an inch. " S " indicates a " straight-side " or conical-sided bulb; " G," a round or globular bulb; " T," a tubular bulb; and "PS," a pear-shaped bulb. In the " A " bulb, the " inside frost " is also implied. The inside-frosted bulb is standard for all general-service lamps from 15 to 100 watts, and for many special lamps. It greatly reduces the brightness of the lamp, while absorbing less than 2 per cent of the light. The smooth outside surface is a great advantage over outside frosting, for which the loss of light is much greater.

The PS-shape is the one most commonly used for general-service lighting. This covers wattages from 150 to 1500. The G-bulb is much used for special service lamps such as floodlighting, spotlighting, etc. The T-bulb is made in lengths from 5 1/2 to 34 in. for standard bases and 17 7/8 in. for the 30- and 60-watt lamps in T8 bulbs based at both ends. Filament dimensions are shown in Fig. 7.

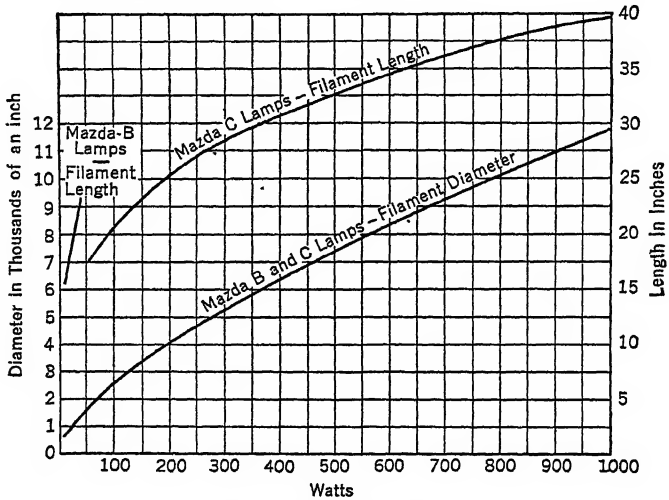

FIG. 7. Filament Dimensions

PREFOCUSED AND BIPOST BASES. When, for projection, it is important to have the space relation of the filament to the lamp base especially exact, the bulb, with its base and filament mounting, may be finally adjusted and soldered to the screw base with the filament lighted and its image projected upon a screen. When the image of the filament is on the screen cross-lines, the attachment to the screw base is made. For large lamps a loose threaded sleeve is used. For automobile headlamps a collar is used, which surrounds the base and has three small bosses. These are designed to set on the reflector-surface, when the bulb is inserted in the headlamp, and thus bring the filament to focus.

In the larger sizes of lamps, also used for projection, the same end is accomplished by using the bipost base. This is a prong base in which the prongs and filament-supports (see Fig. 6) form one rigid structure with, therefore, a definite space relation between prongs and filament. A glass cup is molded around the bipost structure and the bulb is sealed to this cup.

LUMEN OUTPUT, EFFICIENCY, AND LIFE WITH VOLTAGE VARIATION. The high rate of change of light intensity and of filament-life, with temperature, causes incandescent lamps to be extremely sensitive to variations in voltage. The positive temperature coefficient of resistance of the tungsten filament affords a partial compensation to voltage variations and increases the stability of the lamp's performance. The relations of voltage to lumen output, watts, lumens per watt, and life are shown, for modern types of lamps, in Fig. 8. High voltage increases the lumen output and efficiency, but greatly reduces the life of the lamp. Operating conditions are always a compromise between life and efficiency. Under ordinary conditions, circuit voltage and rated lamp voltage should agree closely. The lowering of the luminous flux with reduced voltage is

marked. Satisfactory service requires that the voltage be maintained within 3 per cent, at most, of the rated value for the lamp.

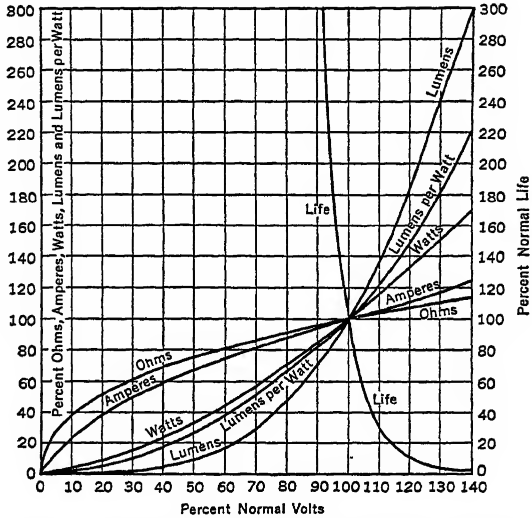

FIG. 8. Properties of Mazda Lamps as Functions of Voltage

The relations between lamp performance and voltage may be completely expressed by a series of simple proportions and exponents given in Table IV. These exponents hold accurately only for a small deviation from normal voltage. The variations of these values, together with those of amperes and ohms, are shown in Fig. 6.

The changes in efficiencies with lamp size, for 115-volt Mazda B and Mazda C lamps, are shown as curves in Fig. 9.

The data for the curves of Fig. 8 may also be expressed as follows: 1 per cent change in volts produces approximately the following changes: ohms, 0.4 per cent; amperes, 0.5 per cent; watts, 1.5 per cent; lumens, 3.5 per cent; efficiency, 1.8 per cent; life, 13 per cent; these figures apply only to the straight portion of the curves, near 100 per cent normal volts. The life characteristics of vacuum and gas-filled lamps, Mazda B and C, are shown in Fig. 10.

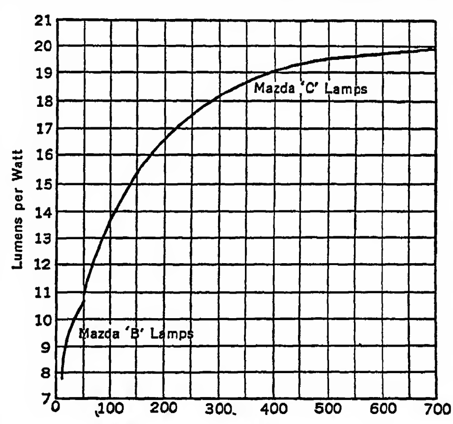

FIG. 9. Efficiency and Lamp Size

Table IV.* Effects of Voltage Increase

Effects of increase in voltage, $V_1/V_2 = R$, upon increase in lumen-output, L; watts, P; lumens per watt, K; and decrease in hours of life, H.

Filament Material	Effects Due to Voltage Change in Ratio $R = V_1/V_2$

Carbon	$R^{5.62}$	$R^{1.96}$	$R^{3.66}$	$1/R^{20.5}$
Mazda B	$R^{3.51}$	$R^{1.58}$	$R^{1.93}$	$1/R^{13.5}$
Mazda C	$R^{3.38}$	$R^{1.54}$	$R^{1.84}$	$1/R^{13.1}$

* General Electric Co. Bul. LD 4.

LAMP RATING AND PERFORMANCE. As all but a small fraction of the lamps made in this country are manufactured under license from the General Electric Co., their published data are given, with acknowledgment, as representative of American practice.

The lamp manufacturers' schedules of standard large lamps show approximately 140 different types of lamp for use on constant-potential circuits. These differ in rated watts and volts, also in shape, color, and other characteristics of the bulbs and bases. In addi-

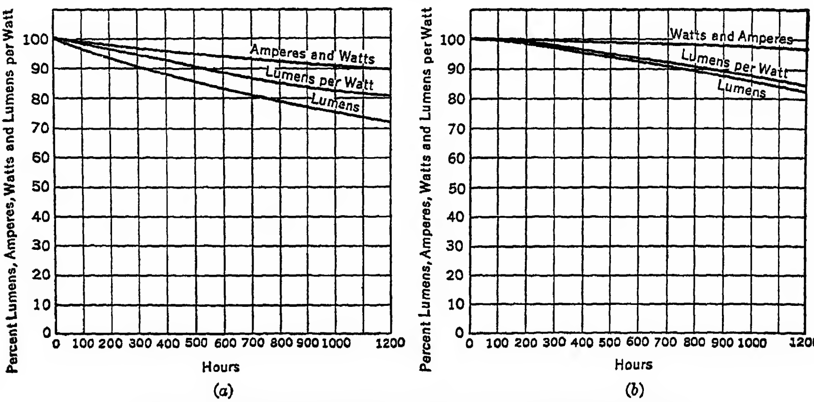

FIG. 10. Life Characteristics of Vacuum (*a*) and Gas-filled Lamps (*b*)

tion to general-purpose lamps, these include lamps for many specialized uses—airway beacons, locomotive and other headlights, floodlights, indicators, locomotive cabs, projection, traffic signals, street-railway cars, spotlights, etc. The differences between these do not include small differences in voltage (110, 115, 120 volts). There are also approximately 40 miniature lamps (Table IX) and 9 constant-current street-lighting lamps. Many lamps are covered in federal specifications WL–101.

Constant-potential lamps are rated in watts, and for the voltage at which they are designed to give a life of 1000 hours and presumably operate most economically. The

Table V. Standard Large 115-volt Mazda Lamps for General Service

1935 data

Watts	Mazda B or Mazda C	Rated Initial Lumens	Rated Initial Lumens per Watt	Mean Lumens Per Cent of Average Initial Lumens

6	B	37	6.1	..
10	B	74	7.4	..
15	B	138	9.2	88
25	B	252	10.1	86
40	C	428	10.7	91
60	C	750	12.5	93
100	C	1,510	15.1	91
150	C	2,400	16.0	91
200	C	3,400	17.0	89
300	C	5,490	18.3	88
500	C	9,800	19.6	88
750	C	14,550	19.4	88
1000	C	20,700	20.5	87

Where, from 150 to 500 watts, both inside-frosted and clear PS bulbs are available, the light data are the same. All the above data are based on 1000-hour life except for the 6- and 10-watts lamps (for decoration, indicators, and sign use) which have 1500-hour life, and the 3-watt "all nite" lamps for which the life is not established. This lamp has the standard prongs of an attachment plug. Three-light, 115-volt lamps have two filaments and three terminals. Either filament or both may be used at once, thus giving a choice of three degrees of illuminaton. The life of these lamps is 1000 hours, and the efficiency of each filament is the same as in the corresponding single-filament lamps. This lamp is available in three sizes: for general lighting, base-up operation, 50–100-watt, 150–200-watt, and 200–300-watt; and for indirect lighting, base down, 100–200-watt.

standard voltages are 110, 115, and 120 volts, and lamps of these three voltages are rated as in the 115-volt class. Similarly the 230-volt class includes lamps of 220, 230, 240, and 250. The lumen-output, given by each size of lamp, is specified in the lamp schedules and determines the performance of the lamp. Efficiency in lumens per watt is also given. A nominal candlepower rating for street series or constant-current lamps was formerly used on the basis of 1 candlepower per 10 lumens output but is now discarded. The standard manufacturing tolerance is ± 5 per cent on watts and ± 7 per cent on lumens per watt. (Lieb, *Trans. I.E.S.*, Vol. 25, 1930, p. 639.) Data on several most-used types of Mazda lamps are given in Tables V to IX.

15,000	20	37.9	757.6	19.8	88
25,000	20	60.7	1213.6	20.6	84

The good maintenance of lumen-output in series lamps is due to the fact that, with constant current, the heat, I^2R, increases as the resistance increases, with the decrease of filament area. During the first half of the rated life, the lumen-output increases about 2 per cent, after which it again falls to about the initial value at its rated life. Characteristic curves for these lamps are shown in Fig. 12.

Type D lamps are not given the name "Mazda." Their rated life is 500 hours, and the cost is about two-thirds that of the Mazda lamps of the same size. Data for the four sizes now (1936) being sold are given in Table VIII.

Table VIII. Type D Large Lamps

* Inside frosted or outside colored.

LAMPS FOR PROJECTION. These are made in sizes from 50 to 1000 watts. They are all in cylindrical bulbs (T8 to T20). The life ranges from 25 to 50 hours. The efficiencies range from 16 to 28 rated initial lumens per watt. The filament is specially designed to give a concentrated light source. The sections of the filament are arranged in one plane (monoplane), or two planes (biplane), so that the combined effects is that of a luminous square. In the biplane grouping there is a staggered arrangement so that the sections of filament in the rear plane are seen through the spaces between those in the front plane. Special glass of high melting point is used with the larger lamps, and forced ventilation is essential when they are enclosed, as for instance, in projection lanterns.

PHOTOFLOOD LAMPS. These are lamps so overrated as to voltage that, when operated on a 115-volt circuit, they give a very white light, equivalent in its actinic effect to lamps of much higher wattage operated at normal voltage. In consequence the rated life is much shortened. As the periods of operation need be measured in seconds only, this short life is not a serious defect. Two sizes of the photoflood lamp are available: a 250-watt lamp in an A21 bulb giving 9000 lumens and having a life of 2 hours, and a 1000-watt lamp in a PS35 bulb giving 35,000 lumens and with a 10-hour life. Both lamps operate with an efficiency of about 35 lumens per watt. The 120-watt lamp has the actinic value of a standard 750-watt lamp at normal efficiency. While arranging the picture a standard lamp of large size may be substituted for the photoflood lamp.

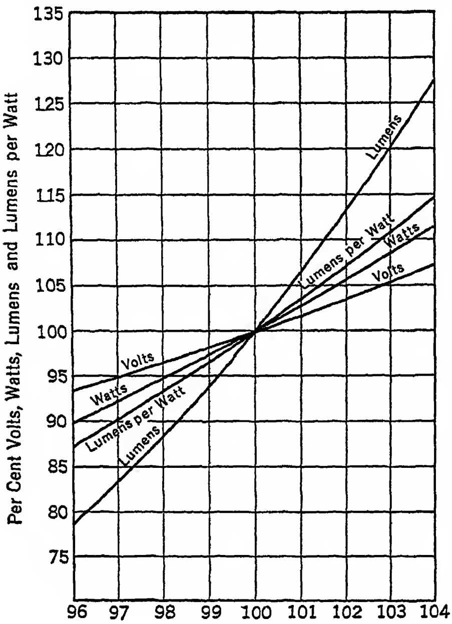

Fig. 11. Characteristics of Series Lamps

MINIATURE LAMPS. In 1929 more than 278 million miniature lamps were sold. Of these 49.8 per cent were used for automobiles, 18.4 per cent for flashlights, 25.4 per cent for Christmas-tree decorations, and the remaining 6.4 per cent for miscellaneous uses, including physical and dental service, signals, indicators, miners' caps, and many others. Except for Christmas-tree decorations, which are usually operated in series groups on 115-volt circuits, the current for these lamps is usually supplied from storage or dry-cell batteries, so that the voltage is very variable, especially with dry cells. Since in the smallest flash-

light unit the periods of use are very short, and for compactness high efficiency is needed, the lamps are designed for only about 3 hours of life. At the other extreme are some radio panel signal lights, where efficiency is of no importance, and where a life of 3000 hours is provided. The schedule of lamps given in Table IX covers more than 90 per cent of the consumption of miniature lamps.

Photoflash Lamps

In an oxygen-filled bulb (A19 or A23) is a small low-voltage filament adjacent to a large crumpled piece of thin aluminum foil. When voltage is applied to the lamp terminals, the filament is momentarily raised to a high temperature and burns out, but in doing so it ignites the aluminum foil which is consumed in about $1/_{50}$ second, with a flash of light equal in intensity, for the largest size, to that of five hundred 1000-watt lamps. This lamps replaces magnesium flashpowder. It will operate on any emf from 2.5 volts up. It is made in 3 sizes, Nos. 10, 20, and 75.

Lamps for the Production of Infra-red and Ultra-violet Radiation

Lamps commonly used in equipment for infra-red medical treatment are large lamps, usually with a carbon filament, underrated as to voltage. These lamps thus have a relatively large proportion of infra-red radiation. They probably offer no advantages, however, over the use of ordinary standard large lamps. (Porter and Ditchman, *Trans. I.E.S.*, 1933, Vol. 28, p. 465.)

Among the light sources designed to give ulta-violet radiation, only one type is distinctly an incandescent lamp. (See also Gaseous Conductor Light Sources.) The Mazda CX lamps are standard 60-, 250-, and 500-watt lamps, except that the bulb is made of a special ultra-violet-transmitting glass, which passes a high percentage of the small volume of ultra-violet produced by filaments operated at a temperature giving a 500-hour life. (*Trans. I.E.S.*, 1932, Vol. 27, p. 28.)

Temperature of Filament and Lamp

The lamp filament, like any other body, will operate at such a temperature that the heat dissipated is equal to the heat produced. The heat produced is definitely determined by the watts consumed. In the small vacuum-type lamp, the heat is nearly all radiated from the filament, though the absorption of the heat by the glass bulb results in convection currents in the air, which carry off the heat from the surface of the lamp. In the gas-filled lamps, convection currents within the lamp itself play an important part in dissipating the heat from the filament. Also, in the larger Mazda C lamps, and in the low-voltage lamps, the heat conducted away by the lead-in wire is a considerable factor.

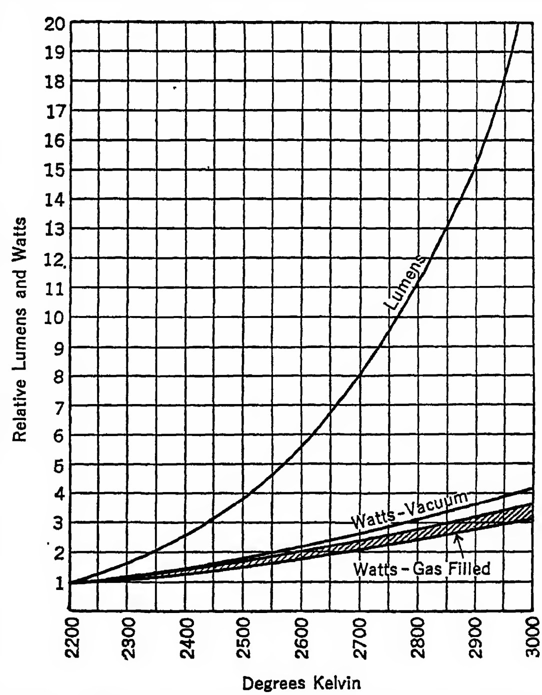

FIG. 12. Relation of Lumens and Watts to Filament Temperature

Filament temperatures range, for Mazda B lamps, between approximately 2400 and 2570 deg K. The temperatures (K) corresponding to any given efficiency for a B lamp (coiled filament) may be obtained from the following equation: $T = 2075 + 47\ l$, where l

is the lumens per watt. The temperature of Mazda C lamps varies from approximately 2680 to 3250 deg K, the latter temperature corresponding to an efficiency of 28 lumens per watt, in the 3- to 10-kw lamps with a 100-hour life. The photoflood lamp has a temperature of 3490 deg at an efficiency of 35 lumens per watt. The temperature for Mazda C lamps is given by the following equation: $T = 2320 + 33.3\,l$. The relation of lumens and watts to filament temperature is shown in Fig. 12.

The temperature of the surface of small lamps is so low as not to be a source of trouble, unless the lamp is in contact with inflammable material; but the temperature of the outside of the bulb of the larger lamps rises to a considerable figure. Examples of maximum temperatures found on the bulbs of the larger lamps when operated in the open air are given in Table X. This maximum temperature is generally found slightly above the level of the filament.

Optimum Lamp Life and Cost of Light

By changing resistance and thus designing the lamp to operate at higher or lower temperature, the maker may select any reciprocal relation of life and efficiency desired. If a low temperature is selected, the life will be long, but the efficiency will be so low that the large amount of energy taken will make the cost per lumen-hour excessive. On the other hand, if a high temperature is used, high efficiency will keep down the cost of energy, but the resulting short life of the lamp will again raise the unit cost of light.

Although varying conditions of operating would suggest a large variety of lamp ratings, it is fortunate that over a considerable range of temperature the combined expense of energy and lamp renewal is so nearly constant as to make two standard temperatures giving standard lives of 1000 and 500 hours respectively satisfactory for all ordinary service. It is only for specialized uses that other temperatures are used.

Let L = the average lumen-output during the given life; C = the average cost (cents) per hour for the power used; c = the cost of the lamp; t = the number of hours operated. Then the total cost per lumen-hour, $K, = (Ct + c)/Lt$. By calculating this cost for several assumed life-periods for a given lamp, the life to give minimum cost per lumen-hour may be determined. The same formula may be used to determine the optimum efficiency to be used, or to compare the cost per lumen-hour of different types of light source. Calculations made in this way indicate, for normal conditions, life of less than 1000 hours, but the matter of inconveneince due to replacement and the psychological objection to short life must be considered.

Table X. Bulb Temperature of Mazda Lamps

Size of Mazda C Lamps, watts	Maximum Bulb Temperature, deg fahr	Size of Mazda C Lamps, watts	Maximum Bulb Temperature, deg fahr
50	257	300	297
100	275	500	379
150	338	750	310
200	330	1000	371

The rated life given as 1000 hours, 500 hours, etc., must be taken as the average life of a considerable number of lamps when operated at the rated voltages. Thus Fig. 13 is given by the makers as a typical burn-out curve for Mazda lamps. It will be noticed that although a few lamps burned out in less than 500 hours, and a few lasted nearly 2000 hours, the great majority held rather closely to the rated life of 1000 hours.

Arc Light Sources

(See Sec. 3, Art. 25, for the theory of the electric arc.) Here will be considered only those light sources in which the current passes through the atmosphere between two solid electrodes. (See also Gaseous Conductor Light Sources.) The positive and negative electrodes are termed respectively anode and cathode. The active conducting medium of the arc is supplied by the electrovaporization of the cathode. With the exception of the carbon arc, it takes a higher, and generally a much higher, voltage to maintain an arc with alternating than with direct current.

VOLTAGE DROP ACROSS AN ARC. The voltage drop across an arc comprises three elements: (1) a sensibly constant drop at the anode, (2) a similar but much smaller drop at the cathode, and (3) a variable drop in the arc stream. The electrode drops in air depend only on the nature of the electrodes. The drop in the arc stream varies with the current according to Ohm's law, but the relation is greatly complicated by the changes in the resistance of the arc stream. Steinmetz (Radiation, Light and Illumination, p.

139) proposes the following general expression for plain carbon arc conduction in air: $E = \{36 + 130\,(l + 0.33)\}/\sqrt{I}$, where E is the total voltage, 36 the electrode drop, l the arc length in inches, and I the current.

STEADYING RESISTANCE. An arc on a constant potential circuit must be compensated by a considerable ballast of stable series resistance or reactance. (See Pender's Handbook, 1922 Ed., p. 50.)

POWER FACTOR. Owing to the distortion of the current wave by the varying resistance of the arc, the a-c solid carbon arc has a power factor of about 85 per cent, although the current and voltage pass through their zero values simultaneously; with some flame arcs the power factor may be nearly 90. (See Sec. 3, Art. 4.) Reactive ballast coils when used in constant-potential solid electrode lamps reduce the overall power factor to values between 60 and 75 per cent.

SOURCES OF LUMINOSITY. There are three distinct modes of light production by electric arcs, viz.: (1) by incandescence of the electrodes, due to their high temperature; (2) by the luminescence, in the arc, of salts derived from mineralized carbon electrodes; and (3) by the luminescence, in the arc, of the conducting vapors from the cathode. The first is exemplified by the plain carbon arc. This arc was the first form of electric light, but is no longer used for general lighting. It is, however, still used to some extent for small projectors. With mineralized electrodes, arc lamps are used for large projection equipment, photography, and the supplying of ultra-violet radiation. The color of the light and its efficiency depend on the nature of the luminescent salts and the temperature attained by the arc. The third type of light production is exemplified by the magnetite or luminous arc.

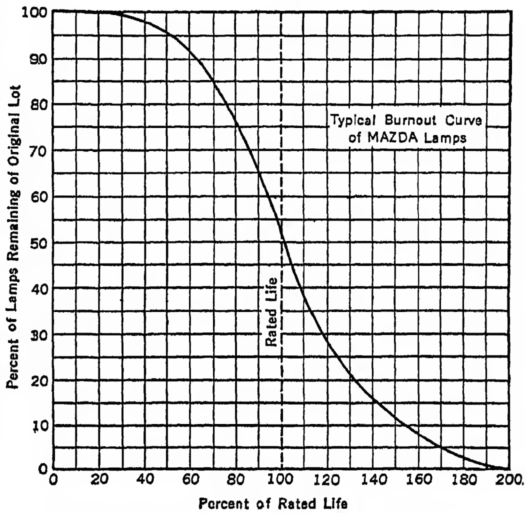

FIG. 13. Typical Burnout Curve of Mazda Lamp

THE CARBON ARC. (See, also, National Projector Carbons, the National Carbon Co., Cleveland, Ohio.) This arc was originally used with two solid carbon electrodes. When on direct current, the upper electrode is used as the positive, or anode; owing to the peculiar action of the arc, its tip becomes hollowed out into a crater and attains a very high temperature. The lower, negative electrode becomes pointed and, while white hot, is still far below the temperature of the positive. To reduce the tendency of the arc to move from point to point on the positive electrode, a core of soft carbon, impregnated with the arc-supporting salts of the alkali metals, is provided in the positive electrode. Also, the diameter of the negative electrode is reduced, thus further steadying the arc. To make up for the reduced carrying capacity of the smaller electrode, a copper coating is provided. A core is also sometimes used in the negative electrode. For currents from 25 to 140 amp, National positive carbon diameters run from $^5/_8$ to $1^1/_8$ in. and negative from $^5/_{16}$ to $^1/_2$ in. Their lengths are 12 and 6 in., respectively. When used on alternating current, the plain carbon arc with unimpregnated electrodes loses the advantage of the high temperature in the positive crater and gives only about half as much light from it as on direct current. To rectify this, for light-projection work, where alternating current must be used, electrodes with cores impregnated with rare earth salts are used. When focused on the positive electrode, and with the white light of the arc which results from the impregnating salts, a good projection light is obtained. For a-c arcs the National carbons range from $^1/_2$- to $^7/_8$-in. diameter for both upper and lower, corresponding to currents of 25 to 100 amp. Reflector lamps use 9- to 14-mm positive carbons and 6.4 to 10 mm negatives. The corresponding currents range from 10 to 35 amp. An improved type of carbon electrode, National SRA, made in 12- and

13-mm sizes, increases the practicable positive carbon current density from between 120 and 165 amp per sq in. to 205. Two types of low-voltage high current intensity a-c arcs, using 6-, 7-, and 8-mm carbons, for 40 to 45, 60 to 65, and 75 to 80 amp, respectively, have recently been developed. These electrodes have a current density of 800 to 1090 amp per sq in., and are metal coated. (Joy and Downes, *Soc. Motion Picture Engrs.*, Vol. 21, 1933, p. 116.) The operation of this a-c lamp with a specially designed constant-current transformer results in high efficiency. High-intensity arcs for direct current, which use cerium fluoride in the positive cores, were first made for searchlights. This type of positive electrode is continually rotated by a motor. These are designed for from 75 to 160 amp. They are also used for condenser-type projection equipment in large theaters; also, taking from 60 to 85 amp, in reflector-type projectors. In a recent further development the positive carbon is non-rotating, and with 6- and 7-mm positive carbons 32 to 65 amp are used. In the 9- to 16-mm rotating carbon type as used for large searchlights and projectors, the candlepower per square millimeter is 400 to 800. The action of these high-intensity arcs depends upon the formation in the positive crater of cerium carbon particles which are heated to a temperature of about 5000 deg cent. (Joy and Downes, *Soc. Motion Picture Engrs.*, 1934, Vol. 22, No. 1, p. 42; T. R. Bassett, *Trans. I.E.S.*, 1932, Vol. 27, p. 623.)

ARC LIGHT SOURCES FOR THE PRODUCTION OF ULTRA-VIOLET RADIATION. (Coblentz, *Trans. I.E.S.*, 1928, Vol. 23, p. 223; Greider and Downes, *ibid.*, p. 637.) See Pender and McIlwain for ultra-violet radiation and its application. The neutral or unimpregnated arc has so little ultra-violet radiation at moderate current values as to be of much less value for therapeutic purposes and similar applications than the later types of arcs. The use of different impregnating materials in the cores of the carbons offers unlimited possibilities as to the type of radiation produced. Cerium and other rare earth salts give a white flame similar to that used for the high-intensity projection arc, but for ultra-violet radiation, are not operated at such high intensity. A core impregnated with metallic salts, including iron, gives about the same radiation just below the visible spectrum with several times as much below about 0.3 micron. Differing types of lamps are built for industrial radiation, individual therapeutic, and solarium therapeutic uses. For the last purpose, lamps taking 60 amp and 50 volts at the arc, or 20.5 amp on a 230-volt circuit, and 3100 line watts input, may be grouped either 2 or 4 in a single housing. In these lamps, the carbons are moved up and down automatically by a small electric motor to adjust the length of the arc, which is also maintained at an approximately fixed location in the lamp. With increase in current, the radiation increases more rapidly than the increase in current, and this is especially true of the ultra-violet portion of the spectrum. This increase, though irregular, reaches, in some cases, several times the increase in current.

Gaseous Conductor Lamps

Here are considered only those lamps in which the gaseous conduction takes place inside of a sealed tube, as distinguished from the atmospheric conduction of the lamps classed above as arcs. (Cady and Dates, *Illuminating Engineering*, p. 131.) At atmospheric pressures, all gases offer very high resistance to the passage of electric current. When, however, a gas is highly rarefied the resistance is greatly decreased; and with sufficient potential, a luminous discharge takes place within the enclosing tube. The phenomena in such tubes are quite complicated and dependent upon the emission of electrons and the ionization of the gas. Where a cold cathode is used, several hundred volts are consumed in the ionization of the gas at that electrode. For a given gas and a given electrode, and up to a critical current density, this is a constant potential gradient through which the ions must drop in order to produce the necessary emission of electrons by the bombardment of the cathode, and since no corresponding light production results this drop tends seriously to reduce the efficiency of this type of light source, and necessitates the use of long tubes and correspondingly high voltages. Step-up transformers with 2000 to 15,000 volts on the secondary, adapted for 9-mm tubes from 2 to 35 ft in length, and for 15-mm tubes from 2 1/2 to 65 ft are used. Besides loss of efficiency and the necessity for high voltage, these cathode phenomena cause two other difficulties. The bombardment of the cathode is so violent that particles are actually torn off and projected to the walls of the tube, thus causing blackening. The bombardment is also associated with a gradual absorption of the gas, with consequent objectionable decrease of pressure. These phenomena affect the satisfactory life of the tube, which, however, even so, is estimated as several thousand hours. The use of reactance as ballast to stabilize the arc results in a low power factor. In the case of neon and other signs it is practicable to compensate with a condenser on the primary side which may well be combined in one unit with the transformer.

HIGH-VOLTAGE, GASEOUS CONDUCTOR LIGHT SOURCES. The use of cold-cathode, gaseous conductor lamps is largely confined to electric signs and decorations. Neon has been the gas most extensively used for this purpose. The diameter of the tubing for these signs varies from about $^3/_8$ in. to about 2 in., though usually not over 1 in. Actual data derived from a survey by H. P. Cook (*Trans. I.E.S.*, 1929, Vol. 24, p. 133) gave the following: watts per foot, 5.5 to 11.6, average 8; power factor 34 to 56 per cent, average 40 per cent; 15-mm tubing, watts per foot, 3.9 to 8.6, average 6.1; power factor 36 to 73 per cent, average 50 per cent. Average period of burning about 14 hours. In addition to the well-known orange color of the neon sign, blue is obtained by combining neon and mercury, and green by using a tube of fluorescent uranium glass. Other colors are being developed.

The neon glow lamp is a cold-cathode lamp in which the electrodes are separated only $^1/_{16}$ in. On a 135-volt circuit, a glow forms, covering both electrodes for alternating, and only one for direct, current. A resistance of several thousand ohms in the base holds the current down so that the watt-consumption ranges from $^1/_4$ in the smallest lamps to 2 in the largest now made. The light flux produced is very low, but enough to be of value for signal purposes and for low illumination for dark-adapted eyes.

THE HOT CATHODE. By substituting for the emission of electrons by bombardment, thermal emission, at the cathode, the drop at this electrode may be reduced to a few volts, thus permitting the use of shorter tubes and higher current density; this likewise eliminates sputtering and the injurious lowering of the gas pressure. Here, also, coating the electrode with an oxide, or with the metal thorium, greatly improves the electron emission. (See Pender and McIlwain, also, Hull, *Trans. A.I.E.E.*, 1928, Vol. 47, p. 743; Found and Forney, *ibid.*, p. 747.)

MERCURY-VAPOR LAMPS. The cathode is not separately heated in mercury-vapor lamps, but the thermal electron emission phenomenon is due to the characteristics of the mercury surface, which results in a very high-temperature spot that serves as a cathode, wandering over the surface of the mercury pool, which connects to the negative terminal of the lamp. The high temperature of this spot results both in the emission of the electrons and in the evaporation of the mercury, thus producing the mercury vapor. The low-pressure mercury lamp, sometimes called the Cooper Hewitt lamp, employs, as generally used, a 1-in. tube, 50 in. long. Tubes 35 in. long are also used, and larger and longer tubes for special purposes. In the d-c lamp, the watts per lamp are nominally 385 for direct, and 450 for alternating, current. Rated lumens are 5200 and 5625, and lumens per watt, with reflector, 13.4 and 12.5. The light output falls 20 per cent in 1800 hours, but only 9 per cent in the next 2500 hours. The a-c power factor is about 85 per cent. The discharge is started by a small mercury switch, which, being tilted by the application of the line voltage, breaks the current shunted through a reactance. As in all other arc and gaseous discharge lamps, the use of a ballast is necessary; this reduces the efficiency and, with alternating current, the power factor of the lamps to the values given above. The color of the light is characteristic of the mercury-vapor spectrum at low pressure. (Buttolph, *Gen. Elec. Rev.*, 1920, p. 741.) The fact that the mercury at the pressure used has a prominent line in the yellow and a lesser one in the yellow-green has led to the claim for monochromatic quality, which has been seemingly substantiated by many successful applications where observation of fine detail is essential. The presence of strong lines at the blue end of the spectrum casts some doubt on the monochromatic claim. The character of the light also increases the effectiveness of the light at low intensities in accordance with the Purkinje effect. (See Art. 3.) It is also useful for certain types of inspection and for photographic work. Combined with incandescent lamps, mercury vapor can be made to produce a fairly satisfactory white light. (See Art. 4.) This low-pressure lamp is also made with a special ultra-violet-transmitting glass, for the purpose of giving sufficient ultra-violet radiation to promote the health of workers who stay for long hours under its illumination.

HIGH-INTENSITY MERCURY LAMP. This a-c lamp, announced in June, 1934, gives 16,000 lumens at 40 lumens per watt, initial net efficiency, thus consuming 400 watts. Mean lumens, 85 per cent of initial; estimated life, 2000 hours. The lamp itself now requires 240 volts to start, but operates with 155 volts. For operation on a 115-volt circuit each lamp requires a 2.8-amp transformer with high reactance, with which is combined a 20-μf condenser, thus raising a 60 per cent power factor to about 92 per cent. The lamp bulb is 1 $^3/_8$ in. in diameter, and is made of a heat-resisting glass, which permits of operation at a high temperature corresponding to about atmospheric pressure. The luminous discharge takes place between tungsten spiral electrodes near the ends of the 7 $^1/_2$-in. bulb; coats of barium compounds on the tungsten spirals provide electrons for starting. Argon also assists in this. A 2-in. by 12 $^3/_4$-in. outside tube conserves heat and protects the circuit run on the outside of the inner bulb to the tip electrode. The

lamp takes about 12 min to come to normal operation, but it reaches 60 per cent of its luminous output in about 4 min. A combination of about equal lumens of high-intensity mercury and of tungsten incandescent (500-watt) is claimed to give a fair approach to daylight quality. Similar lamps giving 4000, 6000 and 10,000 lumens are now made (1936) and smaller lamps are being developed.

When enclosed in a tube molded from fused silica or quartz, the mercury-vapor discharge becomes an important source of ultra-violet radiation. (See Pender and McIlwain.) In this form, mercury-vapor lamps have the trade name Uviarc. (Uviarc Lamps and the Ultra-violet, by L. J. Buttolph, Gen. Elec. Vapor Lamp Co.) These lamps take about 4 amp on a 220-volt d-c circuit and are provided with a transformer and rectifier for use on alternating current. They operate at about atmospheric pressure, and have about 25 volts drop per inch in the arc as compared to 1.5 volts in the low-pressure arc. The operating temperature approaches 1400 deg cent, the softening temperature of fused silica. The spectrum radiated extends from 1.014 μ in the infra-red to 0.185 μ in the ultra-violet.

By the use of a suitable filter, any narrow portion of the spectrum, including a characteristic mercury line or band, can be isolated, thus giving light of a highly monochromatic character. A smaller equipment is also made, especially for laboratory use.

The Sunlight Lamp (General Electric trade name) combines an incandescent filament and a mercury arc between tungsten terminals. This is made in two sizes, the S1 and S2 lamps. A special transformer which accompanies the S1 lamp has a starting voltage of 33, which lights the filament. The heat of the filament vaporizes the mercury and permits the arc to form between the tungsten electrodes. The voltage then falls to 11, and the current rises to 30 amp. The tungsten electrodes are incandescent and give about 68 per cent of the light, 35 per cent coming from the arc and 7 per cent from the filament. The glass of the bulb is especially designed to pass ultra-violet radiation, but to cut it off at 0.28 μ. With the transformer, the S1 lamp takes 400 watts. The smaller S2 lamp takes 130 watts, with 8.5 amp at 15 volts. The approximate lumens are 6000 and 1600 with 18.3 and 12.5 lumens per watt. The power factor for each lamp is about 50 per cent, and the lamps are designed for a life of 300 hours. These lamps are equipped with aluminum reflectors because of the high reflection factor of that material for ultra-violet radiation. (Porter, Egler, and Sturrock, *Trans. I.E.S.*, 1932, Vol. 27, p. 23.) The Type G lamp has a small bulb with two oxide-coated tubular electrodes heated from within by tungsten filaments. It gives but 150 lumens at 3.0 lumens per watt, but a relatively large amount of ultra-violet radiation.

THE HOT-CATHODE NEON LAMP is used on either direct or alternating current. The 2.2-cm diameter lamp, 55 cm long, operates satisfactorily on 125 volts direct current. The a-c tube, either by the use of a transformer with central connection to the cathode and end connections to two anodes, as in rectifiers, or by the use of electrodes in each end of the tube, which will operate either as anodes or hot cathodes, uses both halves of the cycle, and gives a practically non-flickering light. The 220-volt a-c tube, 2.2 cm in diameter and 125 cm long, takes 3 amp and has a luminous output of 10,000 lumens. These tubes are estimated to have a life of more than 5000 hours. In addition to their advertising and display applications, the tubes are used for beacons, and combined with mercury tubes, to obtain an approximately white light satisfactory for photography and for other purposes where an approximation to white is satisfactory.

SODIUM LAMPS. A gaseous conductor lamp using sodium vapor as its light-producing element was introduced in 1934. This lamp combines with sodium, as gaseous conductor, some other gas, such as argon, to facilitate conduction and to make starting possible. At atmospheric temperatures the sodium is solid, but is vaporized by the heat of the discharge through the auxiliary gas. The sodium vapor then takes part in the conduction of the current and gives to the light produced the characteristic yellow sodium color. To maintain the necessary temperature in the lamp it is enclosed in a double-walled tube, or globe, from which the air is exhausted, as in the Dewar flask. Sodium lamps are used only on alternating current and have an anode and a hot cathode in each end of the tube. The following are approximate 1935 data on these lamps.

Lumens	Total	Tube	Net	Tube	Candles per sq in.	Arc Current	Arc Volts	Arc Length, in.	Over-all Length, in.
6,000	165	135	36	40	35	5.0	24	7	14 1/2
10,000	220	200	45.5	50	37	6.6	28	9	16 1/2

The above efficiencies are with an insulating transformer. For series operation, 10,000 lumen lamps may be operated in series, without individual transformers, with an effi-

ciency of 51.3 lumens per watt. The normal life of both lamps is 2000 hours and the arc power factor, 90 per cent. (Buttolph, *Trans. I.E.S.*, 1935, Vol. 30, p. 147; Cleaver, *ibid.*, p. 703.)

Sodium lamps promise to be especially suited to highway and street lighting. The monochromatic character of their light will also adapt them to special uses. While the lamps starts quickly, stable conditions are reached only after some 30 minutes.

3. VISION

The Eye

The pupil, the biconvex lens, and the retina give to the eye the performance of a camera. The lens possesses the image-forming function, and accommodation to distance is provided by its varying curvature. The contraction and dilation of the pupil give automatic accommodation to the intensity and quantity of light entering from the field of view. The retina also adapts itself automatically in sensibility to the flux density of the light falling upon it. The combined effect of these two phenomena is to make the range of sensitiveness of the eye as great as 1 to 8000. The extreme range of brightness of recognizable objects is over 50 billions. (Nutting, *Trans. I.E.S.*, 1925, Vol. 20, p. 529.)

The retina comprises an elaborate structure of microscopic nerve terminals, known as rods and cones. In its periphery, rods predominate; but the ratio of cones to rods increases steadily toward the center or fovea, where the cones greatly predominate. The sharpness of perception diminishes markedly in passing from the fovea to the periphery. At low intensities, rod vision predominates. At moderate and high intensities cone vision predominates.

The adaptation of the eye from darker to brighter surroundings is much more rapid than that for the reverse operation. Thus, to perform 77 per cent of the complete opening of the pupil requires 10 sec, as against 1.6 sec for 77 per cent of the complete closing; that is, the adaptation to brightness, so measured, is more than 6 times as rapid as adjustment to darkness.

Reactions of the Eye

THE SENSIBILITY, OR RELATIVE VISIBILITY CURVE, OF THE HUMAN EYE. The sensibility of the eye to radiation of varying wavelengths differs greatly. Below 0.4 micron and above 0.7 micron radiation does not affect the eye. The maximum sensitivity is for yellow-green light of 0.556 micron. A light source converting all applied energy into radiation of that wavelength would produce approximately 620 lumens per watt. The sensibility curve established as an American standard, as a result of the work of several investigators (*Trans. I.E.S.*, 1924, Vol. 19, p. 176; 1925, Vol. 20, p. 632), is shown in Fig. 14. Lumens per watt for any wavelength may be obtained by multiplying 620 by the proper relative visibility factor from Fig. 14. This curve explains the low visibility found under deep red or deep blue light.

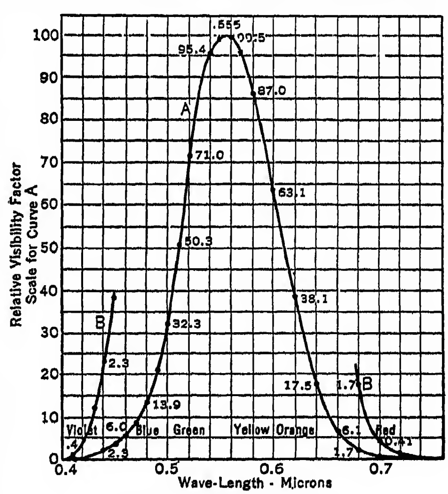

FIG. 14. Sensibility Curve

Purkinje Effect. Transition from vision at high to low intensity involves relative loss of sensibility to red and gain of sensibility to blue, so that two lights of reddish and bluish hue respectively show a ratio of intensities which varies with the brightness of the field of view. This is known as the Purkinje effect. In fields above a brightness of 1 lumen emitted per square foot (1 ft-lambert), the shift is slight. Photometric comparisons involving color differences should be made only in at least moderately bright fields.

VISUAL PHENOMENA. The performance of the eye under varying conditions of illumination is covered in detail in Analysis of the literature concerning the dependency of

visual function upon illumination intensities, by L. P. Troland, *Trans. I.E.S.*, 1931, Vol. 26, pp. 107 to 196, from which the following items are abstracted.

Brightness Discrimination. Fechner's law states that the lowest difference in brightness between adjacent surfaces that can be discerned is a constant fraction of the illumination. From about 7 to 70 ft-c illumination on an 80 per cent reflecting surface, this fraction is in the neighborhood of 1 1/2 per cent. This figure varies considerably, depending upon the conditions under which the test is made.

Effect on Visual Acuity of Increased Illumination. The increase in visual acuity follows an approximately logarithmic law, at least to the neighborhood of 30 ft-c. This makes the increase small above 7 ft-c. These data are based on conditions of high contrast, black on white.

Effect on Speed of Vision of Increased Illumination. The work of many investigators shows a roughly logarithmic relation between speed of vision and illumination. Quantitative results are much affected by such conditions as contrast, size of object viewed, etc. According to this law, speed of vision would show as much improvement between 1/2 and 2 ft-c as between 2 and 8. The logarithmic relation, however, does not hold for very high intensities, probably not above 100-ft-c (100 millilamberts). Luckeish found more than three times as much increase in speed for a certain increase in illumination when reading black type on gray paper of 22 per cent reflection factor, as for black type on white paper. Ferree and Rand found almost twice as much increase in speed of vision when the test object was reduced in diameter from approximately 2 in. to 1 in.

Pupilary Change. Pupilary contraction occurs continuously from 0.0001 ft-c to about 1000 ft-c on white paper. The range in pupil-diameter is from about 8 to about 2 mm. An average diameter of 5 mm occurs for 1 ft-c on white paper.

Effect of Intensity of Illumination upon the Eye. The highest practicable artificial illumination intensities, where properly applied without glare and without excessive contrast, are much lower than natural illumination intensities near north windows, such illuminations as are considered entirely satisfactory. On the other hand, glare from bright or large lights in the field of view, and especially ultra-violet radiation coming directly to the eyes, is likely to be seriously injurious.

Influence of Illumination Intensity upon Practical Operations

(See also Art. 7.) Many practical tests carried on in industrial establishments have indicated considerable increases in production with increases in illumination intensities up to the neighborhood of 10 ft-c for work of medium fineness. Further increase in production with still higher intensities is probable, but except for very fine work such increases are small. Averages taken from 19 sets of figures show an increase of production amounting to 13.8 per cent resulting from an increase in illumination from an original intensity of 2.7 to an approved level of 10.9 ft-c. Some authorities, however, claim that much higher intensities would justify themselves through increased production.

Luckeish and Moss (*Trans. I.E.S.*, 1932, Vol. 27, p. 699) present a new point of view with regard to the advantage of high intensity of illumination. They claim that although very high values cannot be justified from the point of view of increased production, they can on account of decreased drain of nervous energy, as measured by decrease in nervous muscular tension of the subject under test under increased illumination. Over 110,000 observations were taken on 14 subjects. By their methods of measurement, the nervous muscular tension under 1 ft-c illumination averaged 63.2; under 10 ft-c, 54.1; and under 100 ft-c, 43.0. Their probable error was calculated to be less than 1 per cent. Plotted to the logarithms of these three foot-candle values, namely, 0, 1, and 2, these values of nervous muscular tension lie upon a straight line. It is claimed that this saving in nervous strain would justify much higher intensities than are now in general use.

GLARE. Glare may be defined as light shining into the eyes in such a way, or of such quantity, as to cause discomfort, annoyance, interference with vision, or injury to the eyes. "Glare is produced in one or more of three ways: (*a*) excessive flux of light entering the eye, as from a large source of low brightness; (*b*) excessive brightness of any light-source within the field of view, as in the case of unshaded incandescent lamps; (*c*) excessive contrast in brightness between the light-source and surrounding surfaces. Of these three causes of glare, excessive brightness is the cause of more cases of glare than either excessive flux, or contrast." (From Caldwell, Modern Lighting, by permission of the Macmillan Co., publishers.)

One or more of the foregoing conditions must exist in order that glare shall be present, The seriousness of such glare, however, depends upon the following three conditions, not connected with the eye of the observer: (*a*) the duration of exposure to the glare; (*b*) the angle between the source of glare and the line of vision; (*c*) the distance from the

source of glare. (Caldwell, Modern Lighting, p. 18.) If the angle from the line of sight is greater than 30 deg the resulting glare will not interfere with vision, though it may be annoying if the light is too bright. Close to the line of sight, a very small light source may be annoying; but if it is 90 deg or more removed, glare will not result, no matter how bright or large the light source. Light coming from below the line of sight is particularly troublesome. Snow blindness is an example.

In addition to these objective conditions, the health and sensitiveness of the eye itself are important factors in determining the effect of glare. Sensitiveness to glare is a protection to the eyes, and should be cultivated. "Three effects of glare should be differentiated: (*a*) temporary blinding or impairment of vision; (*b*) discomfort, as when looking at the sun, or at a bright artificial light close by. This may be instantaneous or it may be due to continued exposure to a source of light which would not be at once felt as glare; (*c*) injury due to prolonged exposure to glare, often unrecognized. Of these three the last is evidently much the most serious case, though enforced exposure of the second class may easily evolve into it." (From Caldwell, Modern Lighting, by permission of the Macmillan Co., publishers.)

Blinding due to glare is approximately independent of either brightness or area of light sources, but varies as the total light flux transmitted from a source of glare, which enters the eye. That is, the blinding effect of a lamp is not reduced by surrounding it with a globe, except as the total flux is decreased. The comfort and appearance, however, are improved. Brightness values of more than 2 or 3 candles per square inch are glaring if near the line of sight, and $^1/_2$ candle per square inch is to be preferred. Large units of considerable height may be given 5 candles per square inch. In the matter of contrast, a ratio of 200 : 1 is to be regarded as the extreme permissible limit, with 100 : 1 preferred.

Reflected Glare from polished surfaces, as glass desk tops, is particularly bad, because of coming from below. So-called veiling glare reflected from glazed paper, may seriously interfere with the legibility of the type.

Glare is to be avoided by (*a*) keeping down the brightness and light flux of light sources which must come into the field of view; (*b*) avoiding the placing of light sources within the field of view as far as practicable; (*c*) avoiding contrast, by the use of light ceilings and walls. (See also *I.E.S.* Codes of lighting for Factories and Schools.)

SHADE, SHADOWS AND DIFFUSION. Except for the effect of color differences, the forms of objects are recognized only by shades and shadows upon them, and by shadows cast by them upon other objects. While too great uniformity of illumination is therefore undesirable, practical limitations, even with indirect lighting, will hardly ever permit the elimination of shadows to a serious extent. Shades and shadows should not be too black and should not be sharp at the edges. This condition will be accomplished by a suitable number and diffusion of light sources. Diffusion has two different but related meanings. Illumination is diffused when sharp black shades and shadows, and strong contrasts, are avoided. A luminaire is diffusing when it is of sufficient size to give satisfactory diffused illumination. This is in contrast to a virtual point light source such as a bare incandescent lamp. Multiple shadows from a number of sources without sufficient diffused light are annoying.

4. RADIATION, COLORED LIGHT, AND ARTIFICIAL DAYLIGHT

Radiation

The discussion of radiation in the present section is confined to that portion of the general radiation spectrum which affects the eye, namely from 0.4 to 0.7 micron (μ = 0.001 mm). For the fundamentals of radiation, see Sec. 9, Eshbach, *Fund. of Eng.* For vision in connection with radiation, see Art. 3.

In light sources we have to deal with two forms of radiation, and with combinations of these. These are continuous spectra and line spectra. Incandescent solids, as exemplified by lamp filaments, and arc electrodes, give continuous spectra. Starting with a heated body, not yet visible to the eye by its own radiation, as represented by curve a in Fig. 15, and raising the temperature stepwise, a series of radiation curves, b, c, d, e, f, and g, are shown for the temperatures indicated. To obtain relative values the ordinates of these curves must be multiplied by the following factors: a — 1, b — 1.1, c — 8, d — 33, e — 103, f — 265, g — 1100. In so far as these curves cross the region of the visible spectrum between the lines $v - v'$ at 0.4 and 0.7 μ, light is produced, and the efficiency of the body as a source of visible radiation is equal to the ratio of the area cut off between the lines $v - v'$ to the total area under the curve. Such radiation efficiencies are shown for different temperatures in Fig. 16, curve A. It is evident, from this curve, why the

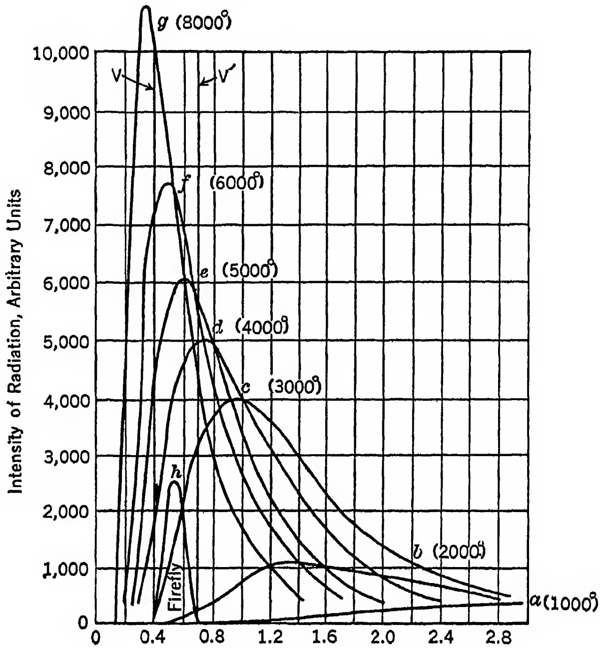

FIG. 15. Radiation Curves for Hot Bodies

efficiency of incandescent lamps increases with temperature, and also why the efficiency of such light sources can never be high. The curve h represents, to its own scale, the curve of radiation from a firefly, with nearly 100 per cent radiation efficiency. All radiation which falls upon and is absorbed by an opaque body heats that body, though the temperature rise may be very small. Cold light cannot exist.

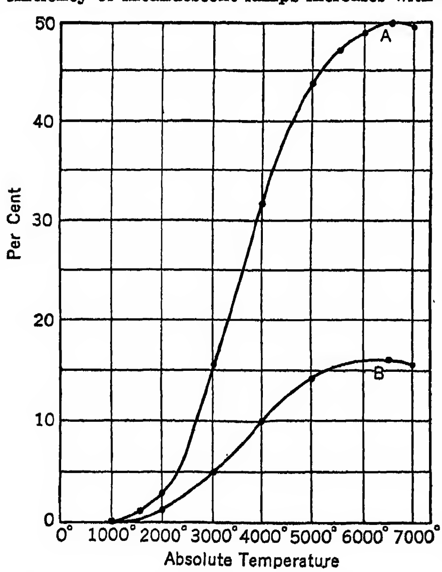

FIG. 16. Radiation Efficiency and Temperature

The curves of Fig. 15 show the total radiation produced at each wavelength, regardless of its effect on the eye or its luminosity. To obtain the luminous effect on the eye, the radiation at each wavelength must be multiplied by the corresponding ordinate of the sensibility curve of Fig. 14. Performing this operation, and then obtaining the efficiencies as for curve A, gives curve B in Fig. 15 (Hyde, I.E.S. Lectures on Illuminating Engineering, 1911), the net luminous efficiency of a black body at different absolute temperatures. Any material whose radiation curve at a given temperature differs in form from the curves of Fig. 15 has selective radiation. If the selectivity is such as to raise the part of the curve between 0.4 and 0.7 μ above normal, there will obviously result an increase in the efficiency of that material. This is the case with

tungsten. (See Art. 2.) The color corresponding to different temperatures, from a just perceptible red to the white light of the sun, is also explained by the relative proportions of the different wavelengths from 0.4 to 0.7 μ, corresponding to the different temperatures. Although sunlight represents the highest black-body temperature of experience, since a definite law between color and temperature exists up to that point it is convenient to extrapolate according to this law for colors, such as skylight, having a still larger percentage of blue than sunlight. (I. G. Priest, *J. Opt. Soc. Am.*, 1923, p. 1179.) Table XI gives color temperatures, abstracted from a table by Norman Macbeth, *Trans. I.E.S.*, 1928, Vol. 23, p. 308. (See also A. H. Taylor, *Trans. I.E.S.*, 1930, Vol. 25, p. 154.) Fig. 17 shows the relative amounts of the various wavelengths relative to white light in different light sources. For each curve the radiation at different wavelengths is compared with that at 0.556 μ as 100 per cent and all curves are scaled to have the same radiation at that wavelength.

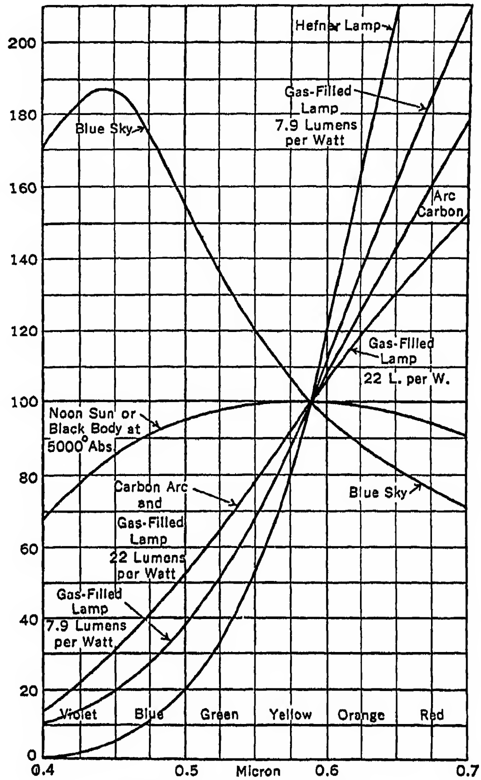

FIG. 17. Relative Radiation

Selective Reflection and Transmission

Any surface exhibits a given color according as it absorbs certain wavelengths of the light which fall upon it, and reflects the remainder. If the incident light is white, then the color, as determined by the combination of colors reflected, is the complement of the color absorbed. White light, or some form of daylight, is the standard for color discrimination. A surface can reflect light only of wavelengths that exist in the incident light. Consequently, if such light is lacking in any wavelength which the material normally reflects, the color of the object will be modified accordingly. If none of the

Table XI. Color Temperatures for Daylight and Artificial Light

Sun, 17 min before sunset	1,900	Sun, 63 min before sunset	3,500
Candle flame	1,930	Mazda daylight, 150-watt	3,600
Sun, 25 min before sunset	2,100	Crater solid carbon arc	3,700
Treated carbon filament, 3.4 lpw	2,170	Tungsten electrode arc	3,800
Tungsten filament in vacuum 5.4 lpw	2,250	Sun, 95 min before sunset	4,000
Acetylene flame	2,380	Noon sun, Washington, average	5,300
Sun, 33 min before sunset	2,500	Uniform overcast sky	6,000 to 7,000
40-watt tungsten filament in vacuum, 10 lpw	2,510		
100-watt gas-filled lamp, 12.9 lpw	2,740	Moore carbon dioxide tube lamp	7,800
Sun, 40 min before sunset	2,900	Blue sky	10,800 to 24,500
500-watt gas-filled lamp, 18.1 lpw	2,910		
1000-watt gas-filled lamp, 20 lpw	2,980		
Projection type, 900-watt, 27.3 lpw	3,220		

Opal glasses generally introduce some long-wave radiation and show color temperatures of 2700 to 2800. Some "white" diffusing glasses go as low as 2600. Blue glasses designed to produce artificial daylight may be had up to 30,000 deg. at 8.7 mm thick. The color temperature for any blue glass rises with its thickness.

wavelengths which the surface normally reflects are present in the incident light, no color will appear; the surface will be black or gray.

In the same way, a transparent or translucent colored material transmits selectively the colors which are not absorbed. If a pure blue glass is placed in front of a pure red, the combination ceases to be transparent, or passes only a little light, if the colors are not entirely pure. For the purpose of obtaining light of special spectral qualities, screens which cut off definite portions of the spectrum, as indicated by transmission or absorption curves, are available. These curves give as ordinates the transmission corresponding to each wavelength of the visible spectrum. Such screens, or filters, are available either in glass (H. B. Gage, *Trans. I.E.S.*, 1916, Vol. 11, p. 1050; also, *Trans. Soc. Motion Picture Engrs.*, May, 1924; see also *Bur. Standards Scientific Paper* 325, Vol. 14, p. 653), or in stained gelatin (Wratten Light filters, Eastman Kodak Co.). A greater variety of colors is available in gelatin, but the spectral characteristics are not as permanent as with glass.

Artificial Daylight

Because of the standard character of daylight-colored light, it is desirable for various purposes to produce it artificially. The principal use of artificial daylight is where color discrimination or color matching is important. The imitation of daylight can be so satisfactorily accomplished that it is customary to shut out the daylight, which is highly variable, both in color and intensity, and perform color-matching operations entirely by a standardized artificial daylight. Some persons who have difficulty in working under the usual artificial lighting claim to find artificial daylight much more comfortable for their eyes. The production of artificial daylight is generally accomplished by the use of a carefully designed blue glass filter, which takes out the excess of radiation of the long wavelengths, and thus passes the light having the proper proportions of the long and short waves. For accurate color matching, the light so produced should have a color temperature closely approximate to that of clear noon sunlight and the accompanying sky light. According to Taylor (*Trans. I.E.S.*, 1930, Vol. 25, p. 154), any color temperature between 5500 and 6500 deg K will give a satisfactory equivalent of daylight. Taylor gives the color temperatures of 100-, 300-, and 500-watt daylight lamps as 3600, 4250, and 4500 deg K. These pass from 62 1/2 to 64 per cent of the lumens produced. He also gives data on other "daylight" units running up to one of 15,000 deg, which passes only 8.7 per cent of the produced lumens. For noon sunlight color, 5800 deg K is required, the efficiency for which is 14.7 to 17.2 per cent of the lumens generated. If the comparison is made for both bare lamp and daylight units in aluminum reflectors, the above percentage becomes for noon sunlight 20.5 to 24 per cent and for north skylight 11.3 to 16 per cent. For many purposes the blue "daylight" lamps, although passing the yellow color of late afternoon sunlight, give entire satisfaction as an imitation of sunlight.

Light which is apparently white may be obtained by mixing different groups or pairs of complementary colors which, nevertheless, are far from giving, by their combination, a continuous color spectrum, and therefore are imperfect for color-matching purposes. Also, a blue filter may give what seems to the eye to be white light, and which yet seriously distorts some colors viewed by it. The true whiteness of a light cannot be determined by its appearance to the eye.

Gaseous Conductor Light Sources

(See also Art. 2.) Hitherto, only the continuous spectrum, and the effects of absorbing filters upon such light, have been considered. The gaseous conductor light sources, as distinguished from the continuous spectrum light sources, give line spectra. That is, their light flux is produced at a number of definite wavelengths. Usually certain of these wavelengths predominate, thus giving the light an especially monochromatic color. Spectra for a number of gases and metal vapors are given by Rentschler, *Trans. I.E.S.*, 1934, Vol. 29, p. 439. Spectra and other data are given by Buttolph, *Trans. I.E.S.*, 1933, Vol. 28, p. 153. He also gives the following data on the efficiency, in lumens per watt, of various gaseous conductor lamps, including accessories. Sodium arc, on a constant potential, 32; mercury arc, 21; low-pressure arc, 18; neon, with inductive ballast, 17; mercury, with tungsten electrode, 12; helium with resistance ballast, 4. For series operation, sodium lamps have an efficiency in the neighborhood of 50 lumens per watt. The strong colors produced at high efficiencies by these lamps are of value for advertising and spectacular effects. The monochromatic character of their lights limit them in their availability for lighting purposes, though the sodium lamp and the high-pressure mercury lamp bid fair to be useful for highway and perhaps for street lighting. By a combination of about 2 watts of high-efficiency incandescent light, with 1 watt of mercury-arc light, or 2 1/2 lumens of incandescent to 1 lumen of mercury arc, a fairly satisfactory

imitation of daylight can be produced with an efficiency far higher than is possible by means of glass filtering equipment. (Grandy, *Trans. I.E.S.*, 1933, Vol. 28, p. 762.)

Colored Incandescent Lamps. Apart from their use for the production of artificial daylight, colored incandescent lamps are in extensive use for decorative purposes. The effect of color is obtained at a considerable expense because of absorption of light. (Taylor, *Trans. I.E.S.*, 1924, Vol. 19, p. 136.) Luckeish and Taylor give as practicable efficiencies for colored lamps as compared to unmodified light: amber, 40 to 60 per cent; red, 15 to 20 per cent; green, 5 to 10 per cent; blue, 3 to 5 per cent. An important application of colored bulbs is the "flame tint" color used in small lamps to imitate flames. Luckeish (Color and Its Applications, p. 254) states that the flame-tint glass used for this purpose passes 80 per cent of the light produced. He also compares the energy required to produce the same color by means of a carbon lamp at 4 watts per mean horizontal candle and finds it to be about 2 1/2 times that required for the tungsten lamp in the flame-tint bulb. The use of colored lamps also has an extensive place upon the stage, as well as for signal lights, such as automobile tail lights, port and starboard lights on shipboard, etc., traffic signals, and railway signals.

5. LIGHT-MODIFYING DEVICES

PURPOSES OF LIGHT-MODIFYING DEVICES. The two principal purposes of such equipment are: first, to prevent glare and promote diffusion, by cutting off the direct vision of the light source, or increasing its size; second, to change the natural distribution of the light source by reflectors, diffusing globes, or refractors, in order to adapt it better to the purpose in hand. Such equipment also improves the appearance of the light source and, out-of-doors, protects it from rain and snow. A classification of modifying equipment may be made as follows:

Reflectors, direct or inverted: Opaque—enameled steel, aluminum, stainless steel, metal plated with silver or chromium, silvered glass. Translucent—white glass, prismatic glass, synthetic materials.

Globes: lanterns, urns, etc., white glass, prismatic glass.

Shades and Screens: art glass, parchment, fabric.

REFLECTORS. As compared with globes, reflectors are less expensive and more efficient. They have the disadvantage, however, of showing the exposed lamp from below the luminaire. Globes and similar devices lend themselves better to artistic effects. For the use of reflectors in light projection and floodlighting, see Art. 6.

Opaque Reflectors cut off all upward-directed light and should therefore be used only with dark ceilings, or where the illumination of the ceiling is not desired. With the diffusing surface of enameled steel, the dome-shaped reflector of large diameter absorbs only about half as much light as the deep bowl-shaped reflector. The General Electric Co. has copyrighted the trade name RLM, and permits its use only on reflectors that meet certain specifications, among which are: a minimum diameter of 12 to 20 in., a maximum cut-off angle of 17 1/2 deg from the horizontal, and a minimum reflection factor for the enamel of 70 per cent. Such reflectors may be provided with a glass neck to throw some light upon the ceiling. Aluminum is much used for small, close-fitting reflectors but hitherto has suffered from considerable tarnishing. Recent developments promise notable improvement, especially in permanence. (Edwards, *Trans. I.E.S.*, 1934, Vol. 29, p. 351; Dickerson, *ibid.*, p. 358.) Because of high reflection factor for ultra-violet radiation, about 80 per cent, aluminum is regularly used for this purpose. (See Sec. 9, Eshbach, *Fund. of Eng.*) Silver, which gives the highest reflection factor when clean, suffers greatly from tarnishing. Chromium and stainless steel have lower reflection factors, but maintain them much better than silver. Silvered glass has high reflection factor and greatest permanency. Its principal use is for small reflectors for indirect lighting luminaires, also for industrial lighting, the lighting of show windows and show cases, and for floodlighting. These glass reflectors are also especially adapted to concealed lighting, either built into the walls and ceilings or mounted above a ceiling skylight. Their specular reflection surface makes the exact design of distribution curve practicable, but is sometimes objectionable from the point of view of glare, where it is in a position to be visible to the eye.

Translucent Reflectors, white glass and synthetic compositions, are like enameled metal, in that the form of the reflecting surface does not determine the distribution curve. They have wide application, however, because of their good appearance, low cost, low brightness, and provision of light for the ceiling. Prismatic glass reflectors are smooth on the inside, and covered with 45-deg prisms on the outside. Light from the lamp passes through the smooth interior, is reflected 90 deg by one of the 45-deg surfaces of a

prism, strikes the other side of the prism, also at 45 deg, and thus is reflected back at an angle with its original path, determined by its angle of incidence to the inside surface. As referred to the prism this phenomenon is called "total reflection." Rounded prism edges and fillets between them allow some diffused light to pass through. A high reflection factor is thus obtained, together with complete control of the distribution curve. Thus Fig. 3 shows a concentrated distribution from such a prismatic glass reflector. The reflection factor is considerably decreased by any dirt that sticks to the reflector. For large industrial reflectors, therefore, a close-fitting aluminum cover is provided.

GLOBES. The best white glass, as used in globes, combines efficient diffusion, designed to give uniform brightness, with low absorption. Standards for the characteristics of white glass and other diffusing media are now being developed by committees of the Illuminating Engineering Society (1936). Globes are usually either flattened or elongated. The distribution curve for lights with globes is considerably affected by the shape of the globe. Thus Harrison gives the data for two globes, having ratios of vertical to horizontal candlepower of $^3/_4$ and 2, respectively. The flattened globe also gives considerably more light flux to the upper 45 deg. Owing to internal reflection, followed by transmission, the overall efficiency of a globe may be much higher than the transmission factor of the glass itself. Satisfactory diffusion requirements limit the transmission of white glass to about 60 per cent, but a globe of such glass may have an overall efficiency as high as 85 per cent.

The prismatic glass globe has horizontal prisms surrounding it, which bend the light by refraction. (See Sec. 9 of *Fundamentals of Engineering*.) These prisms may be designed to give any practicable vertical distribution desired. On the inside of the globe, as used for interior lighting, are vertical flutes for the purpose of spreading and diffusing the light. Such globes are called "refractors." As used for street lighting, these globes are made in two pieces that fit inside of each other, with an air space between. The inner bowl is smooth on the inside and has the horizontal prisms on the outside. The outer bowl has the vertical fluting on the inside and is smooth on the outside. The two are joined together with an airtight seal. The fluting may be replaced by prisms of designed form, by which the horizontal distribution can also be adjusted to throw the light upon the street as desired. Such refractors are called asymmetric. (See Art. 9, also Fig. 21.) Table XII gives the brightness for different sizes of enclosing globes fitted with a 100-watt lamp. Table XIII gives recommended globe sizes for different size lamps, as taken from the I.E.S. Standards of School Lighting, p. 33. In all refractors, as well as in all reflectors with specular reflecting surfaces, the position of the lamp filament vitally affects the form of the distribution curve.

SYSTEMS OF LIGHTING. Lighting systems are classified as general and local "For rooms of considerable size, general lighting has the following advantages over local lighting: (*a*) the whole floor is illuminated so that work can be done at any point; (*b*) troublesome shadows are eliminated; (c) danger of glare is reduced; (*d*) the luminaires are up out of the way of breakage and theft; (*e*) the large lamps are more efficient, and the light is whiter; (*f*) there are fewer lamps to clean and maintain, and the cost of replacement is less than where many local lamps are used; (*g*) the appearance of the room is better." (From Caldwell, Modern Lighting, by permission of the Macmillan Co., publishers.) General lighting is direct, semi-indirect, or indirect. Direct lighting includes all downward-directed reflectors and all globes which throw at least as much light downward as upward. Semi-indirect luminaires emit from 65 to 90 per cent of the light upward, the remainder passing through the bowl, or if closed, through the lower part of the globe. Indirect lighting reflects all the light upward to the ceiling, from which it is

Table XII. Brightness and Size of Enclosing Globes of Good Diffusing Glass *

re-reflected downward. Direct lighting includes opaque reflectors, which have 100 per cent downward distribution, translucent reflectors, and most globes and other enclosing units. Semi-indirect and indirect lighting, though desirable from the point of view of

diffusion, necessarily give low efficiency and, especially when the units are open toward the ceiling, depreciate greatly from dust. Their efficiency is also dependent upon the maintenance of a high reflection factor of the ceiling. Indirect lighting by lamps in specular reflectors concealed in coves around the ceiling, ornamental wall brackets, and floor columns is to be preferred, from an esthetic viewpoint, to that from luminaires suspended from the ceiling.

BUILT-IN LIGHTING. In this type of lighting, recesses are built in walls, ceilings, and columns, in which the lamps, with suitable reflecting equipment, are placed. By careful design very pleasing effects with good illumination and fair efficiency can be obtained. For design data, see Beggs and Woodside, *Trans. I.E.S.*, 1931, Vol. 26, p. 1007; Potter and Meaker, *ibid.*, p. 1025; Higbie and Bychinsky, *ibid.*, 1934, Vol. 29, p. 225.

6. LIGHT PROJECTION

METHODS. Light projection is accomplished by: (1) **lenses,** (*a*) simple, (*b*) compound; (2) **reflectors,** (*a*) parabolic, (*b*) spherical, (*c*) elliptical, (*d*) non-symmetrical forms.

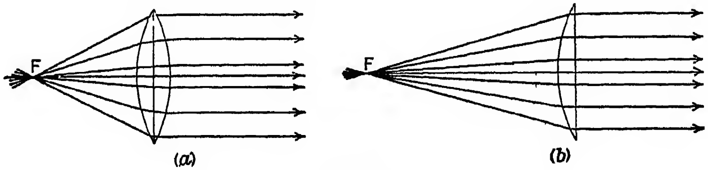

FIG. 18

LENSES. A lens bends the light rays by refractive action of its convergent surfaces, as in a prism. If the light is placed at the proper point, *F*, in Fig. 18, the rays will leave the lens as an approximately parallel beam, as in a spotlight. If it is desired to concentrate the light at a point, as in lighting the stage of a microscope or in the condenser of a lantern, moving the light nearer to the lens will cause more bending and hence a convergence of the rays.

A spherical lens will not bring the rays to an exact focus. It is less costly to correct this error by making a compound lens than by making a non-spherical lens. The compound lens is a combination of two lenses made from glass of different densities and cemented together.

CHROMATIC ABERRATION. The diffraction of the light into different wavelengths, as in the spectrum, also occurs in lenses. This defect also may be corrected by the compound lens. Both defects are lessened by the use of the center of the lens only, with the help of a diaphragm as in a camera. **The Fresnel lens,** shown in Fig. 19, is spherical as to its component rings, but these are offset to keep down the thickness and weight of the lens as a whole. It is extensively used for railway signal lights.

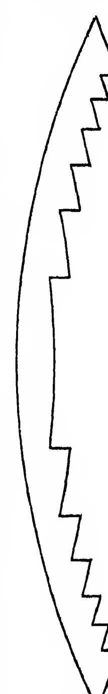

FIG. 19.

Reflectors

THE PARABOLIC REFLECTOR. (Benford, *Trans. I.E.S.*, 1915, Vol. 10, p. 905.) This reflector depends upon the characteristics of the parabola. If a line be placed tangent to the surface of a parabola at any point, and then a line drawn from the point of tangency to the focus, and also one parallel to the axis, these two lines will make the same angle with the tangent. Thus, if a light is placed at the focus, *F*, Fig. 20, a ray striking an element, *M*, of the reflector is reflected parallel to the axis. (See Art. 1.) If the light is moved along the axis toward the reflector, the rays will be caused to diverge; if away from the reflector, the rays will converge, cross, and then diverge. This phenomenon is a means of adjusting the angle of spread of the beam, which, owing to the fact that the light source is not a point, and to imperfections of the paraboloid, is never cylindrical. If the light source is moved upward, that portion of the reflector back of the focal plane will reflect the light downward, and the portion forward of the focal plane will reflect it upward. For a light source of uniform distribution, one-half of the flux is reflected back of the focal plane. The part of the flux reflected forward of the focal plane will depend upon the depth of the reflector, or the angle of the aperture.

The focal length is the distance from the focus to the vertex of the reflector. On its value depends the form of the reflector. A short focal length gives a narrow, deep reflector; a long focal length, a shallow, wide reflector. The 8- to 10-in. automobile headlamps of the recent past have focal lengths from 1 $^9/_{16}$ to 1 $^3/_4$ in. and intercept 60 to 70 per cent of the light from the lamps. (Brown and Roper, *Trans. I.E.S.*, 1934, Vol. 29, p. 128.) A 5-in. reflector intercepting the same amount of light would have a focal length of $^7/_8$ in. Where the focal length is increased much above these values, as in searchlights, the diameter must be much increased, or the proportion of the light flux intercepted is decreased, or both. (See Searchlights.) Because of the long distance of the light source from the reflector surface (lever arm), deviations of the surface from the true paraboloid produce much less effect on the beam in a long-focus projector than in a short—hence the advantage of the long focus for high-grade searchlight projectors. When an actual parabolic mirror is observed from a point in a beam near the reflector, light is received from only a small unit of the mirror surface. As the eye is withdrawn further from the reflector, the area producing illumination at a given point increases, owing to the finite area of the light source. After a certain point has been reached, the whole surface of the reflector appears luminous and gives light to every point in the beam. From this point on, the illumination varies inversely as the square of the distance. Benford gives this distance as:

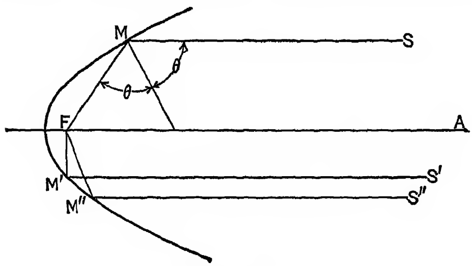

Fig. 20.

$$L = (F + R^2/4F)(R/12\,r),$$

where R is the radius of the mirror in inches, F the focal length, and r the radius of the source, in inches. (*Trans. I.E.S.*, 1915, Vol. 10, p. 905.) All tests on candlepower of reflectors should, therefore, be made at a greater distance than this. The I.E.S. code specifies 60 ft for tests on automobile headlamps. With a finite source the spread of a beam is directly proportional to the diameter of the source, and inversely proportional to the focal length. Because of the longer distance to the reflector surface, the outer portion of the surface of the parabolic reflector is more accurate in its light projection than the portion near the vertex.

THE SPHERICAL REFLECTOR reflects back the light along the radial line of incidence, if the light source is at the center, because the radius is perpendicular to the tangent. Then so much of this light as can pass the body of the light source joins with the emergent flux, and increases the effective lumens. If the light source is placed at one-half radial distance from the spherical reflector, the flux emerging from it is nearly parallel. This fact was taken advantage of in the Mangin mirror, which is a spherical reflector the two surfaces of which have different centers, the glass becoming thicker towards the edges of the reflector. The back is silver plated, and the prismatic or refracting effect of the glass is used to bring the rays reflected from this silvered surface into parallelism.

THE ELLIPSOIDAL REFLECTOR. This has the characteristic that, if a point source is placed at one focus, all reflected rays will pass through the other focus. Such a reflector can therefore be used if it is desired to concentrate the light upon a small object, as on a moving-picture film, by means of a reflector. This reflector is used with an arc-light in picture projection to concentrate the light flux on the film-picture area. The effect of the angular direction from which the reflected rays come to the conjugate focus is to give a highly concentrated form of distribution curve after the flux leaves this focus. (Benford, *Gen. Elec. Rev.*, 1923, Vol. 26, p. 163.)

Comparison of the Use of Lenses and Reflectors

The greatest difference in the use of these two projection devices is that in the lens the light source can be completely enclosed, so that the only emergent light is that coming from the lens. With the reflector, the open front necessarily permits a considerable part of the flux from the light source to pass out along conical lines, thus illuminating the surroundings. Reflectors direct from 30 to 70 per cent of the flux from the light source into the beam. The small angle subtended by a lens inevitably reduces this figure, for lenses,

to 20 per cent. Usually a reflector will be less expensive than the lenses which will perform a similar function.

Applications of Projection

PICTURE PROJECTION. The most important application of lenses, for picture projection, is so extensive and technical that it cannot be treated here. The reader is referred to Cady and Dates, Illuminating Engineering, pp. 481–497; Richardson, Handbook of Projection, Chalmers Publishing Co.; Farnham, *Trans. I.E.S.*, 1928, Vol. 23, p. 1241, for further information.

SEARCHLIGHTS. In the smaller sizes, up to 30 in., 1000-watt incandescent lamps are used, with parabolic or Mangin mirrors, and with the generation of several million candlepower at the center of the beam. Such searchlights have a wide application on shipboard and for other commercial uses. For the larger projectors, beginning with 30-in. and running up to the largest 60-in. reflectors, open arcs with special carbons are used. (See Art. 2.) The focal length of the mirror is about 40 per cent of its diameter. The positive electrode is directed along the axis of the reflector, and thus, in spite of the long focal length, nearly all the flux reaches the mirror, which subtends an angle of about 125 deg. Beams of as little as 1 1/2 deg spread are used. Searchlights, especially those for military purposes, may have louver or iris shutters for cutting off the light, without extinguishing the arc. All searchlights are arranged for easy orientation in any direction, which their application demands, and the large ones are operated with remote-controlled motors, so that the operator may not experience the blinding effect of the beam. The success of the searchlights of the present day is largely dependent upon the high-intensity arc. (See Art. 2.)

FLOODLIGHTING PROJECTORS. These are projectors having a fairly wide angle of spread, usually from 10 to 45 deg; they range in diameter from 11 to 24 in., being usually about 18 in. They use incandescent lamps ranging from 200 to 1500 watts. The maximum candlepower of floodlights of the narrowest spread ranges up to nearly 40,000 candlepower.

Floodlights are, as a rule, permanently located for the lighting of a given area of wall, ground, waterfall, or other object. Thus, though they are designed for convenient permanent orientation, facility in adjustment is not usually included. If this is needed, a small searchlight is preferred. The mirrors are of silver- or chromium-plated metal, or silvered glass. The last has high efficiency and permanence, but suffers from fragility. Fluted cover glasses may be used to spread the beam, either horizontally or vertically, where needed. Straight or circular louvers may be provided to reduce spilled light.

In the design of floodlighting, the problem is to obtain efficient illumination on the surface to be lighted, and sufficient uniformity so that the variations will not be noticed, even when the surface is observed from such a distance that the whole area enters into a single field of view. Madgick gives recommended illumination values for different types of surface, as in Table XIV. To obtain satisfactory uniformity, every point on the area should

Table XIV. Desirable Illumination Values for Floodlighting

Building Surfaces	Foot-candles *	Miscellaneous Applications	Foot-candles
White or cream terra cotta	4– 8	Flags and signs	5–25
Select gray limestone	5–10	Beaches and swimming pools	3– 6
Indiana or Bedford stone	5–10	Golf greens	2– 6
Buff limestone	6–12	Stadia	4– 8
Buff artificial stone	6–12	Pageants	10–20
Standard gray limestone	6–12	Playgrounds	1– 5
Smooth buff face brick	6–12		
Brief Hill sandstone	8–16		
Smooth gray brick	8–16		
Gray limestone	8–16		
Common tan brick	10–22		
Dark field gray brick (rough finish)	14–28		

* Depreciation in service may usually be taken as of the order of one-third.

NOTE.—Buildings composed of dark red brick or brownstone should not be floodlighted unless there is a large amount of light trim. Often, when color is employed, lower foot-candle values (but greater wattages) will be effective.

receive considerable illumination from at least two projectors. In producing an esthetic effect, where, usually, the light must come from below, the loss of the shadows produced by horizontal projecting architectural elements, as normally lighted by sunlight, should be

considered, also the shadows produced by architectural elements, when it is necessary to place the floodlights close to the surface to be lighted. (Cady and Dates, Illuminating Engineering, p. 419; Hallman, *Trans. I.E.S.*, 1934, Vol. 29, p. 287.)

Although the average illumination over a given area may be determined by dividing the total lumens by the area lighted, as in interior illumination (see Art. 7), the need for a fair degree of uniformity calls for a point-by-point study based on the distribution curve of the projectors used. For this purpose, Benford proposes the use of a spherical web, similar to the one used for isocandle curves (Art. 1). For this purpose he uses a special chart. (*Gen. Elec. Rev.*, 1923, Vol. 26, p. 579.) The artistic and spectacular possibilities of floodlighting are greatly increased by the use of color, though the necessary power to produce effective lighting is also much greater.

FLOODLIGHTS FOR INDUSTRIAL LIGHTING, TEMPORARY AND PERMANENT. Banks of floodlights are mounted on tall structural columns and on buildings, and directed down toward the ground for illumination of railway switching yards and other outdoor working places. (Mahan and Swackhamer, *Trans. I.E.S.*, 1928, Vol. 23, p. 189.) For temporary use on construction work, and when mounted at a sufficient height above the workers, floodlamps are very useful, but the danger of blinding glare must always be kept in mind.

AUTOMOBILE HEADLIGHTING. This is, probably, the most extensive and important form of light projection by means of reflectors. The difficult problem, with present-day road speeds and braking equipment, is to provide light enough along the highway so as to prevent colliding with any obstacle on the road, even when such an obstacle is to the rear and right of an oncoming car provided with similar headlight equipment. Also while having such adequate road illumination, to avoid causing troublesome glare for the oncoming driver. The headlighting should likewise facilitate vision of pavement defects, of persons and other objects close to the side of the road, and of road signs. In addition, there should be enough light above the horizontal to make visible any overhanging object. Incidentally the headlight also serves as a warning to cars approaching on cross roads. (See also, Sec. 17, Art. 20.)

At present the most generally accepted solution of this problem is the use of two beams, the upper for driving on a clear road, and the lower for meeting and for city driving. Model specifications for these two beams were drawn up by committees of the Illuminating Engineering Society and the Society of Automotive Engineers. With increasing speeds, the use of these two-beam lamps has become less and less satisfactory. The upper beam is not adequate when driving at the rate of, say, 50 miles an hour. This has resulted often in the tilting up of the headlamps so as to get more light at a distance. Again, drivers have been unwilling to sacrifice their road visibility, at such a speed, by depressing when meeting other cars.

Specifications for a new type of headlamp, known as asymmetric, using three instead of two beams, were recommended in 1934 by the Illuminating Engineering Society and the Society of Automotive Engineers, which, it was hoped, would eventually better the situation. In addition to upper and lower beams, as in the earlier type, a third beam, the meeting beam, is provided. In this beam, the right side remains high, while the left side is lowered to a position corresponding to the old depressed beam. With this third beam made available for meeting, it was proposed to set no upper limit on the beam for clear road use.

Obviously, the success of this system depends upon the possibility of training drivers to make use of the meeting beam at all proper times. State automobile authorities have questioned the practicability of this, and the unlimited clear road beam has not yet received general approval.

Except that the earlier limitations on the candle-power of the upper beam have been retained, this three-beam system is now being used on several important makes of cars.

The headlighting situation is in a condition of rapid development at the present time, so that only general statements may advantageously be made with regard to candle-power distribution. The latest authoritative data, at any time, may be obtained from the Illuminating Engineering Society, 29 W. 39th St., New York.

To obtain adequate illumination of objects on the road at 300 to 400 feet, an intensity of several thousand candles is needed straight ahead and on the horizontal 3000 candles with a 32-cp lamp has been specified, but this is an unsatisfactory compromise. In this direction and just below it, the desirable candles are limited only by danger of glare due to the occasional tilting up of the beam.

Such tilting may be due either to bad adjustment, to loading of the back seat, especially in smaller cars, or to slight convex curvature of the road surface. An intensity of 7500 candles at 1 deg down has been specified, which is also an unsatisfactory compromise.

Most of the light-flux from the lamps should be emitted within the upper two deg of

the light beam, but below this, the intensity should fall off rapidly, but uniformly, to prevent excessive brightness of the road-surface near the car.

To make objects ahead of the car, say at 100 feet, which are at or near the side of the road, visible, spreads of the beams of about 6 deg to each side at 1 deg down, and 12 deg at 2 deg down are needed. Thus the top of the bright portion of the beam cross-section should be curved, falling off toward each side of the road. This also makes possible the limitation of the intensity at 1 deg up and 4 deg left to 1000 candles or less, thus keeping down the glare for a car which is being met. For the same reason there should not be over about 2500 candles 1 deg up, along the axis of the car. A plan for using polarized light for headlighting is being developed, which may revolutionize this art.

Contrary to the usual understanding, several surveys have shown that more traffic accidents are due to inadequate road illumination than to glare. A large part of present-day headlighting trouble is due to failure of the automobile owner to keep his headlamps in proper adjustment, particularly as to vertical direction of the headlighting beam. It is a simple matter, at night, to determine whether the top of the beam is approximately horizontal, and if not, to adjust the lamps to make it so.

The recently developed **prefocused automobile bulb** (see Art. 2) is making it possible to reduce the diameter of headlamps to 4 or 5 in., and still obtain satisfactory distribution. Also building the lamps into the front of the car, to obtain streamlining effects, should improve the permanence of their mounting. (Brown and Roper, *Trans. I.E.S.*, 1934, Vol. 29, p. 175.)

7. SPECIFICATION, DESIGN, AND MAINTENANCE OF ILLUMINATION

USES OF ILLUMINATION. Illumination may be classified under three heads, as follows: (1) To facilitate activity; this includes all kinds of work or play. (2) To facilitate the observation of objects; this may be called exhibitive lighting. (3) To promote general comfort and convenience; this is the case where no definite activity or observation is to be provided for. Of the requirements for good lighting, the absence of glare, proper diffusion, shades and shadows, and color have been discussed in Arts. 3 and 4; adequacy remains to be considered.

ADEQUACY. The amount of illumination required for a particular case depends upon the following: (*a*) reflection factor of object, or objects, to be observed; (*b*) fineness of detail; (*c*) length of period during which attention must be fixed upon fine detail; and (*d*) need for the maintenance of bright and cheerful surroundings.

In line with the above principles, much consideration has been given to illumination intensities needed for different activities, and various tables of data have been published; the most authoritative of these are given in the I.E.S. code for the lighting of factories, and for school lighting. An abridgement of these data is given in Table XV. The latest edition of either code, and of various other authoritative publications on the subject of illumination, may be obtained from the Illuminating Engineering Society, 29 W. 39th St., New York City. Mention was made in Art. 3 of the work done by Luckeish and Moss on the relation of the illumination to the nervous strain involved in work. In connection with their claim that, from this point of view, much higher intensities can be justified than are now in use, and recommended in the codes, they call attention to the fact that, since vision follows a logarithmic law, illumination must be increased 10 times in order to double its effectiveness for vision. Hence, they say, a range of illumination such as from 8 to 12 ft-c is not a reasonable one. (Luckeish and Moss, *Trans. I.E.S.*, 1931, Vol. 26, p. 1061.) It should also be said that, from the beginning of modern lighting, illumination intensities to be considered satisfactory have been steadily increasing. Also, that since the best artificial illumination values now in general use are not more than $^1/_5$ to $^1/_{10}$ of that received on a desk by a north window, there seems to be no practical limitation to the process of increase which has been going on. It thus appears logical to use higher, rather than lower, values than those now generally accepted. Incidentally, electric wiring should certainly be designed with the possibility of increased demand in view.

LUMENS REQUIRED FROM THE LIGHTING SOURCES. Two methods are in use for the determination of the required number and size of electric lamps. The point-by-point method is applicable to places where reflection from walls and ceilings is negligible, and where the lights may be regarded as essentially point sources. This is based on the inverse-square and cosine laws, explained in Art. 1. In most cases of interior lighting, however, the contribution of flux from the ceiling and walls is so great as to vitiate the method entirely. When this method is used, it is assumed that the distribution curve of the complete luminaire is known. For determining the size of lamp to be used, the

Stores, medium size	15– 8

* From Standards of School Lighting.
† From General Electric Co., Nela Park Bul. LD-6.

illumination values with an approximately correct size of lamp have to be determined, then, correcting for any differences in the distribution curve, the size of lamp to give the desired values of illumination can be determined by proportionality.

DEPRECIATION FACTOR. In both the point-by-point and the light flux methods, the lumen data used are generally based on new and clean lamps and accessories. During the life of a lamp, there is always a considerable falling off in lumen output, owing both to the depreciation of the lamp itself, and to the accumulation of dust and dirt on the lamp and accessories. A larger lamp, therefore, must always be used than the illumination required would indicate. This may be allowed for by the use of depreciation percentages, which depend upon the type of equipment, the surrounding conditions, and the frequency of cleaning. The depreciated light flux will usually lie between 60 and 80 per cent. It

should probably never be lower than 50 per cent, which indicates a serious loss of light. See also the data of Table XVII.

LIGHT FLUX METHOD. In designing the lighting for large rooms, it is usually assumed that the lamps are close enough together so that the average instead of the minimum illumination may be used. The lumens to be provided from the lamps are then determined from the following equation: $F = \frac{e_h \times a}{u \times d}$, where F = flux to be supplied, e_h = horizontal illumination required, a = area to be lighted, d = depreciated percentage, u = utilization coefficient.

UTILIZATION COEFFICIENT. This is the ratio of lumens available on the working plane or illuminated surface to the total lumens produced by the lamps. It increases with increase of reflection factor of ceilings and walls, and with the ratio of horizontal to vertical dimensions of the room to be lighted. It also depends upon the type of accessories, as indicated in Table XVII.

The success of the light flux method depends largely upon the knowledge of the proper utilization coefficient to use. For this purpose, a large amount of data was gathered together by Harrison and Anderson, and given in *Trans. I.E.S.*, 1920, Vol. 15, p. 97. These data have been revised and extended in *Bul. LD-6*, Nela Park Engineering Department, General Electric Co., in which will also be found a useful chart of reflection factors. A similar reflection factor chart is given in Cady and Dates, p. 298, which also quotes the utilization coefficients table. An abstract of the data of *Bul. LD-6* is given in Tables XVI and XVII. By interpolation, quite satisfactory values of utilization coefficients can be obtained from the figures of Table XVII, not only for the lighting units given, but also for others similar in form and characteristics. The RLM type of reflector with glass neck, known as the glass steel diffuser, runs from 3 to 4 per cent below the RLM with a white bowl lamp, and is given 5 per cent more depreciation. The oxidized aluminum reflector with a clear lamp runs 1 to 2 per cent below the mirror glass reflector. The enclosed semi-indirect unit, for which data are given, is the most efficient of four shown, values on the others running from 1 to as much as 7 per cent lower, the latter figure for high values of the room index.

90	5	5	5	5	5	5	2 1/2	3	3

* L = length, W = width.

For indirect lighting, use ceiling height and add 2, 4, and 8 ft, respectively, to the mounting heights given.

LUMINAIRE MAINTENANCE. The bad effects of luminaire depreciation have already been considered. To the causes of depreciation should be added the loss due to blackening of the ceiling. Where this is supposed to be light colored, it should be regarded as a part of the lighting system, and the maintenance of its reflection factor considered from that point of view. The elements of depreciation, then, are: (*a*) reduced output of the lamp; (*b*) soiling of the lamp; (*c*) soiling of the reflector or globe; (*d*) soiling of the ceiling. Assuming that the illumination is not allowed to fall below a satisfactory minimum, the cost of lost lumen-hours should be balanced against the cost of cleaning, and an economical minimum illumination or an economical cleaning period should be established. This period is likely to differ at different times in the year. Two abnormal causes of loss of light are: reduced voltage due to inadequate wiring (see Fig. 6) and the failure to replace burned-out lamps.

Table XVII. Coefficient of Utilization and Depreciated Percentage

* See Table XVI.

SPACING OF LAMPS. This is likely to be largely affected by the dimensions of the room or the beams on the ceiling. A single lamp should be used only in very small rooms; two lamps, only in long, narrow rooms. In general, the smallest number of lamps used

should be four. As far as practicable, the distance between lamps should be the same in both directions, both across and along the room. Data with regard to mounting height and spacing of units, given by Ward Harrison, are reproduced in Table XVIII. (Cady and Dates, p. 288.) In determining mounting heights, it should be remembered that, with the light ceilings, illumination does not vary inversely as the square of the distance, but is not greatly affected thereby; also that greater mounting height promotes uniformity of illumination. Where very high mounting has to be used, on account of cranes, or for some other reason, a concentrating type of lighting unit should be used.

ILLUMINATION ON VERTICAL SURFACES. So far, only illumination on a horizontal working plane has been considered. Frequently illumination on a vertical plane or some inclined plane is important. In such cases, lighting units must be selected which have a relatively large horizontal component of candlepower in their distribution curve. In some places, where it is desired to provide special illumination for a fixed vertical surface, angle reflectors are recommended. Frequently, in a system of general lighting, special local lighting is provided where extra high intensities are needed. The general illumination should then be sufficient to prevent strong contrasts with the local illumination. It will be noted from Table XVIII that, for moderate mounting height, spacing equal to the mounting height gives satisfactory uniformity.

8. INTERIOR ILLUMINATION. SPECIAL CASES

LIGHTING FOR ACTIVITY. INDUSTRIAL LIGHTING. (See also Kotch, Sturrock, and Staley, *Trans. I.E.S.*, 1933, Vol. 23, p. 57.) Good factory lighting improves operation in the following particulars: (*a*) increases production, by promoting more rapid perception; (*b*) increases accuracy of work; (*c*) promotes healthful conditions for the eyesight of the workers; (*d*) promotes cheerfulness of surroundings; (*e*) tends to prevent accidents; (*f*) facilitates careful oversight by the supervisors; and (*g*) promotes order and neatness. For good industrial lighting, in addition to the features already specified (Art. 7), emphasis is to be placed upon absence of reflected glare, where work is being done on polished materials, high illumination on vertical surfaces, absence of dense shadows, gradual transition from high-grade interior lighting through lower values in hallways to low exterior illumination. Inadequate illumination and blinding glare play parts of considerable importance in industrial accidents. Simpson (*Trans. I.E.S.*, 1920, Vol. 15, p. 576) estimated the cost of industrial accidents where poor lighting was involved as $300,000,000, which exceeded the whole factory lighting bill for the country. Prevention of accidents is the basis upon which legal lighting codes are enacted. Such

codes are usually based upon the I.E.S. Model Code of Lighting Factories, Mills and Other Work Places. *Trans. I.E.S.*, 1930, Vol. 25, p. 607.

Office Lighting. Large clerical offices should be provided with general lighting, usually with large enclosing globes of low brightness. (See Art. 5.) Where typewriters are used, a large component of illumination on vertical surfaces is needed.

Drafting Rooms. Lighting of these calls for special care in the prevention of glare. To provide the high illumination needed, a general system, giving about 10 ft-c, combined with local luminaires with opaque reflectors, may be advisable.

EXHIBITIVE LIGHTING. In exhibitive lighting three general principles apply: (*a*) the light sources must not be visible to the observer—they must either be at his rear, or be screened by reflectors; (*b*) the light sources must be placed to give the most effective distribution over the object to be observed—for flat objects, uniform distribution is generally required; (*c*) an illumination high, as compared with the surroundings, must be provided, if emphasis is desired; (*d*) the direction of the light rays must prevent reflected glare from the surface of the object; (*e*) the color of the light must be suitable. Generally white light is appropriate.

Illuminated Signs, as distinguished from those where the lights themselves form the letters, are usually lighted by one of three methods. (*a*) Floodlights or spotlights (see Art. 6); (*b*) small lamps in frames surrounding the sign; (*c*) the most usual method, lamps with specular reflectors on brackets, generally above the sign, which must be from 1 to 2 ft above the sign to minimize the effects of glare, and for uniformity of illumination must be in front of the sign, by a distance of 60 to 70 per cent of its height. The general range of sign illumination is 2 to 15 ft-c. (Atherton, *Trans. I.E.S.*, 1925, Vol. 20, p. 148.)

Picture Lighting is similar to sign lighting, except that it calls for much more careful design, especially in the matter of color. For pictures painted out-of-doors, daylight color should be supplied. Wall decorations, which will be seen principally by artificial light, as in theaters, should be painted under the light by which they will be seen. Ten to twenty foot-candles is recommended for pictures. The lighting of important pictures by projection lanterns placed at a distance should be considered.

For **show window and show case lighting,** special angle reflectors of mirrored glass or prismatic glass with narrow beams are available. A careful consideration of the general principles of exhibitive lighting is needed. Use of spotlight, possibly colored, to emphasize certain objects in a window, may be effective.

Stage Lighting is, perhaps, the highest form of exhibitive lighting. For lectures and concerts, care must be taken to avoid having the background so bright that the speaker or singer appears as a silhouette. Spotlights directed downward from the sides of the halls to illuminate the speaker or singer are effective. In the footlights and borders, lamps of alternating colors are used. Red, blue, white, and green are desirable. Vacuum tubes are now used to control dimming.

The following additional forms of spectacular lighting may be mentioned: fountains, waterfalls, trees, shrubbery, and garden planting. (Powell, *Trans. I.E.S.*, 1929, Vol. 24, p. 325; La Wall and Cutler, *ibid.*, 1933, Vol. 28, p. 239; Caldwell, Modern Lighting, p. 174; see also Art. 6, Floodlights.)

LIGHTING FOR PHOTOGRAPHY. Mercury-vapor tubes and carbon-arc lamps with special impregnated electrodes are often used. The special photoflood and photoflash lamps (see Art. 2) are inexpensive and convenient. (See also Arts. 2 and 7.)

LIGHTING FOR COMFORT AND CONVENIENCE takes a wide variety of forms. Simple hallways and passageways call for only a moderate illumination—1 to 2 ft-c recommended. (I.E.S. Lighting Codes.) Stairways, on account of the danger of falling, call for special care in lighting. Three to five foot-candles are recommended. Lights must not be so placed that they will shine in the eyes of a person descending the stairs. The use of contrasting color, or reflection factor, on the upper surface at the edges of stair-treads is recommended.

Auditoriums and Churches constitute a high type of lighting for comfort and convenience. Where little or no use of the eyes for reading will be made, 2 or 3 ft-c suffices, unless a higher intensity is desired to produce a bright and cheerful effect. Where reading, as of hymn books, is expected, at least 5 ft-c should be provided. In lecture halls and churches, the lighting on the speaker's manuscript calls for particular care in order to avoid glare in the eyes of the audience. A lens spotlight, mounted in the ceiling, has been used successfully for this purpose. If there is a gallery, care must be taken that its occupants do not suffer glare from low-hung luminaires. Auditoriums, and all rooms, such as hotel dining rooms, which are likely to be used as audience rooms, should be wired for connecting a projection lantern, and also for the control of at least a low, and preferably for both low and high, values of illumination from the lantern location. In the lighting of Gothic churches, special consideration to the esthetic effects is needed.

Residence Lighting. (Caldwell, Modern Lighting, p. 200; Powell and Harrington, *Trans. I.E.S.*, 1919, Vol. 14, p. 394; Artificial light and its application in the home, I.E.S. Committee on Residence Lighting.) This type of lighting, so important to everyone, does not generally receive the careful design which it should have. At least one light should always be placed beside the front entrance, preferably on the wall at the side of the doorway. A low illumination in the hallway is permissible, both for the adaptation of the eyes in coming from out-of-doors, and for economy's sake. Provision, however, should be made for additional illumination for special occasions. For the living room, the taste of the owner should be given special consideration. The choice lies between a general, more or less shadowless illumination from a central ceiling luminaire, or the effects obtained by several portable luminaires and wall brackets. These give a moderate general lighting, with higher local lighting for points where this is needed. More artistic effects can be obtained with this type of lighting. Lamps for reading and writing, especially by students, call for particular attention. A portable lamp, specially designed for this purpose by a committee of the Illuminating Engineering Society, is known as the **I.E.S. study lamp,** and is made by over 40 manufacturers. It carries a special I.E.S. certificate tag. (*Trans. I.E.S.*, 1934, Vol. 29, p. 327.) The exhibitive aspect should always be an important consideration in residence lighting. The **dining room** calls for a central luminaire, throwing the light down upon the table, which should be the point most emphasized in this room. The **kitchen** and other service rooms call for application of the principles of industrial lighting. In the kitchen, two or three wall luminaires may be provided, to light the three important points, the table, the stove, and the sink. **Bedrooms and bathrooms** call for low-placed light sources of moderate brightness at one or both sides of the dressing table. In the bedroom these may well be provided by luminaires attached to the dressing table, and supplied from an attachment outlet in the baseboard. There should also be an attachment receptacle by the bed for a light mounted on the bed, or a portable on a bedside stand. A ceiling luminaire is of doubtful value in a bedroom. A wall bracket or other provision for a 1- to 3-watt night lamp is desirable.

SCHOOL LIGHTING. This is especially important because children's eyes are immature and easily deformed. The I.E.S. Standards for School Lighting covers the subject adequately. In the schoolroom where the children sit and study, particular care must be taken. A minimum illumination of 10 ft-c, obtained generally from 4 luminaires, should be provided. Enclosing globes of low brightness are essential. In special cases, the principles of sign lighting may be applied to lighting a blackboard.

9. STREET ILLUMINATION

PURPOSES. Street lighting is intended to promote public safety from traffic accidents and crime, to promote the comfort and convenience of the users of the street, and to increase its attractiveness. Experience shows that good street lighting attracts traffic and stimulates retail trade. The most important factors affecting the degree of street illumination required are the density of traffic, prevalence of retail business, degree of police supervision needed, and the architectural character of the thoroughfare. In dim light, vision depends primarily on differences of brightness and is but slightly assisted by color distinctions.

TRAFFIC ACCIDENTS AND CRIME. Extensive studies have been made of the effect of lack of visibility, due to inadequate lighting, upon the occurrence of traffic accidents. Through a comparison of the number and character of such accidents during those evening hours which are light in summer and dark in winter, it has been clearly demonstrated that a large part of the accidents which occur after dark could be prevented if streets and highways were more adequately lighted, and that, from a broad point of view, the economic savings resulting from the prevention of accidents would be much more than enough to pay for the needed additional illumination. Conclusions formed in this way have been confirmed by other methods. Rolph, *Trans. I.E.S.*, 1931, Vol. 26, p. 787; Caldwell, *ibid.*, 1932, Vol. 27, p. 828; Simpson, *ibid.*, 1933, Vol. 28, p. 780.) One study of crime made in Cleveland indicated a reduction of 40 per cent due to improved lighting in the retail district; and another study indicated 25 per cent less crime on those thoroughfares, and 50 per cent less on those residence streets, where there was adequate illumination.

STREET CLASSIFICATION. The Committee on Street Lighting of the Illuminating Engineering Society, in its 1927 report (*Trans. I.E.S.*, 1927, Vol. 22, p. 107), recommended the following classification of streets from the point of view of lighting: primary business streets; secondary business streets; thoroughfares, heavy, medium, and light traffic;

residence streets; alleys; highways. Primary business streets generally include those where retail stores, hotels, and theaters are located. Secondary business streets include wholesale districts, factory districts, and sometimes minor retail districts. In primary business streets, extra lighting for the purpose of greater attractiveness is often provided by special assessments. Thoroughfares, sometimes called arterial, are those streets which are the principal routes from the suburbs to the center of the city. Their major lighting problem is due to the heavy automobile traffic between five and six in the winter evenings. Residence streets have usually been quite inadequately lighted. The large

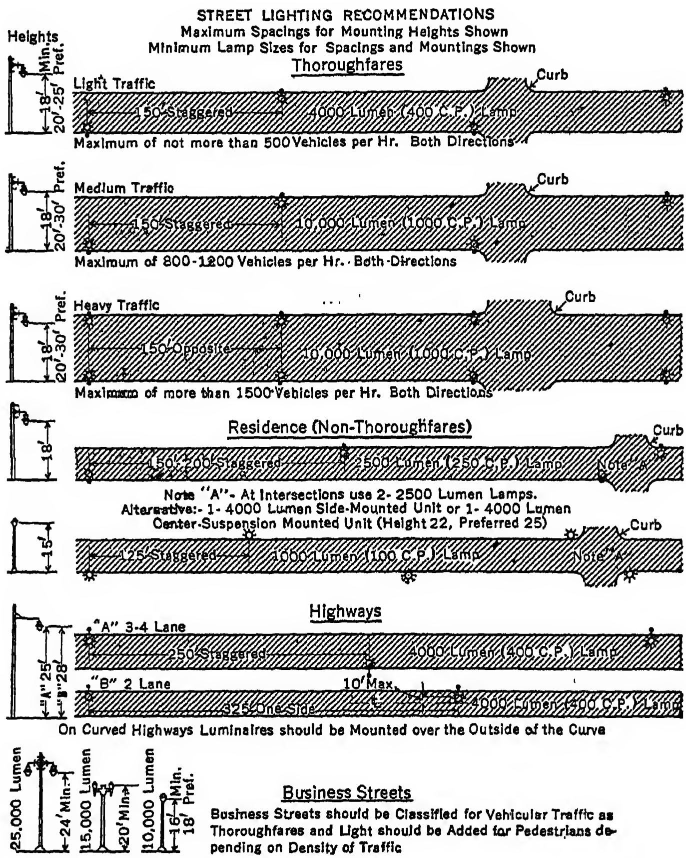

Fig. 21. I.E.S. Street Lighting Recommendations. (Based on the most effective equipment used in the most effective manner.)

mileage of this type of street makes the cost of sufficient lighting a serious problem. Extra lighting of sections of such streets by special assessment is sometimes provided. Lighting data for these different types of streets are shown graphically in the chart of Fig. 21, which was drawn up from the recommendations of the I.E.S. Committee by A. F. Dickerson.

Lighting Conditions on Streets

DIFFERENCE BETWEEN INDOOR AND OUTDOOR LIGHTING. The conditions which differentiate street lighting from interior lighting may be listed as follows: large areas per lamp and hence low illumination; long and narrow areas to be lighted, with special emphasis on illumination of the ground surface; little or no useful light by reflection; vision principally of large objects, generally with limited time for observation.

METHODS OF VISION ON STREETS. Except on unusually well-lighted streets, objects are generally perceived as dark spots against a lighter background. This is known as **silhouette vision**, and largely takes the place of the direct vision of interior lighting. Direct vision, however, plays a greater or lesser part near all street lamps, and on especially well-illuminated streets. Discernment may take place occasionally by the specular reflection of the street lights from a wet or polished surface, and by the shadow caused by some object on the street pavement, or by the sides of a hole in the pavement.

CHARACTER OF PAVEMENT SURFACE. Pavement surfaces may be light, dark, or medium in color, and may be mat or specular, as to their reflecting characteristics. Obviously, so far as the silhouette effect is concerned, the reflection factor of the pavement plays an important rôle. If a dark paving material is used, twice as much light will be needed to produce a given quality of vision as would be needed with a material of double the reflection factor. Every effort should therefore be made to develop and maintain light-colored pavements. When a pavement is wet, the specular reflection from the glossy surface determines the silhouette production, and the color becomes of minor importance.

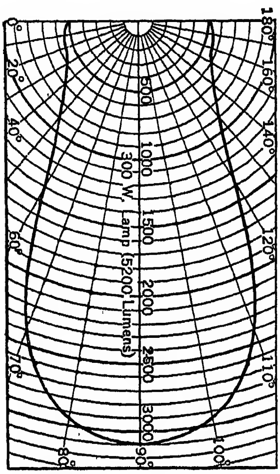
GLARE IN STREET LIGHTING. The code of street lighting (*Trans. I.E.S.*, 1931, Vol. 26, p. 15) gives the following as the effects of glare in street lighting: (1) reduction in ability to see; (2) ocular discomfort; (3) detraction from good appearance of streets. The following facts with regard to glare are well established: all effects of glare are diminished as the glaring light sources are removed further from the center of the field of vision, as by the use of higher mounting. Glare decreases as the candlepower of the light source is decreased, but, for a light source of a given candlepower, glare, as reducing ability to see, is not materially affected by change in brightness, that is, by the presence or size of an enclosing globe. On the other hand, comfort and street appearance are improved by reduction in brightness in the manner indicated above.

Arthur J. Sweet performed an extended series of tests in 1914. (Caldwell, Modern Lighting, p. 223.) Mr. Sweet found that the blinding effects of glare varied as the square root of the candlepower of the light source. He also determined the following relations between height and glare: at 15 ft the glare was $1/2$ of its value at a 12 $1/2$ ft mounting. At 22 ft it was about $1/4$ and at 32 ft $1/8$ of the value at 12 $1/2$ ft. In a test of three systems of 10,000-lumen lamps 300 ft apart with mounting heights of 16, 21, and 26 ft (Harrison, Haas, and Reid, Street Lighting Practice, p. 114), made by some 2000 observers, about 80 per cent picked the 21-ft mounting height, and the other 20 per cent picked the 26-ft mounting height. None chose the 16-ft as being desirable. Increasing mounting height decreases glare, but it also decreases illumination, especially that on the pavement below the lamp, which produces silhouette vision. Many tests made by shielding off the street lighting from the eyes of the observer have indicated that the effect of glare was to reduce the effectiveness of the street lighting from 25 to 50 per cent. Globes of square horizontal cross-section which can be equipped with a rectangular screen to keep glare off of residence porches and windows are made. The trunks of trees planted between the sidewalk and the curb frequently cause serious shadows on the sidewalk. It is very desirable, for this and other reasons, that street trees should be planted on the lot-line instead of near the curb line.

LIGHT DISTRIBUTION OF STREET-LIGHTING LUMINAIRES. Peculiar conditions found in street lighting put special importance on the light distribution of the luminaires. As already indicated, the relative importance to be given to direct vision and to silhouette effects is largely determined by the grade of illumination to be found upon the streets. In the best of business street lighting, direct vision is important, but as the grade of illumination is lowered, on second-grade business streets and thoroughfares, the use of direct vision decreases, and there is a considerable range where the relative importance of the two types of vision is open to argument. To promote direct vision, it is evidently important that there should be a high candlepower, somewhat below the horizontal. On the other hand, for silhouette vision on moderately light mat pavements, the greatest effect is usually attained by silhouette against the bright spots below and near the lamps. With highly specular pavements, no such spots exist, and the silhouette effect also will be due to the light directed slightly below the horizontal.

To meet these different conditions and points of view, a variety of modifying accessories, diffusing and prismatic globes, urns, bowls, and lanterns, are available. A plain white or diffusing glass globe of sufficient density gives a fairly uniform candlepower distribution, resulting in a great difference in illumination at different points on the street, but with comparatively low brightness of the luminaire surface. In diffusing bowls and in lanterns with metal frames, reflectors are often used over the lamps to bend down the upward-directed light. By making the reflector an inverted cone with properly curved elements,

some of the upward-directed light may be sent along the street. Where such opaque reflectors are used on business streets, an unpleasant effect is often produced by the sharply cut-off shadows on the fronts of buildings, above the level of the lamps. Desirable architectural features may also be concealed. Similar conical reflectors may be used below the lamps, but here the question arises as to whether the light so reflected would not be more useful in producing the bright spots for silhouette effects on the pavement. This flux, because of the nearness of the pavement surface, is quite effective in producing a high illumination near the lamp, but the same flux spread out over 360 deg near the horizontal will add very little to the illumination in this direction.



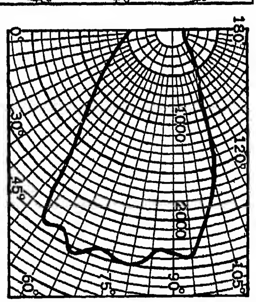


Fig. 22. Horizontal or Lateral Distribution Curves for Holophane Refractors. *A*. Refractor No. 4376, 300-watt lamp. *B*. Refractor No. 4377, 300-watt lamp.

The horizontal prisms on refractors (see Art. 5) may be designed to give almost any vertical distribution of the light which is desired for the lighting of the street, and it is upon these that principal dependence has been placed for obtaining high candlepower directed about 15 deg below the horizontal, at the expense of upward- or downward-directed light or both. Where it is desired to use only the upward-directed light in this way, a hemispherical refractor is used above the light source and extending slightly below it. Such a lighting unit is often enclosed in a stippled or rippled glass bowl with a metal cap. Deep bowl-shaped refractors which surround the lamp and fit into a metal top may be designed to take as much of the downward-directed light as can be spared from the pavement beneath the lamp, and to redirect it nearer to the horizontal. Asymmetric refractors (see Art. 5) are used to direct the light in two beams 180 deg apart, or in four beams 90 deg apart, or in two beams somewhat less than 180 deg for lamps mounted at the curb. Fig. 22 shows the general character of distribution curves for two such refractors.

LAMPS FOR STREET LIGHTING. The only lamps now in extensive use for street lighting are gas-filled incandescent lamps, either constant current or constant potential. (See Art. 2 for data.) The use of constant-current series systems has come over from the days of arc-lamps, and it seems not unlikely that the future will see a gradual change to constant-potential lamps, which are, indeed, already in extensive use for street lighting.

"There are no conditions of street lighting prevailing in the United States which justify the use of smaller than 1000-lumen lamps. The 2500-lumen lamp is the smallest size which may be used with good economy." (Street Lighting Code, *Trans. I.E.S.*, 1927, Vol. 22, p. 107.)

Luminous or magnetite arc lamps were installed extensively at one time, and many are still in use, but they are no longer being put in as new equipment. Two other light sources are seriously advocated for street and highway lighting. These are the sodium-vapor and the high-pressure mercury-arc lamps. (See Art. 1 for data.) One or both of these types of lamps will probably replace incandescent lamps in some cases, especially for highway lighting, on account of their high efficiency. How much their peculiar color characteristics will affect their usefulness remains to be seen. Carefully designed aluminum reflectors are claimed to increase the effectiveness of incandescent lamps, about four times.

LOCATION AND SPACING OF LIGHTS. Two principal methods of mounting street lamps are: (*a*) upon brackets, or yardarms, carried on ornamental poles, trolley poles, or distribution line poles; (*b*) on the tops of ornamental columns or posts. The first of these methods is the one most commonly used on residence streets and thoroughfares. Except where the illumination is high, this method is much to be preferred to the mounting on the tops of columns, both because it permits of higher mounting and also because it facilitates having the lamp over the street pavement, thus greatly improving silhouette vision, especially when the pavements are wet or polished.

Spacing, mounting heights, and lamp sizes are given in the lighting code chart of Fig. 21. It is to be noted that the figures given therein are not claimed to be optimum, but to repre-

sent good current practice. As indicated above under *Traffic Accidents and Crime*, it is probable that much higher illumination than that obtained with these recommendations can be justified from a broad economic point of view. As shown in Fig. 21, one-side mounting should be used only on low-traffic highways. Staggered mounting is suitable for all except heaviest traffic thoroughfares and business streets, and here the opposite mounting recommended is principally on account of appearance. The overhang, beyond the curb, of lamps upon brackets or yardarms, is determined principally by appearance and cost. From the point of view of illumination, the center of the traffic lane is the ideal location, but conditions of cost and appearance and the cleaning of lamps often necessitate shorter arms.

There should always be at least one lamp at every intersection. This is especially important on residence streets and minor thoroughfares, where driving speeds are likely to be great and illumination values low. On curves, it is best to have all lights on the outside of the curve; also on dead-end streets, to have a lamp opposite the center line.

APPEARANCE OF THE STREETS. The increasing importance that is being given to esthetic values indicates the careful selection of all street-lighting equipment from this point of view. In such selection of equipment, it is desirable to have involved some one with artistic and architectural training, or better still, a committee of several such persons.

SPECIFICATION AND JUDGING OF GOOD STREET LIGHTING. The design of lighting should, but seldom does, begin with the reflection factor of the pavement. The selection of type of equipment, size of lamp, mounting height, and spacing should be made in line with the principles and practice set forth in the foregoing statements. In the construction specifications, these specific data should be definitely set forth. In comparing different systems as to their effectiveness in street lighting, it is advisable to analyze them into a number of elements, and then, by using weightings for these various elements, as judged on a percentage basis, the net or total percentage value for each of the two or more equipments may be obtained. Such an analysis with recommended weightings was undertaken by the Street Lighting Committee of the Illuminating Engineering Society. These weightings were never published as an authoritative report, but doubtless they constitute the best information at present available. These are given in Table XIX. (Charles J. Stahl, Electric Street Lighting, p. 187.)

Because of surrounding conditions, illumination tests made upon streets are very unsatisfactory. It is much better to make or obtain distribution curves or isocandle curves for the units to be used, and then to calculate the illumination values on the street from these data. To facilitate this work, useful curve sheets and nomograms have been developed by Benford, Goodall, Putnam, and others.

Table XIX. Suggested Weightings for Judging Street Lighting

	Maximum Points Allotted	
	Residence Side Street	Traffic Thoroughfare
A. To Motorist:		
1. Average pavement brightness	23	25
2. Distribution of brightness	11	14
3. Vertical illumination	11	17
Negative—Glare		
B. To Pedestrian between Curbs Including All Cross Walks		
1. Conspicuity	11	11
2. Visibility	8	8
Negative—Glare		
C. To Pedestrian on Sidewalk:		
1. Horizontal illumination	6	4
2. Vertical illumination	8	5
3. Distribution of illumination	9	6
Negative { Glare, Shadows		
D. To Occupants of Property:		
1. Protection afforded	9	7
2. Visibility	4	3
Negative—Glare		
Total	100	100

HOUSEHOLD HEATING APPLIANCES AND COOKING

By Frank Thornton, Jr.

11. POWER RATING OF APPLIANCES

The following table shows the range of rated inputs for the principal household applications of electricity and also the probable average yearly consumption of power, which is, of course, subject to wide variation depending on habit, size of family, climate, etc.

Application	Power Consumption		Application	Power Consumption	
	Input, watts	Annual Consumption, kwhr		Input, watts	Annual Consumption, kwhr
Hair curler	18	1.0	Portable heater	600–1250	96.0
Waffle iron	600–900	30.0	Range	7000–10000	1,600.0
Toaster	500–850	50.0	Water heater	1500–6000	3,900.0
Percolator	450	50.0	Ironing machine	1320	100
Pressing iron	550–1000	72.0			

See Sec. 2, Art. 6 and Sec. 18, Art. 21 for resistor materials. Also Sec. 2, Art. 10 and Sec. 18, Art. 22 for insulating materials.

12. SMALL APPLIANCES

The most widely used appliance is the pressing iron. These irons are usually 6 lb in weight, highly polished, and either nickel or chromium plated. Non-automatic irons are 550 watts input. The automatic iron contains a built-in thermostat to regulate the temperature, thereby eliminating the necessity of watching the temperature to avoid scorching.

Adjustment of the temperature is possible by means of a button on the top of the iron. The maximum is set at some point below 600 deg fahr surface temperature, because it has been found that this is above the usual ironing temperature and still not high enough to ignite readily the padding on an ironing board and start a fire if inadvertently left standing too long.

Automatic irons with inputs up to 1000 watts are now available. These irons are fast enough to avoid all delays due to wet cloth or fast work by the operator.

Waffle irons are also available with automatic temperature regulation.

Toasters are on the market with time control features.

Percolators have protective thermostats or fuses.

There is a multitude of small appliances of many different types of construction. Nickel chromium wire or ribbon is used in all of them. For electrical insulation a number of different materials are used, the principal one being mica. The usual practice is to design a mica form to fit the space available for the heater and wind the wire or ribbon on it. This is insulated on both sides with other sheets of mica and clamped solidly between two metal parts. Another type consists of a tube containing a coil of wire embedded in powdered magnesia. The tube is contracted upon the insulation to make good thermal contact, and the whole assembly formed by bending into a shape to fit the available space in the appliance.

Radiant heaters are made by assembling a helical coil of resistance wire on a porcelain insulator of spool or other shape. Reflector-type portable radiators are examples of this construction. Mica is often used as the support for radiant heaters as in toasters.

In view of the fact that the heater must be designed as a part of the completed appliance there are no standardized heating elements for use in these devices.

13. RANGES

HOUSEHOLD RANGES. Household ranges are built in a wide varaiety of sizes and shapes. They all consist of an oven and two or more surface burners. Some include warming compartments and storage spaces.

Ovens are most commonly available in 14-, 16-, and 18-in. widths. They are usually well insulated with mineral wool to reduce loss of heat.

Surface burners are usually approximately 6 or 8 in. in diameter. Different makes vary slightly from these dimensions because of differences in design details. The following table gives approximately the range of watts input found in ovens and surface burners.

Table of Heaters in Electric Ranges

Heater	Wattage
Bottom heater—14-in. oven	1320 to 1500
" " —16-in. oven	1500
" " —18-in. oven	1500 to 1800
Surface burner—6 in.	1200
" " —8 in.	1500 to 2250
Warming compartment	300

Oven heaters consist of open coils supported in heat-resisting porcelain insulation arranged to radiate heat directly into the oven. Top heaters are generally duplicates of the bottom heaters and are used only for quick heating of the oven, broiling, browning, or searing.

Hand control is provided for each heater. In some cases three heats are provided; others provide only single heat. Ovens are usually equipped with automatic temperature control and often with a clock so that the cooking can be automatically started at a predetermined time.

Surface burners are of two types—open and enclosed. Open burners are most commonly used and consist of a special heat-resisting porcelain molded into a circular disk with grooves in the surface in which the bare wire coils are assembled. Transfer of heat to the bottom of the cooking utensil is largely by radiation from the red-hot wires. Enclosed burners are made in several ways, and in all designs the heating coils are enclosed in a metal casing of some kind. In some makes this takes the form of flat castings with grooves in the bottom in which the coils are embedded. Another has a sheet-metal casing containing heater coils embedded in a cement processed in a special manner. In a third make the casing is a tube in which the heater coil is assembled with a compacted insulation of magnesia powder.

Surface burners are each controlled by a three-heat series-parallel switch.

The total capacity of an electric range may be from 7000 to 10,000 watts depending on size and number of burners, but the average is about 8000 watts. All burners are almost never used simultaneously at full heat so that the maximum demand is usually much less than this value.

THE COST OF COOKING depends on the number of persons in the family, the kind of meals served, the skill of the user, and the rate for current. The curve in Fig. 1 gives an idea of the power requirements for electric ranges under average conditions. This does not include the power required for lights, extra appliances, water heating, etc.

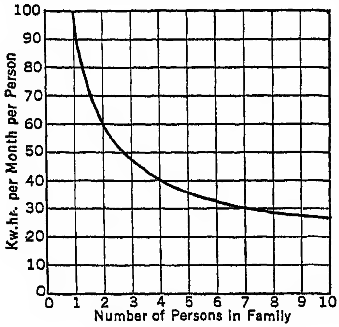

Fig. 1.

COMMERCIAL COOKING. Hotel and restaurant kitchen equipment is available for all the operations of cooking that are needed.

RANGES consist of a flat cooking top with oven beneath. Automatic controls are available for ovens. A typical range is as follows:

Cooking surface 36 in. wide by 24 in. deep with four cooking plates, two front plates at 5000 watts each and two rear plates at 4000 watts each.

Oven 22 in. wide by 28 in. deep by 14 in. high, heaters in top and bottom each 3000 watts.

Total maximum load, 24,000 watts.

Bread ovens are usually of the sectional type capable of baking 20, 40, 60, and 100 loaves of bread (1 lb per loaf) on each shelf. Sometimes two and occasionally three shelves may be assembled one above the other on the same base. Each shelf is a complete oven in itself with heaters and automatic temperature control.

The average energy consumption will be between 100 and 200 watthours per loaf, depending on the character of the dough, size of loaf, and skill of the baker.

Other appliances are coffee urns, steam tables, waffle irons, sandwich toasters, hot plates, griddles, fry kettles, etc.

The cost of operation varies in different kinds of restaurants. Institutions in which a definite menu is prepared and served at a definite time can be operated at the lowest cost, whereas special-order restaurants which must be ready to serve at all hours must of necessity keep their kitchen equipment hot continuously. However, the following table will give some idea as to the approximate energy requirments of the completely electrified kitchens of various types of restaurants.

Energy Requirements

Type of Restaurant	Watthours per Meal Served
Cafeterias	300– 600
Clubs	600–1000
Hotels	350–1000
Hospitals	200– 350
Institutions	150– 350
Restaurants	600–1000

WATER HEATING

By C. J. Fay and J. H. Reifenberg

15. PRINCIPLES

Water is usually heated by electricity by immersing an insulated resistance type of heater in the water to be heated. Occasionally resistance heaters are clamped to the outside of the tank or vessel in which the water is to be heated, and very rarely induction-type heaters are used. The size of heater for any particular application is dependent upon the amount of hot water required, its temperature, the capacity of storage tank, and the length of time the heater may be connected to the power circuit.

One Btu is required to heat 1 lb of water 1 deg fahr.
One gallon of water weighs 8.336 lb at 62 deg fahr.
One kwhr is equivalent to 3412 Btu.
2.443 watts will raise 1 gal of water 1 deg fahr in 1 hr.

$$\text{Size of heater in kilowatts} = \frac{\text{Gallons of water} \times \text{deg fahr rise desired} \times 2.443}{1000 \times \text{Time in hours}}$$

One kilowatthour will heat 4.1 gal of water 100 deg fahr.

For the various household uses the following table gives the approximate quantities of hot water required and the temperatures at which it is to be used.

	Quantity, gal	Temperatures, deg fahr
Bathtub	10 to 15	95 to 100
Shower	12 to 20	95 to 100
Dishes	2 to 5	115 to 145
Face washing	1/2 to 1	95 to 100
Hands	1/2 to 1	100 to 105
Washing machine	10 to 20	145 to 160
Rinsing—first	5 to 10	115 to 120
Rinsing—second	5 to 10	90 to 95

16. DESIGN OF HOT WATER HEATERS

Immersion heaters permit constructions of complete water heaters giving the most economical operation. Such complete heaters consist of storage tank completely surrounded by heat insulation, with the heating element mounted in the storage tank, and the whole encased in a sheet-metal casing. Thermostats for controlling the temperature of water are either mounted in the headers of the heating elements on the storage tank, or suspended in the tank, usually in tubular casings.

STORAGE TANKS. Storage tanks are usually constructed of sheet steel with electrically welded seams and joints and are completely galvanized inside and out. Where foreign matter in the water attacks and corrodes galvanized steel, copper, copper-alloy or monel tanks are used. On copper tanks, the seams are usually riveted and soldered while the copper-alloy or monel tanks have welded seams. Copper and copper-alloy tanks usually are lined with block tin, as some water will react with the copper to produce a bluish-green tinge in the water. Tank sizes vary from 2 to 120 gallon capacities with special ones even larger.

IMMERSION HEATERS. Immersion heaters are of two kinds: (1) helical coils of nickel-chromium wire surrounded by magnesium oxide, or one of the various insulating cements, within a tubing or casing, usually copper; and (2) helical coils of nickel-chromium wire mounted in or on blocks of porcelain or other refractory material. Heaters of class 1 are generally mounted in a header either singly or in multiple, and the header is threaded with standard pipe thread or arranged for bolting to adaptors welded to the tank. The casings of heaters of class 2 are usually water-tight tubular wells welded to the tank. Heaters may be inserted horizontally through the side wall of the tank or vertically through either top or bottom heads. In those designs using vertical mounting the heaters are usually surrounded by a circulation tube extending practically the full length of the tank. The cold water drawn in at the bottom end of the tube is heated by the heater and discharged from the top of the tube. In this manner it is possible to heat a small quantity of water rapidly and deposit it at the top of the tank. This is also accomplished in those tanks having heaters inserted in the side walls by using two heaters, one at the bottom and one near the top of the tank; the top heater will heat only the water above it.

EFFICIENCY. The efficiency of operation of an electric water heater depends primarily on the effectiveness of the heat insulation in reducing the radiation losses from the tank and its fittings. Balsam wool, mineral wool, paleo bark, hair felt, and granulated cork are the heat insulations generally used. Thickness of insulations vary from 2 1/2 to 5 in. For equal thicknesses the insulating values of these materials differ but slightly. Practically all outside casings are of sheet steel with japanned or enameled finishes.

THERMOSTATS. Thermostats are usually adjustable, permitting the maintenance of water temperatures most suitable for the particular user. The heat-responsive member may be bimetal in the form of a formed disk with snap action or a strip operating a toggle mechanism, gas-filled bellows, or rods of dissimilar metals. When non-adjustable thermostats are used, temperatures of water are usually maintained from 145 to 160 deg fahr.

When economy of operation is not an important factor immersion heaters may be assembled in the 1-in. openings in the side walls of the ordinary range boilers or in a pipe casing and used as a circulation heater outside of the tank, or strap-on heaters may be clamped around the tank. Since bare tanks will radiate heat very rapidly, the tanks should at least be covered with a commercial tank cover. With water 70 deg fahr above the temperature of the surrounding air, the ordinary 30-gal bare range boiler will radiate approximately 725 watthours per hour and a 40-gal tank approximately 850 watthours.

Commercial tank covers are built up of layers of air-cell-asbestos, magnesia, or similar materials formed to fit the ordinary tanks and covered with canvas or duck. Such covers will reduce the radiation losses approximately 75 per cent.

17. TESTING

Electric water heaters are tested for (1) rate of heating, (2) heat loss, and (3) draw off. Thermocouples and potentiometer are used for measuring temperatures of the water, the thermocouples being soldered to the storage tank, one on each tank head and four equally spaced from top to bottom on the side wall. For draw-offs additional thermocouples at inlet and outlet are used to measure temperatures of water drawn into and from tank.

RATE OF HEATING. In this test the tank is filled with cold water, the heater turned on and allowed to heat until the thermostat cuts the heater off. The efficiency of heating is determined by the following formula:

$$\text{Per cent efficiency} = \frac{C \times (T_2 - T_1) \times 0.00243 \times 100}{\text{Kwhr}}$$

where C = actual capacity to tank in gallons.
T_1 = average water temperature at start.
T_2 = average water temperature at end.
Kwhr = kilowatthours consumed by heater.

HEAT LOSS is determined by permitting the heater to operate under control of its thermostat, without any water being drawn from the tank, and measuring the wattage consumed. The water must be permitted to reach constant cut-off and cut-on temperatures, and then the test must be started just after the thermostat cuts off, be permitted to run for not less than 72 hours, and be terminated just after the thermostat cuts off.

$$\text{Heat loss in watthours per hour at } (T - t) = \frac{\text{Watthours input}}{\text{Time in hours}}$$

where T = average water temperature.
t = average room temperature.

All temperatures must be read at least every hour and at every cut-on and cut-off operation of the thermostat in order to get a correct average. For all practical purposes the heat loss varies directly as temperature rise $(T - t)$ for the well-insulated tanks.

DRAW-OFF TESTS. Extensive studies have shown that the average family of 4 to 5 persons in the northern part of the United States uses approximately 1285 gal of 145 deg fahr water per month. Different quantities of water are used each day, but the days may be divided into three classes, as minimum, normal, and maximum days, with average usages of 20, 50, and 75 gal, respectively. In a month there are 12 minimum, 13.4 normal, and 5 maximum days.

Table I

Time	Minimum Day	Normal Day	Maximum Day
6:30 A.M.	..	8	8
7:30 A.M.	3	4	4
8:00 A.M.	2	2	13
9:00 A.M.	2	3	10
10:00 A.M.	..	3	10
11:00 A.M.	2	3	3
12:00 N.	3	3	3
1:00 P.M.	1	5	5
5:00 P.M.	..	2	2
6:00 P.M.	1	3	3
7:00 P.M.	2	4	4
9:00 P.M.	4	..	..
10:30 P.M.	..	10	10
Totals. . .	20	50	75

On the basis of the above, standard draw-off schedules given in Table I are used for comparison of water heaters.

The heater should be preheated and idling on its temperature control, so that a tank full of hot water will be available at the start of the test. A test extends over a period of 24 hours. Water meter in the cold water line is used to measure quantity of water drawn. Curve-drawing temperature recorders should be used for measuring tank temperatures; however, when they are not available readings should be taken of each thermocouple 15 minutes before first draw off and at 30-minute intervals throughout the 24-hour test. Temperature must be read of each gallon of water withdrawn.

Records are made of the following: (1) average temperature of water in tank at beginning of test; (2) average temperature of water in tank at end of test; (3) average temperature of incoming water; (4) average temperature of water withdrawn; (5) average

room temperature; (6) kilowatthour input; (7) average temperature of water in tank during 24-hour period.

These data are corrected to a common basis of 75 deg fahr room temperature, 50 deg fahr incoming water, and 150 deg fahr water withdrawn, and the following calculations are made:

(1) Tank losses = Input − Output

(2) $\text{Tank efficiency} = \dfrac{\text{Output}}{\text{Input}}$

(3) $\text{Gallons of water of 100 deg fahr rise per kilowatthour} = \dfrac{\text{Input}}{\text{Gallons drawn}}$

(4) $\text{Daily load factor} = \dfrac{\text{Input}}{24 \times \text{Connected load}}$

By obtaining above results for each of the three daily demands, i.e., minimum, normal and maximum, and combining in the ratio of 12, 13.4, and 5, similar results are obtained for monthly operation.

18. PERFORMANCE

Since 1 kwhr will raise the temperature of approximately 4 gal of water 100 deg fahr the amount of water that any water heater will heat depends upon the rating of the heater and the length of time the heater may be connected to the power line. Radiation losses reduce the amount of effective heat supplied. In the factory-built complete tanks, radiation losses vary from approximately 35 watts for some of the smaller tanks to as much as 135 watts for some of the 120-gal sizes with water in tank 70 deg fahr above room temperature. For 30-gal range boilers equipped with immersion heaters or strap-on heaters and commercial tank covers, radiation losses vary from 105 to 185 watts under similar conditions, and 30-gal factory-built heaters from 60 to 90 watts.

The quantity of hot water that can be drawn from a tank at any one time depends on the storage capacity of the tank, the rating of the heating element, and the length of time the heating element has had to preheat the water.

19. INSTALLATION

Electric water heaters should be installed as closely as possible to the point at which the most hot water is used so as to require a minimum of hot water piping. All hot water piping should be covered with heat insulation to minimize radiation losses therefrom. Heat losses from bare pipe are shown in Table II.

Table II. Heat Loss from Bare Pipe

Size of Pipe, in.	Watthours Lost per Foot Length per Hour per Degree Fahrenheit Difference in Temperature	Size of Pipe, in.	Watthours Lost per Foot Length per Hour per Degree Fahrenheit Difference in Temperature
1/2	0.133	1 1/2	0.298
3/4	0.165	2	0.373
1	0.200	2 1/2	0.451
1 1/4	0.260		

Return circulation systems should be avoided since hot water is circulating continuously in such systems and, therefore, heat being lost by radiation continuously.

20. OPERATION

Water heaters are operated either continuously or intermittently. Continuous service may be on peak, off peak, or semi-off peak.

For intermittent service the heater is equipped with switch for manual operation and is turned on only when hot water is desired and turned off as soon as the immediate requirement is satisfied. This is the most economical method of operation, as radiation losses are very low. The user, however, must anticipate his needs far enough in advance to allow the heater time to heat the water to the temperature desired and must also remember to turn the heater off or equip it with a time limit switch. A thermostat prevents the water from heating above the maximum desired temperature. A small or medium-

sized tank (10 to 18 gal) with high-wattage heater (3 to 5 kw) is commonly used for this type of service.

For **on-peak service** the heater is connected to the power service permanently and its thermostat maintains the water between definite limits. Any combination of tank and heater can be used, depending upon the demands of the consumer and the capacity of the utilities transmission system and generating equipment. Hot water is always available. Operating costs are slightly higher since more hot water is used where it is constantly available. Standby losses are also slightly higher.

For **off-peak service** the heater is connected to the power service through a time switch or a relay, actuated from the power plant. Power is supplied to the heater only at such times as the demand for power for other service plus that for hot water service does not exceed the peak load of the system. Generally utilities sell power for off-peak service at lower rates than for on peak. Thermostats prevent the water from attaining temperatures higher than desired. Tanks must be of sufficient capacity to supply the maximum demand for hot water between heating periods, and heaters must be of high enough rating to reheat the full tank of water during the heating period. Proper selection of tank size and heater rating will give the lowest cost continuous hot water service.

Tanks for **semi-off-peak service** are equipped with two heaters: the bottom heater on off-peak service and the top heater on on-peak service. When abnormal demand exhausts the hot water before it is time for the bottom heater to reheat the tank again, the top heater will supply normal demands. Power for this top heater is usually paid for at the on-peak rate and for the bottom heater at the off-peak rate. Two meters are required.

HEATING AND AIR CONDITIONING OF BUILDINGS

By Otto W. Walter

22. HEAT LOSSES AND CALCULATIONS

In order to maintain a constant room or building temperature, heat must be supplied at the same rate as that at which it is lost from the inside. The heat losses are of two kinds:

(*a*) Transmission losses by direct conduction through walls, windows, doors, ceilings, and floors.

(*b*) Infiltration losses due to air leakage around windows and doors, through cracks, and to some extent through porous walls, ceilings, and floors.

The evaluation of these losses in Btu per hour constitutes the correct basis for the selection of the proper size of heating equipment for any building.

HEAT LOSSES BY TRANSMISSION. Heat loss by conduction directly through walls, ceilings, and other areas occurs when the temperature on the outside is lower than the temperature on the inside.

Let H_t = heat lost by transmission in Btu per hour.
U = heat transmission coefficient in Btu per hour per square foot of surface (wall, window, ceiling, etc.) per degree Fahrenheit temperature difference.
S = area of wall, glass, ceiling, etc., in square feet.
t = temperature of air inside room in degrees Fahrenheit.
t_0 = temperature of outside air in degrees Fahrenheit.

$$H_t = US(t - t_0) \tag{1}$$

The value of U may be taken from Table I, or from more complete tables of these coefficients given in Mechanical Equipment of Buildings by Harding and Willard, the Guide of the American Society of Heating and Ventilating Engineers, and other handbooks. (See Bibliography.) The heat transmission coefficients may also be calculated from the thermal conductivities and the thickness of the wall or ceiling materials. For a wall of a single homogeneous material

$$U = 1\Big/\left(\frac{1}{f_i} + \frac{1}{f_0} + \frac{x}{k}\right) \tag{2}$$

Where f_i and f_0 are inside and outside air surface conductances for the material in contact

with air expressed in Btu per square foot per hour per degree Fahrenheit temperature difference; k is the thermal conductivity of the homogeneous building material expressed in Btu per hour per square foot per inch of thickness per degree Fahrenheit temperature difference; and x is the thickness of the building material.

For a compound wall having several materials and air spaces

$$U = 1 \Big/ \left(\frac{1}{f_i} + \frac{1}{f_0} + \frac{x_1}{k_1} + \frac{x_2}{k_2} + \ldots + \frac{1}{a_1} + \frac{1}{a_2} + \ldots \right) \tag{3}$$

where the x's and the k's are respectively the thicknesses and the thermal conductivities of the different homogeneous building materials, and the a's are the conductances of the air spaces. Thermal conductivities may be taken from Table II, and air space conductance from Table III. Thermal conductivities are given in Table II, that is Btu per square foot per inch thickness per degree Fahrenheit temperature difference, except in cases indicated where a standard thickness applies, when the conductance C is given in Btu per square foot per degree Fahrenheit per thickness specified. The value of f_i may be taken as 1.65, which is an average value for the air surface conductance for a smooth surface with still air expressed in Btu per hour per square foot per degree Fahrenheit temperature difference. The value of f_0 may be taken as 6.0, which is an average value of air surface conductance for a 15-mile-per-hour wind velocity expressed in Btu per hour per square foot per degree Fahrenheit temperature difference.

In some cases, in calculating the heat-loss coefficients for walls or ceilings which are insulated by filling between the studs or joists, it is necessary to take into account the fact that the space occupied by the studs or joists will not be filled with insulation. This can be done by considering the path through the studs and the path through the insulation as parallel paths analogous to parallel resistances in the electric circuit. In frame construction where 2-in. studs are 16 in. on centers about 15 per cent of the wall area is not filled with insulation if a small allowance is made for headers and fire stops. A close value of the average coefficient is obtained by calculating the coefficient for the section through the studding and the coefficient for the section through the insulation and combining these two values according to the law of parallel conductances by the formula

$$U = 0.85U_i + 0.15U_s \tag{4}$$

where U_i and U_s are the heat-transmission coefficients for the sections through the insulation and the studs, respectively. In ceilings where headers and obstructions are less likely to occur the space occupied by the joists may be taken as 10 per cent instead of 15 per cent, and formula (4) can be modified accordingly. This method of calculating the average coefficient assumes that the direction of the heat-flow lines are always perpendicular to the surface of the walls. Another method assumes infinite conductance to lateral flow of heat perpendicular to the wall surface. The true value lies between the values obtained by these two methods. In calculating the coefficients for complicated compound wall structures, a great deal of assistance will be obtained by considering the analogous electrical circuit.

INFILTRATION LOSSES. The calculation of the heat loss by infiltration is based on the volume of outside air leaking into the building

$$H_i = 0.018Q(t - t_0) \tag{5}$$

where H_i equals Btu per hour required to raise the temperature of the air leaking into the building, Q equals cubic feet of air entering per hour, t equals inside temperature in degrees Fahrenheit, t_0 equals outside air temperature in degrees Fahrenheit, and 0.018 equals the product of the density and specific heat of air (0.075 × 0.24), or the Btu to raise 1 cu ft of air 1 deg fahr.

An approximate method of getting the volume of air leakage is to assume a certain number of air changes per hour in accordance with the average values given in Table IV or Table VI. However, the more accurate method is to base the leakage estimate on crackage. The crackage around doors and windows and the area of any porous or poorly constructed walls are multiplied by leakage coefficients giving the cubic feet of air leakage per hour. A brief list of leakage coefficients summarized from research studies is given in Tables V and VII. Since the leakage is caused chiefly by pressure built up by the wind velocity, the cold air leaks in on the windward side of the building and the warm air leaks out on the opposite side. Therefore in calculating the volume of infiltration air only half of the total crackage of the building is used. In getting the feet of crackage, add the perimeters around all outside doors and window sash, including the perimeter along the meeting-rails of the sash.

In some cases it is necessary to provide air for ventilation in addition to that entering by natural infiltration. The amount of air required per person for various classes of

service for good ventilating practice is given in Table VI. The heat required to heat this air must be included in the total heat loss estimated.

HEAT-LOSS CALCULATIONS. A formal detailed calculation of the heat losses of the building is the most accurate and the proper basis for selecting heating equipment. However, a preliminary or rough estimate may be made by using any one of several rule-of-thumb methods, but these short rules should not be relied upon except as first approximations. In Carpenter's short rule the loss in Btu per hour is given by

$$H = (0.02\,NC + G + 0.25\,W)(t - t_0) \tag{6}$$

where N equals the number of air changes (see Table IV).
C equals the volume of the building in cubic feet.
G equals the glass and door area in square feet.
W equals net wall and ceiling area in square feet.
$(t - t_0)$ equals temperature difference between inside and outside air in degrees Fahrenheit.

Harding and Willard's rule is similar to Carpenter's rule except that the infiltration loss is based on crackage.

$$H = (1.2\,P + G + 0.25\,W)(t - t_0) \tag{7}$$

where the notation is the same as above except that P equals not less than one-half of the total window and door crackage in feet.

The following procedure is given for making a detailed formal calculation of the total heat loss for a building:

1. Ascertain the inside temperature which is to be maintained at the breathing line (5 ft from the floor) during the coldest weather.
2. Determine the minimum outside temperature to be used in the estimate, basing this temperature on Weather Bureau records.
3. Calculate and tabulate the net outside wall, ceiling, window, door and floor areas, as well as areas adjacent to unheated spaces.
4. Select the proper heat-transmission coefficient for each area from Table I, or calculate the coefficients by the use of formulas (2), (3), and (4).
5. Compute the heat loss for each area by multiplying the areas in square feet by the heat-transmission coefficients times the temperature difference. Increase the losses computed in this manner for the walls and glass on the sides of the building next to the prevailing wind by adding 15 per cent to allow for exposure and higher than 15 miles per hour wind.
6. Compute the cubic feet of cold air entering the building per hour, preferably by the crackage method. Calculate the Btu per hour required to warm this air by formula (5). The heat to warm any air admitted by artificial ventilation must also be included.
7. Add the heat losses obtained in 5 and 6. The result represents the total Btu per hour which must be supplied by the heating system on a cold day after the building is up to temperature and operating under steady state conditions.

INSIDE TEMPERATURE. The inside room temperature schedule should be stated in the heating specifications. Inside air temperature is understood to mean the temperature at the breathing line, 5 ft above the floor and not less than 3 ft from the side walls. Inside temperatures recommended for different types of buildings are given in Table VIII.

Owing to the tendency of warmer air to rise, the temperature is usually higher at the ceiling and lower at the floor than at the breathing line. The temperature at the floor may ordinarily be taken 5 deg fahr lower than at the breathing line provided the latter is not less than 55 deg fahr. For ceilings and other areas it is common practice to allow a 2 per cent increase in temperature per foot above the breathing line in estimating the probable air temperature. With unit heaters or other types of equipment with forced air circulation the temperature difference between ceiling and floor may be much less. However, the difference should not be assumed to be less than 1 per cent per foot unless the equipment is guaranteed by the manufacturer.

The comfort in a heated room is found to depend not only on the temperature, but also upon the humidity and the velocity of air circulation. Where the humidity is raised by artificial means, it is found that the same comfort is obtained with an inside temperature 1 deg fahr lower for each increase of 10 in the per cent relative humidity. Thus if the relative humidity is raised from 20 to 40 per cent, the same comfort will be felt at 68 deg fahr as was felt at 70 deg fahr before raising the humidity. Higher than 40 to 50 per cent relative humidity usually should not be used in freezing weather because of danger of condensation of moisture on walls and windows. Also humidities above 60 per cent may feel uncomfortable. Very low humidities are to be avoided not only because of the higher room temperatures required, but also because low humidities are apt to be unhealth-

ful and are injurious to furniture. The consensus of opinion is that 40 to 60 per cent relative humidity is the best from the standpoint of health.

OUTSIDE TEMPERATURES. The outside temperature to be used for estimating the capacity of heating equipment should be based on Weather Bureau records taken over a period of years. The temperature taken can ordinarily be slightly higher than the lowest temperature recorded for the locality, usually from 5 to 10 deg higher.

HEAT AVAILABLE FROM SOURCES OTHER THAN THE HEATING PLANT. Sometimes the heat supplied by the heating plant is supplemented by heat supplied by persons, lights, motors, and machinery. The amount supplied from these sources is usually so small that it may be neglected, but in certain instances it must be evaluated and taken into account, as in assembly halls, theaters, and some industrial plants. In special cases waste heat may be used to supply all or most of the heat required.

A man at rest gives off about 400 Btu per hr, and at work about 500 Btu per hr. This quantity of heat is not of sufficient importance to be taken into account except in assembly halls and theaters.

Lamps. The heat (Btu) supplied by the electric lamps in a room is equal to

$$3.415 \times \text{(Watts per lamp)} \times \text{(Number of lamps)}$$

The heat supplied by gas lamps may be calculated from the following data:

1 cu ft producer gas	150 Btu
1 cu ft illuminating gas	530 Btu
1 cu ft natural gas	1000 Btu

A Welsbach burner averages 3 cu ft of gas per hr, and a fishtail burner 5 cu ft per hr.

Motors and Machinery. Motors and the machinery which they drive, if both are located in the room, convert all the electrical energy supplied to them into heat which is retained in the room if the product being manufactured is not removed until its temperature is the same as the room temperature. In this case

$$\text{Btu supplied per hour} = 2546 \left(\frac{\text{Hp output of motor}}{\text{Efficiency of motor}}\right)$$

If power is transmitted to the machinery from the outside, then only the heat equivalent of the brake horsepower supplied is used, in which case

$$\text{Btu supplied per hour} = 2546 \times \text{(Brake horsepower)}$$

In high-powered mills the heat given out by the machinery is the chief source of heating and is frequently sufficient to overheat the building even in zero weather, thus requiring cooling by ventilation the year round.

In a transformer substation or other room from which electrical energy is transmitted, the heat supplied by the electrical apparatus is of course only the losses in the apparatus. The loss is equivalent to 3415 Btu per kw hr of loss.

SEASONAL HEATING LOAD. The number of degree-hours (or degree-days) per heating season is usually accepted as a fair index of the seasonal heating load. (One degree-day equals 24 degree-hours.) The number of degree-hours for a given heating period for a building in which a given inside temperature is maintained is found by a summation over the period of the hourly differences in temperature between the inside and outside air. Tables giving the seasonal degree-hours for residence heating may be found in several heating and ventilating handbooks and journals (see Bibliography), or the value for any given locality may be calculated from hourly weather data which can be secured from the Weather Bureau.

An estimate of the fuel consumption of a building for a heating season may be made by the following formula:

$$H_s = (H_c/Dc)D_s \tag{8}$$

where H_s = the Btu which must be delivered by the heating system for the season.
H_c = Btu required by the building for 24 hrs on the cold day.
D_c = degree-hours (or degree-days) for the cold day.
D_s = degree-hours (or degree-days) for the season.

The heat requirements for a given season will depend upon the degree hours of the actual season, the room temperature schedule actually followed, habits of the occupants of the building, average wind velocities over the season, and numerous other factors. Therefore, the actual consumption may vary considerably from that estimated for normal conditions. The variation of the degree-hours for the severe and mild season is different for different localities, but the average variation is of the order of 20 per cent above or below normal.

The Btu requirement for the season divided by the product of the average overall seasonal efficiency of the heating system and the Btu content per unit of fuel gives the required fuel consumption for the season.

BUILDING INSULATION. There are several important advantages in building insulation. Fuel savings as high as 50 per cent may be obtained with complete insulation where 2 or 3 in. of insulation are applied to the walls and ceilings, and weather strips and double glass are used on windows and doors. Aside from fuel savings, insulation gives a more uniform inside temperature in winter and makes the building more comfortable in summer.

Insulation is often installed on the basis of the most economical thickness. This thickness can be estimated from the formula

$$t = \left(\frac{U\,D_s\,F}{n\,B\,M\,r} \times 10^6\right) - \frac{k}{U}. \tag{9}$$

where t = economical thickness of insulation in inches.
U = heat-transmission coefficient of wall or ceiling in Btu per square foot per hour per degree temperature difference before insulation is applied.
D_s = degree-hours per season.
F = cost of fuel in dollars per unit quantity.
n = overall efficiency of heating system for the season in per cent.
B = Btu value per unit of fuel.
M = cost of insulation installed in cents per square foot per inch of thickness used.
r = return required on insulation investment in per cent.
k = conductivity of insulation in Btu per square foot per hour per inch of thickness per degree temperature difference.

This formula assumes that M, the cost of insulation per square foot per inch of thickness installed, is proportional to the thickness used. Where this does not hold, it will be necessary to assume values of M and solve the equation by trial and error.

For electric heating, eq. (9) can be expressed in a more convenient form, as follows:

$$t = \frac{U\,D_s\,e}{0.3415\,n\,M\,r} - \frac{k}{U} \tag{10}$$

where t, U, D_s, n, M, r, and k are defined the same as in eq (9), and e is the cost of electrical energy in cents per kilowatthour.

It should be noted that the economic thickness of insulation increases directly with the cost of fuel. Therefore with the use of electricity, gas, or any higher-priced fuel, a greater thickness of insulation will be justified.

In installing insulation greater efficiency is obtained with a given amount of insulation where it is applied over the whole heat-loss area rather than where the insulation is concentrated in a thick layer over a small part of the heat-loss area. Where sufficient insulation is used, it is possible to make a reduction in the size and cost of the heating system. If this saving is to be taken into account in determining the amount of insulation justified, it will be necessary to make a detailed heating estimate both with and without insulation.

HEATING APPARATUS. For dwellings, small stores, shops, etc., steam, hot water, warm air, and electric heating systems are used. For large buildings less than three or four stories high, either hot water or steam may be used, but in tall buildings only steam or vapor may be used because of the high static head encountered with hot water.

In steam and hot water systems the heat is delivered by standard metallic radiators of various types. Some of the enclosed and recessed types are more properly called convectors. It is now the general practice of the manufacturers to rate all radiators in Btu per hour, in 1000 Btu per hour designated as Mb per hour, or in equivalent square feet of heating surface. One square foot of equivalent heating surface emits 240 Btu per hr when located in a room of 70 deg fahr and supplied with steam at 215 deg fahr. For other than standard conditions, the transmission may be taken as equal to

$$H_r = H_s \frac{(t_s - t_r)^{1.3}}{(215 - 70)} \tag{11}$$

where H_r = the rate of heat emission in Btu per hour per equivalent square foot of surface at temperature t_r.
H_s = the rate of heat emission in Btu per hour per equivalent square foot of surface under standard conditions.
t_s = the temperature of radiator (assumed to be temperature of steam or hot water).
t_r = the temperature of the room in which the heater is located.

When hot water is used in the radiators, the emission is assumed to be the same as for steam of the same average temperature as the water. Where the average hot water temperature is 170 deg fahr and the radiator is located in a room at 70 deg fahr the emis-

sion is usually taken as 150 Btu per hr per sq ft of equivalent heating surface. Conversion factors based on eq. (11) are given in Table IX for convenience in calculating the emission where the conditions are not standard.

There are three principal classifications of solid fuel boilers in general use: (1) cast-iron sectional boilers, (2) steel boilers of the fire-tube or water-tube type, (3) magazine-fed boilers.

Working pressures in most cases are limited to 15 lb per sq in. for steam, and 30 lb per sq in. for hot water. Boiler ratings are given in Btu per hour, in equivalent square feet of radiation, or in boiler horsepower which is equivalent to 33,471.9 Btu per hr. The boiler should have sufficient capacity to supply (1) the estimated emission for the connected radiators, plus (2) the estimated emission of the piping connecting the radiation and boiler, plus (3) an allowance for starting up cold radiators. The piping loss may vary considerably, but it is common practice to add a flat percentage, 25 per cent for steam systems and 35 per cent for hot water systems, to the connected radiation to take care of this loss. The allowance for heating up varies with conditions and the size of the system. The minimum requirements specified by the American Society of Heating and Ventilating Engineers' code are as follows:

Up to 100,000 Btu per hr add 65 per cent.
100,000 to 200,000 Btu per hr add 60 per cent.
200,000 to 600,000 Btu per hr add 55 per cent.

These percentages are percentages of the radiation plus the piping loss.

Other important factors affecting the operation of the boiler which should be carefully considered are: (1) chimney and draft capacity, (2) fuel contemplated, (3) quality and frequency of attention, (4) design of piping and heat-emitting surfaces, (5) character of water for use in boiler. Proper selection of equipment with reference to these points can usually be assured by careful study of the recommendations and data supplied by manufacturers.

23. SYSTEMS

ELECTRIC HEATING. The many advantages of the use of electricity for building heating, together with the attractiveness of this load for the power companies, have led to lower rates and new developments in electrical heating equipment. Three different classes of equipment are now in use: (1) direct radiators and space heaters which take electrical energy coincidental with the heating demand, (2) thermal storage equipment which takes electrical energy only at off-peak hours when the power system is operating sufficiently below rated load to allow it to carry the added heating load without additional plant or distribution capacity, and (3) equipment using the reversed refrigeration cycle.

From the standpoint of the heating customer, advantages offered by electrical heating are: (1) elimination of dirt, soot, and fumes; (2) elimination of firing and other furnace labor; (3) elimination of fuel and combustion products from the premises; (4) accurate and reliable room temperature regulation; (5) minimum radiation losses in the basement and other parts of the building where heat is not required; (6) minimum maintenance and reconditioning; (7) efficient and low-cost servicing and supervision by competent public utility staff in territories where heating rates are established. From the standpoint of the power company, the heating load offers an opportunity of improving the system load factor and power factor, and at the same time greatly increasing the kilowatthour output. The off-peak load especially is very desirable since it fills in the valleys in the load curve and does not increase the generating or distribution capacity required. In some territories, usually where hydroelectric power is available, rates of 2 cents per kwhr or less are available for on-peak electric space heating. Where the power use is controlled by a time switch and limited to the off-peak hours, off-peak rates, as low as 1 $^1/_2$ to $^3/_4$ cents per kwhr, have been made available. In heating their own buildings with off-peak energy utilities often figure the energy as low as $^1/_2$ cent per kwhr.

A comparison of the cost of heating by electricity with that of heating with coal, oil, or gas is readily obtained by assuming the efficiencies that may be expected and calculating the equivalent prices for these fuels to give the same cost for a given amount of heat delivered to the radiators. On this basis the equivalent rate for coal in dollars per ton to give the same cost of heating as electricity at any given rate per kilowatthour is given by the formula

$$R_c = (R_e/E_e)\ (5.85\ B_c\ E_c) \times 10^{-3} \tag{12}$$

where R_c = cost of coal in dollars per ton (2000 lb).
R_e = cost of electricity in cents per kilowatthour.

E_e = overall efficiency for electric heating in per cent.
B_c = Btu per pound of coal.
E_c = overall efficiency for coal heating in per cent.

The equivalent rate for oil is given by

$$R_o = (R_e/E_e)\ (2.92\ B_o\ E_o) \times 10^{-4} \tag{13}$$

where R_o = cost of oil in cents per gallon.
R_e = cost of electricity in cents per kilowatthour.
E_e = overall efficiency for electric heating, in per cent.
B_o = Btu per gallon of oil.
E_o = overall efficiency for oil heating in per cent.

The equivalent rate for gas is given by

$$R_g = (R_e/E_e)\ (0.292\ B_g\ E_g) \tag{14}$$

where R_g = cost of gas in cents per thousand cubic feet.
R_e = cost of electricity in cents per kilowatthour.
E_e = overall efficiency for electric heating in per cent.
B_g = Btu per cubic foot of gas.
E_g = overall efficiency for gas heating in per cent.

If electric thermal storage heating at 1 cent per kwhr is compared with heating with manufactured gas by substitution in formula (14), using an overall efficiency of 90 per cent for electricity, 530 Btu per cu ft for gas, and an overall efficiency of 60 per cent for gas heating, the equivalent price of gas is found to be $1.03 per 1000 cu ft. The 60 per cent overall efficiency for gas heating assumes a boiler efficiency of 70 per cent and a basement piping loss of approximately 15 per cent, giving an overall efficiency of 60 per cent. The overall efficiency for electrical heating assumes 10 per cent tank and basement piping loss for the storage system.

If electric thermal storage heating at 1 cent per kwhr is compared with coal heating by substitution in formula (12), assuming $B_c = 13{,}000$, $E_c = 36$ (45 per cent heater efficiency and 20 per cent piping loss), and $E_e = 90$, the equivalent price of coal is $30.80 per ton.

The overall efficiency for electric space heaters and direct radiators is 100 per cent. The efficiencies used in the examples above for electric thermal storage, gas, and coal are representative, but these values vary with conditions and the design of the equipment. A representative overall efficiency for oil heating may be taken as 50 per cent, which assumes a seasonal heater efficiency of 60 per cent and a piping loss of about 17 per cent. Fuel oil used for heating runs around 143,000 Btu per gal.

DIRECT RADIATORS AND SPACE HEATERS. This class of equipment includes radiant heaters, convection heaters, unit heaters, and electric hot water and electric steam radiators using immersion-type heating units. Each has certain characteristics and certain advantages.

The first cost of this equipment is usually low. Another advantage is that it may be made portable so that it can be moved from place to place where needed. Small heaters may be connected directly to appliance outlets, but larger ones involve the installation and cost of electric wiring of the proper capacity. Care must be exercised to comply with the National Electrical Code of the National Board of Fire Underwriters which specifies (1) that portable electric heaters rated at 6 amp or 660 watts or less may be used on lighting branch circuits or on combination lighting and appliance branch circuits, (2) fixed or portable electric heaters of not over 1320 watts may be supplied by an ordinary appliance branch circuit, (3) up to 1650-watt equipment may be supplied by a medium-duty or heavy-duty appliance branch circuit. Equipment of higher rating be supplied by power circuits of proper capacity.

The radiant electric heaters deliver most of their heat by radiation. Reflectors direct the heat rays in the direction desired. This type of heat gives an immediate and pleasant sensation of warmth when the heat rays strike the body. These heaters have a high efficiency of utilization, but are not satisfactory for general heating, as radiant rays do not warm the air through which they pass. The location of the heaters is important, since they must be directed toward the objects to be heated. They must not face a window, because any radiation toward the window would pass through and be lost. Radiant heaters are built in portable types, and in wall types for both flush and recessed mounting.

Convection types of electric heaters are built in a number of different forms. They are designed to deliver heat by convection air currents set up by the tendency of the heated air to rise. The heating units are made of coils of resistance wire, metal ribbons,

grids, and other forms and shapes of resistance materials. The heating elements should have comparatively large area and operate at moderately low temperatures (temperatures below that which makes the element visibly red). The enclosures should give proper stack effect in order to draw cold air from the floor and direct it into the room.

Electric unit heaters are similar to steam or hot water unit heaters in that they combine the heater with a fan or blower. They are made in portable, wall mounting, and built-in types in sizes ranging from 1 to 50 kw or larger if required. This type is the best form of electric heater for many applications. The warm air can be directed toward the floor or in any direction desired. The positive air circulation insured by the fan reduces stratification of the air and high ceiling temperatures. Because of the forced air circulation the area of the heating elements may be made smaller and the weight and cost of the resistors reduced to a minimum. None of the electrical energy taken by the fan is lost, since it is all delivered to the air as heat and kinetic energy. Portable units of artistic design, free from radio interference, are available for home use. Larger units may be used for industrial plants, power plants, substations, and for temporary use during construction work, repairs, etc.

Electric hot water and electric steam radiators have been built by one or two manufacturers. In this design immersion heating elements are used to heat water in the lower part of the radiator. The temperature of the water or the pressure is controlled by a thermostat or by a thermostat and a pressure switch which automatically cuts the heating element off and on as required. The cost of this type of equipment is high because of the relatively expensive construction required. The only advantage is a larger area of low-temperature direct radiating surface. The water and steam do not increase the efficiency of the heating elements.

ON-PEAK CENTRAL HEATING. Central warm air electric heating systems which take electrical energy coincidental with the heating requirements have the heating installed in a plenum chamber connected to the warm air duct system. A fan or blower circulates the air past the heating units and through the ducts. In this system it is important to provide the proper value of air in order to give the desired air temperature. Since the electric heating units supply a constant amount of heat, the air temperature equals the kilowatts times 3415 divided by the product of the cubic feet of air times the density times the specific heat of the air at the warm air temperature.

Central electric hot water or steam systems differ only in the use of electric boilers to supply the hot water or steam. For hot water, small, heavily insulated boilers with immersion-type heating units are used. The same type of boiler can also be used for steam. In Canada and Europe for larger installations an electrode boiler is used for generating steam. In this type the resistance of the water between the electrodes is used to generate the heat. The amount of heat is controlled automatically by raising and lowering the movable electrodes. To cut off the electric current the upper electrodes are raised above the water into the steam space. There is no danger of injury to the boiler due to low water as the current is automatically interrupted when the water becomes low. Only alternating current may be used in this type of boiler because of electrolysis. Some trouble has been experienced with electrode boilers on account of the formation of gases which have caused explosions in the boiler. Manufacturers have been able to overcome this trouble by proper design.

On-peak central electric heating is usually expensive with the rates available for this purpose. However, in certain localities rates of 2 cents per kw and below are available. In mild climates this method of heating may be permissible with these rates. It may be found economical to shut down the main boilers and use electrical boilers as an auxiliary source of supply at the beginning and end of the heating season.

OFF-PEAK THERMAL STORAGE SYSTEMS. A number of different types of thermal storage electric heaters have been developed in Europe and America. One arrangement is a modification of the old stone warming block. An appropriate size metal container, insulated on the outside, is filled with solid material in which electric heating elements are imbedded. The storage material is heated during the off-peak hours. The stored heat is utilized as needed by passing air through ducts in the heated material. These units are placed inside the room where heat is desired; they are semi-portable, although somewhat heavy to move.

Another type of thermal storage system uses a well-insulated central storage tank filled with water. The tank is heated to a temperature of 250 to 300 deg fahr during hours designated by the power company. Charging periods ranging from 12 to 20 hr are used, depending upon the characteristics of the utility's load curve. During the charging period the storage tank absorbs enough heat to meet the demands of the 24-hr period. Heat is delivered under thermostatic control as required to maintain the desired room temperature. Several different arrangements of the equipment have been developed,

depending on the type of radiation used to distribute the heat to the building. These may be listed as follows:

(a) Hot water with thermal circulation through standard hot water radiation.

(b) Hot water with pump circulation through standard hot water radiation.

(c) Warm air utilizing a central blast heater.

(d) Warm air utilizing unit heaters.

(e) Warm air utilizing stored heat in connection with waste heat from synchronous condensers or other equipment.

The essential parts of all the different arrangements of this equipment are:

(a) Heavily insulated storage tank.

(b) Immersion-type heating elements.

(c) Automatic charging control.

(d) Radiation system.

(e) Automatic room temperature control system.

The heating element capacity required is found by dividing the Btu requirement of the building for the coldest day by the product of 3415 times the number of hours that charging is permitted. This should be increased to allow for a small tank loss, irregularity in heating element rating, and low voltage, remembering that the heating element capacity varies as the square of the voltage. Where the voltage remains practically constant 10 to 15 per cent is sufficient allowance to cover these factors.

The size of the storage tank depends upon the following factors:

(a) The number and allocation of the hours during which heat must be supplied from storage.

(b) The temperature range over which the storage water is worked.

(c) The Btu requirements of the building during the time that heat is supplied from storage.

Various charging schedules have been used, depending on the times that peak loads occur on the electric system. A number of schedules have permitted charging of the tank at any time except for 4 to 7 hr during the evening lighting peak. In other places, charging has been prohibited for an additional 2 hr in the morning to care for a morning peak. Charging schedules as short as 12 hr have been used successfully by power companies having a large industrial load and a high load factor. Where the hours of heating from storage are broken up the tank will recover or partly recover its charge between discharge periods so that the size of the tank is materially reduced.

It has been found that with the use of standard hot water radiation a storage temperature of 250 deg fahr giving a pressure of 15 lb per sq in. may be used, and that the water may be returned from the radiation at a temperature of about 150 deg fahr, giving a working range of 100 deg fahr. The temperature of the water to the radiators is varied by means of a mixing valve controlled automatically by the heat requirements of the building. The return water stratifies at the bottom of the storage tank so that the hot water above remains at almost a constant temperature until the whole tank is nearly discharged. For warm air systems the storage tank is used to supply steam and vapor to unit heaters or blast heaters, in which case it is found that a working range of 300 to 200 deg fahr can be obtained. The working temperature range can be increased by increasing the amount of radiation used, which lowers the return water temperature, or by raising the storage tank temperature to the limit that the pressure will permit. Where the heating from storage is confined to a single period, the capacity of the storage tank in gallons equals the maximum Btu storage required divided by the product obtained by multiplying the working temperature range of the storage water by the weight of a gallon of water at the fully charged temperature by the storage tank efficiency allowing for a small tank radiation loss. Where the hours of heating from storage are broken or short, and the heat required is low, the storage tank acts like a storage battery floating on the line. The effect is to smooth out the charging curve and reduce the connected load to an average value over the whole charging period. Since in this case the heat stored in the tank fluctuates up and down, it is necessary to calculate the input and output over the whole 24-hr cycle in order to determine the maximum Btu storage at any one time and the size of the tank.

The space required for the tank and the auxiliary equipment is usually less than that allowed for the coal bin with a coal heater. In new buildings where openings to the basement permit, factory-fabricated tanks are used; otherwise, the tanks are electrically welded in the basement. As yet there has been no definite specifications of storage tanks with reference to the boiler code, but this has been under consideration by the Hartford Boiler Code Committee. The present tendency is to limit electrical welding to tanks of not over 4 $^1/_2$-ft diameter and not over 15 lb per sq in. gage pressure (250 deg fahr), and use a single V butt weld on both circumferential and longitudinal seams, all edges being bevel planed. Tanks of larger diameter and higher pressures are usually riveted in accord-

ance with the American Society of Mechanical Engineers' code for unfired pressure vessels. All tanks should be provided with manholes for inspection.

Standard immersion-type heating elements, usually 5 or 10 kw in size, are inserted directly into the tank in a group assembly in a nozzle welded into the tank, or they are installed singly through smaller nozzles. The tank construction, piping, and the connections to the tank are made quite simple, so that the whole unit lends itself to efficient insulation. The automatic charging control is obtained by the use of a synchronous time switch and a suitable tank thermostatic switch which opens and closes the main magnetic contractors supplying current to the heating elements.

A great deal of improvement in storage heating equipment would result if a better and lower-cost storage medium could be found. An ideal storage liquid would be one that is dense, with a high specific heat, that could be raised to a high temperature without developing pressure. It should be non-inflammable and should not break down with continued heating. A chlorinated diphenyl product which has been developed by the Swan Research Corporation for heat-transfer purposes shows promise for heat-storage applications.

Over a period of a number of years a few off-heat thermal storage installations have been made in Europe. Between 1928 and 1932 approximately 75 installations were made in the United States. These were installed in residences, office buildings, substations, and other buildings. The connected load for these installations varied from 30 to about 300 kw. The first cost of this equipment varies greatly, but in general it is only slightly higher than that of modern gas and oil heating equipment with fully automatic control. If put on a regular production basis, the cost could be made as low as that of other types of equipment.

HEATING BY THE USE OF A REVERSED REFRIGERATION CYCLE. Considerable discussion and experimental investigation have been made of the application of Lord Kelvin's "warming engine" or "heat pump" as a practical means of heating. The method utilizes a reversed refrigeration cycle whereby heat is absorbed from a cold body and rejected to a warm body. Electrical energy for heating is first used to operate a refrigeration unit. The evaporator absorbs heat from a water supply or from the outside air. The condenser is arranged so that the heat given off is delivered to the building for heating purposes. Thus the total heat obtained is equal to the amount expended in driving the refrigeration apparatus plus that extracted by the evaporator. The maximum heat obtainable is that given by the ideal case where the system operates on the reversed Carnot cycle. In refrigeration this ideal cycle of operation gives a coefficient of performance (ratio of heat extracted to heat expended) equal to $T_2/(T_1 - T_2)$, where T_1 equals the absolute temperature of the hot body and T_2 equals the absolute temperature of the cold body. In applying reversed refrigeration to heating, the ratio of the heat delivered to that expended, which may be called the coefficient of heating, is equal to $[T_2/(T_1 - T_2)] + 1$, since the heat rejected equals the heat extracted plus the heat expended. When this expression is simplified it gives a heating coefficient equal to $T_1/(T_1 - T_2)$, which is the maximum theoretical value.

In commercial refrigeration practice about 1 hp-hr of work (2546 Btu) is required per ton of refrigeration (12,000 Btu), and 14,546 Btu are rejected through the condenser. If the same operating temperatures could be used, this would mean a coefficient of heating of approximately 5.7, that is 5.7 Btu of heating would be obtained for each Btu expended to drive the refrigerator. However, the working temperatures would usually be less favorable and the actual performance would fall a great deal short of that indicated by the ideal coefficient of heating.

A number of installations have been made over the past few years, mainly in warmer climates. In most of them outside air has been used for the evaporator. A disadvantage in this case is that the lowest heating capacity occurs in the coldest weather when maximum capacity is needed. Recently an installation has been made in a two-story office building of the American Gas and Electric Co. of Salem, N. J., which uses water at about 57 deg fahr pumped from a well instead of outside air for the evaporator. The reversed refrigeration is obtained by four four-cylinder compressors each driven by a 5-hp three-phase motor. The refrigerant is raised to a temperature of 135 deg fahr in the condenser. Air, which is circulated over the condenser, is heated to 115 deg fahr, humidified, filtered, and carried to various parts of the building by the duct distribution system. In severe weather it has been found that an electrical input of approximately 20 kw for the driving motors produces a heat delivery to the building equal to about 70 kw or about 240,000 Btu per hr. A novel feature of the equipment is that by opening and closing several valves the evaporator is changed into a condenser and the condenser into an evaporator, so that the equipment cools rather than heats. Two units of the four have a capacity of approximately 100,000 Btu per hr when operating on the cooling cycle.

Heating equipment based on the heat pump principle is theoretically and practically sound. The principal drawbacks are (*a*) the high cost of the equipment; (*b*) the objection to installation of rotating machinery, which decreases safety and simplicity of operation; (*c*) increased cost of supervision and maintenance. These objections have been greatly decreased by the development of improved equipment for cooling and air conditioning. Where a part of the cost of equipment can be charged to cooling and air conditioning it will be found that in many cases the use of the heat pump for heating can be justified. New developments in this type of equipment seem sure to widen the field of application.

PANEL HEATING AND FLOOR WARMING. A new type of heating has been developed in Europe, principally in England, which is known as panel heating and floor warming. Only a few installations have been made in America, one of which is in the British Embassy in Washington.

Low-temperature hot water (130 deg fahr or below) is circulated through pipes imbedded in the ceilings, walls, or the floors of the building; or electricity is utilized by imbedding heating elements instead of pipes. The heating is accomplished mainly by a low-temperature radiant heat. The piping or heating elements are distributed over a large area so that radiant heat impinges on the body from all directions to give the warmth required. That the heating is principally by radiant heat will be clear in the case where the heating elements are confined to the ceiling area. Here a thin blanket of heated air lies against the ceiling, and the only heating below is by radiation. It is claimed that comfort is obtained with room temperatures from 10 to 15 deg fahr below that required with other systems, and that healthfulness is increased. With lower average room temperature the heat losses from the building are proportionately reduced, resulting in economy in operating costs. It should be possible to apply this method of heating in connection with the heat pump, using the equipment for cooling in summer as well as heating in winter.

24. AIR CONDITIONING

AIR CONDITIONING. In the last few years great advances have been made in new methods and new equipment for increasing comfort and healthfulness in homes and public buildings. The engineer, who was once called upon for the design and installation of equipment for heating and the supply of a sufficient quantity of fresh air, must now concern himself also with the quality of the air, and in many cases he must provide cooling in summer as well as heating in winter. Many new factors affecting comfort are now better understood. The temperature, humidity, purity, odor, and movement of the air are all controlled in the modern air-conditioning system.

The temperature sensation of the human body depends not only upon the dry-bulb temperature of the surrounding air, but also upon the humidity (or wet-bulb temperature) and upon air movement. This is because of the effect of humidity and air movement on the dissipation of body heat. The best representation of the combined effects of these factors on comfort is given by comfort charts which have been prepared by the American Society of Heating and Ventilating Engineers and published in the Guide and *Transactions* of this society.

In addition to heating, winter air conditioning consists in humidification as well as filtering and sometimes deodorizing. As stated under the section on heating, relative humidities between 40 per cent and 60 per cent are desirable in winter, which usually requires the addition of moisture to the air. In warm air systems this is accomplished by passing the air through sprays or over surfaces wetted by a continuous flow of water. With steam or hot water heating systems the moisture is added by unit humidifiers, or, where more adequate equipment cannot be supplied, some improvement in the humidity may be obtained by the use of radiator pans.

Complete summer air conditioning consists of lowering the effective temperature by cooling, and by reducing the relative humidity, filtering, deodorizing, and circulating the conditioned air. However, the temperature must not be lowered too far below that of the outside, and the relative humidity must be kept low enough (50 per cent or less) to induce a rate of evaporation which will keep the clothing and skin dry. The desirable indoor conditions corresponding to given outdoor temperatures are given in Table X.

There are four methods of lowering the effective temperature as follows:

1. Lowering the dry-bulb temperature by the removal of sensible heat without change of the dew-point temperature through the use of some form of refrigeration.
2. Dehumidifying and lowering of the dew-point temperature without change of the dry-bulb temperature.
3. Evaporative cooling, which lowers the dry-bulb temperature by evaporation of moisture without addition or subtraction of heat.
4. Increasing the air movement, which results in higher evaporation from the skin.

The best method to employ depends on climatic and other conditions. The first two methods are as a general rule the most satisfactory. Satisfactory cooling by evaporation and air motion alone requires a low relative humidity, and thus depends upon climatic conditions beyond the engineer's control. With the use of refrigeration both the removal of sensible heat and dehumidification are usually obtained.

Dehumidification may be obtained in three ways:

1. Cooling the air below the dew-point by refrigeration.
2. Extraction by moisture absorption.
3. Extraction by adsorption.

Dehumidification by the first method is based on the fact that as the temperature of air is lowered the amount of moisture that can be retained is decreased. For a given moisture content (grains per cubic foot) there is a definite temperature called the dew-point temperature for which the air will be saturated (100 per cent humidity). If the temperature is dropped below the dew-point temperature, a definite amount of moisture condenses out until the amount left corresponds to that required to give 100 per cent relative humidity for the new temperature. Thus by lowering the temperature to the proper point, reducing the moisture, and reheating, air at any desired temperature and relative humidity can be obtained.

In extraction by absorption, moisture is taken up by a substance which undergoes a change in chemical or physical structure; in extraction by adsorption a substance is used which does not undergo a change in chemical or physical structure. Absorbers include sulfuric acid, calcium chloride, etc.; adsorbers include such substances as silica gel and lamisilite. Silica gel (SiO_2) will absorb about 25 per cent of its own weight of moisture from air passed over it. After the substance has become saturated, the moisture is driven off by heat without change in structure.

COOLING LOAD. The cooling load for any building or part of a building is made up of four parts:

1. Heat transmitted through walls, roofs, and glass with allowances for sun-exposed surfaces and heat capacities.
2. Solar radiation transmitted through windows.
3. Heat and moisture from infiltration of outside air.
4. Heat and moisture from occupants, lights, and machinery.

The transmission for surfaces not exposed to the sun is calculated by using the heat-transmission constants and temperature difference in the same manner as for a heat loss. For surfaces exposed to the sun, the heat transmission will be greater. This may be taken into account by raising the outside air temperature by a certain amount depending on the color and character of the surface and the angle of incidence of the sun as indicated in Table XI.

One hundred per cent of the sun's solar energy is transmitted into a building through an opening which is without glass or other obstructions, and which is normal to the sun's rays. The solar radiation for the different hours of the day and for different angles of incidence of the sun's rays is given in Table XII. The note given below indicates the percentage of the solar heat which should be taken if the opening is obstructed by glass, shades, etc.

AIR-CONDITIONING EQUIPMENT. Air-conditioning systems may be classified as central air-conditioning systems and unit air conditioners. The first is used principally in theaters, restaurants, office buildings, and manufacturing plants. The second is used in homes, separate offices, and for other applications where the requirements are not too great. In the central system the fans, dehumidifiers, filters, etc., as well as the refrigeration units are located in a suitable apparatus room from which the conditioned air is supplied through distribution and return ducts. In the unit conditioner the fans, dehumidifier, cooling unit, controls, and other equipment form a complete unit which is assembled at the factory. The various parts of the central air-conditioning system are usually purchased and assembled by the heating and air-conditioning contractor, who guarantees the performance of the complete equipment. The manufacturer is responsible for performance of the unit conditioner.

Unit air conditioners usually have capacities below 30,000 Btu per hr for cooling and below 60,000 Btu per hr for heating. The different types may be classified as all-year units, summer units, and winter units. The all-year units perform all the functions of air conditioning: namely cooling, dehumidification, air circulation, air cleaning, heating, and humidification, with suitable controls. Summer units provide cooling, dehumidification, air cleaning, and air circulation. The winter units provide heating, humidification, air cleaning, and air circulation. Units which do not provide simultaneous control of at least four of the recognized functions of an air conditioner are usually more properly classified as unit heaters, unit ventilators, window-type ventilators, humidifiers, coolers, or dehumidifiers.

Cooling is usually accomplished by the use of mechanical refrigerators using low-temperature evaporation of a liquid to absorb the heat. Air or water is cooled by passing it over the evaporator. The evaporated liquid is compressed and then cooled by passing air or water over the condensing coils. The apparatus exclusive of the evaporator or cooling coils is called the condensing unit and is usually located in the basement or some other convenient place. There are two methods of applying the refrigeration. In the direct-expansion system the evaporator is located in the assembly in the room where cooling is required. The expansion valve is next to the evaporator so that the refrigerant lines need not be insulated. In the indirect-expansion system the evaporator is located near the condensing unit and water surrounding the evaporator is chilled and circulated through coils in the room unit. For the direct system, odorless, non-toxic refrigerant fluids, such as methyl chloride or freon, are used. Indirect systems may use ammonia, sulfur dioxide, and carbon dioxide, since the piping is not located within the conditioned areas. Compressors of multicylinder or rotary designs driven by electric motors are used. These units have very carefully designed shaft seals which minimize leaks. The whole assembly is carefully mounted to give quiet operation. Much of the success in building cooling is due to the improvements in the design, efficiency, and dependability of this part of the equipment.

Filters or air cleaners are of three general types: (1) dry air filters, (2) air washers, (3) viscous filters.

Dry air filters are made up in the form of a screen from felt, cloth, wool, and other materials. The filter material may be designed for vacuum cleaning or for replacement as it becomes filled with dust and dirt. The air-washer type cleans the air by passing it through sprays. In the viscous type of filter the dust and dirt are trapped by allowing them to impinge on viscous sheets placed in the air stream from the fan. A great many different arrangements and substances are used. The viscous screens are washed and the viscous coating renewed either manually or automatically.

The automatic controls for heating and air conditioning constitute a very important part of the equipment. This apparatus is made up of devices sensitive to temperature, devices sensitive to relative humidity, and devices sensitive to pressure, together with relays, contactors, valves, dampers, time switches, and other auxiliary equipment. Compressed air and electricity are both used for operating the auxiliary equipment. The temperature-sensitive devices are used to actuate electric or pneumatic switches and are called thermostats. Depending on their intended use, thermostats may be classified as room, duct, pipe, or tank thermostats, etc. They may also be classified according to the type of temperature-sensitive element, as straight, curved, or spiral bimetal strip thermostats, diaphragm type filled with either volatile liquid or a gas, and liquid bulb type. Devices which are sensitive to changes in humidity are used to cause the humidifying apparatus to increase or decrease the supply of moisture. These devices, which are called humidistats, or hydrostats, operate on several different principles. One type which is directly sensitive to humidity uses wooden blocks, hair, fiber, paper, and membranes. A second type uses a wet-bulb and a dry-bulb thermostat; still another type uses a photoelectric cell which is so arranged that it cuts off the moisture supply whenever moisture condenses on the windows.

Table I. Coefficients of Heat Transmission (*U*)* for Walls, Ceilings, Floors, Roofs and Glass

No.	Type	Description of Construction	Btu per Sq Ft per Hr per 1° F
1	Solid brick wall....	8-in., no interior finish	0.50
2	" " "	8-in., 1/2-in. plaster on brick	0.46

* Calculated from conductivities and conductances recommended by Am. Soc. Heat. & Vent. Eng., 1935 Guide. See Harding and Willard or the Guide for more complete lists.

† The coefficients given for roof and ceiling are the combined coefficients of the roof and ceiling expressed in Btu per hr per sq ft of ceiling area and apply only where the attic is unheated. The combined value is obtained by calculating the separate constants for the roof (U_r) and ceiling (U_c), and then combining these two values by the law of series thermal resistances by the formula

$$U = \frac{N\,U_r \times U_c}{N\,U_r + U_c}$$

where N equals the square feet of roof area per square foot of ceiling area. The values given in the table were calculated using a 1/3 roof pitch (making $N = 1.2$), but the coefficients are sufficiently accurate for pitches ranging from one-fourth to full pitch.

The combined coefficients for roof and ceiling should not be used except where the attic is tight and the infiltration is low. If there is much infiltration of cold air the attic temperature should be taken as equal to that of the outside and only the resistance of the ceiling should be considered.

‡ It is sufficiently accurate to use 1.13 as the coefficient for doors which have wood panels, making it possible to combine glass and door areas for convenience.

Table IV. Air Changes Taking Place under Average Conditions Exclusive of Air Provided for Ventilation

Kind of Room or Building	Number of Air Changes per Hour	Kind of Room or Building	Number of Air Changes per Hour
Room, 1 side exposed..............	1	Reception halls............	2
Room, 2 sides exposed..............	1 1/2	Living rooms...............	1 to 2
Room, 3 sides exposed..............	2	Dining rooms..............	1 to 2
Room, 4 sides exposed..............	2	Bathrooms................	2
Room with no windows or outside doors	1/2 to 3/4	Drug stores................	2 to 3
Entrance halls.....................	2 to 3	Churches, factories.........	1/2 to 3

Table V. Infiltration or Air Leakage Coefficients for Windows in Cubic Feet per Hour per Foot of Crackage

Part or Type of Window	Description	Cubic Feet of Leakage per Foot for Various Miles per Hour Wind Velocities					
		5 mph	10 mph	15 mph	20 mph	25 mph	30 mph
Around window frame	Uncalked...........	1.4	11.3	22.6	31.1	....	53.6
Double-hung wood sash windows with 1/16-in. cracks and 7/64-in. clearance *	No weather strips, unlocked............	39.3	84.9	124	161	....	233
	Weather stripped.....	3	11.7	22.9	34.9	....	59.6
Double-hung metal windows	No weather strips, locked............	20	45	70	96	125	154
	No weather strips, unlocked............	20	47	74	104	137	170
	Weather stripped, unlocked............	6	19	32	46	60	76
Rolled section steel sash windows	Industrial pivoted, 1/16-in. crack.......	52	108	176	244	304	372
	Architectural projected, 3/64-in. crack.......	20	52	88	116	152	208
	Residential casement, 1/32-in. crack.......	14	32	52	76	100	128
	Heavy casement, projected, 1/32-in. crack	8	24	38	54	72	96
Hollow metal, vertically pivoted.......	....	30	88	145	186	221	242

* Crack is the clearance of the window in the frame in the plane of the wall. Clearance is the amount the window may be pushed in or out in the direction perpendicular to the plane of the window. Most new sash are fitted with cracks of at least 1/16 in. which become greater as the sash dries out and shrinks. The values given in the table for double-hung wood sash apply for windows with cracks up to 1/4 in.

Table VI. Air Required for Ventilation *

Type of Building	Cu Ft of Air per Hour per Person	Type of Building	Cu Ft of Air per Hour per Person
Hospitals, ordinary	2500	Schools, theaters, prisons	1800
Surgical cases	3000	Factories and shops	2000
Contagious diseases	6000	Factories (unhealthy trades)	2500

* Especial care should be taken to comply with state and city laws in the case of schools and public buildings.

Table VII. Infiltration of Air Leakage Coefficients through Walls in Cubic Feet per Hour per Square Feet of Wall Area

Type	Description	Cubic Feet of Leakage per Square Foot for Various Miles per Hour Wind Velocities					
		5 mph	10 mph	15 mph	20 mph	25 mph	30 mph
13-in. brick wall	Plain	1.4	3.9	7.5	11.6	16.3	21.2
	Plastered	0.005	0.013	0.025	0.043	0.067	0.097
Frame wall	Lath and plaster	.03	.07	0.13	0.18	0.23	0.26

Table VIII. Inside Air Temperature Usually Specified

Type of Building	Temperature, deg. fahr	Type of Building	Temperature, deg fahr
Warm air baths	120	Schools	70
Steam baths	110	Public buildings	68–70
Hospitals, private rooms	70	Factories and machine shops	60–65
Hospitals, operating rooms	85	Stores	65–68
Hospital, bath rooms	70–80	Hotels	70
Paint shops	80	Theaters, seating space	68–72
Residences	70		

Table IX. Conversion Factors for Direct Cast-iron Radiation *

Steam Pressure		Temperature of Steam or Water, deg fahr	Temperature of Room					
Vacuum, in. Hg	Lb Absolute		80° F	75° F	70° F	65° F	60° F	50° F
22.4	3.71	150	0.388	0.424	0.462	0.499	0.538	0.617
20.3	4.75	160	0.462	0.499	0.538	0.577	0.617	0.697
17.8	5.99	170	0.538	0.577	0.617	0.657	0.697	0.782
14.7	7.51	180	0.617	0.657	0.697	0.740	0.782	0.868
10.9	9.33	190	0.697	0.740	0.782	0.825	0.868	0.955
6.5	11.52	200	0.782	0.825	0.868	0.911	0.955	1.045
Lb. Gage								
1	15.7	215	0.911	0.955	1.000	1.045	1.091	1.183
2	16.7	219	0.947	0.991	1.036	1.081	1.128	1.220
3	17.7	222	0.973	1.018	1.063	1.109	1.155	1.249
4	18.7	225	1.000	1.045	1.091	1.137	1.183	1.277
5	19.7	227	1.018	1.063	1.109	1.155	1.202	1.296

* These conversion factors multiplied by the heat emission of a radiator operating at 215 deg fahr in a room at 70 deg fahr give the heat emitted by the radiator operating under the conditions indicated.

Table X. Desirable Inside Air Conditions in Summer Corresponding to Outside Temperatures

Outside Temperature, deg fahr Dry Bulb	Inside Air with Dew-point Constant at 57° F		Effective Temperature *
	Dry Bulb	Wet Bulb	
95	80.0	65.0	73
90	78.0	64.5	72
85	76.5	64.0	71
80	75.0	63.5	70
75	73.5	63.0	69
70	72.0	62.5	68

* The effective temperature of air at any relative humidity for any given air motion is the temperature of saturated air which will induce the same sensation of warmth or cold with an air velocity of 15 to 25 ft per min.

Table XI. Degrees Fahrenheit to be Added to Outside Walls and Roofs to Allow for Solar Heat

Type of Surface	Black	Red Brick or Tile	Aluminum Paint
Roof horizontal	45	30	15
East or west wall	30	20	10
South wall	15	10	5

Table XII. Solar Intensity on Surfaces for Different Angles of Incidence of the Sun's Rays at Different Hours of the Day *

Time	Btu per Hour per Square Foot

* The heat transmission for angles of incidence which differ from those represented in the table can be calculated by multiplying the values given for a surface normal to the sun by the cosine of the actual angles of incidence. The amount of the heat transmitted through bare and shaded windows may be taken as 97 per cent for bare window glass, 28 per cent where shaded by canvas awning, 45 per cent where inside shade is fully drawn, and 68 per cent for shade one-half drawn.

INDUSTRIAL APPLICATIONS OF MOTORS

By Francis A. Westbrook

1. ADVANTAGES OF ELECTRIC DRIVE

The more important advantages of electric drive are the following:

The various machines can be placed in almost any desired position, and the use of portable tools is readily made possible.

Clear headroom is obtained by the elimination of belting. This gives better illumination and ventilation and permits overhead cranes to be used freely.

Power can readily be distributed from a central supply station to the different buildings, and changes or additions to the system can always be made without difficulty.

The electric system offers greater reliability than belt drive as a breakdown is usually confined to a single machine or group.

Meters of either the recording or indicating type can be installed easily where desired and the performance of every individual machine ascertained. It is then possible to maintain all the machinery in the best operating condition. Any excess power taken is at once readily detected and the defect can be promptly corrected. An accurate record can also be kept of the cost of power for the different operations.

2. GROUP VERSUS INDIVIDUAL DRIVE

There are two general systems of drive, namely, group and individual. When line shafting is to be changed to an electric drive, the most obvious and simple way of making the change is to split the shafting up into such sections as would be most convenient, and drive each of these by means of a comparatively large motor. On the other hand, it may frequently happen that it is necessary to operate only one machine of the entire group for a considerable time, as in overtime work, and to do this it would then be necessary to keep the motor and the line shafting of the whole group running. Since the efficiency of the motor at this light load would be small, and the friction losses of the entire drive would have to be supplied, it is evident that such a method of operation would result in a waste of power and be most inefficient.

On the other hand, if a large number of similar machines is involved which run continuously if at all, as with much textile machinery, they are often driven in comparatively small groups. If the plant is not on full production certain groups are shut down while others will be operated without any individual being idle in the working group. In this way the investment in motors is reduced but the advantages of simplified shafting, and protection against complete paralysis of operations due to the breakdown of one motor, are realized.

Modern installations, therefore, indicate a tendency toward the use of both the group and individual drive.

INFLUENCE OF CHARACTER OF LOAD. It is generally agreed that all large tools or other machinery should be equipped with individual motors, especially if their service is of an intermittent nature. With the group drive there are two distinct loads, the variable load of the machines and the friction of the line shafting and belting.

INFLUENCE OF SPEED. Wide ranges of control and the possible variations of speed are reasons which in many cases are sufficient in themselves for the selection of an individual drive. With group drive the methods of speed control for the individual machines are obviously more limited. It is then generally accomplished by shifting of belts on cone pulleys or by change of gears. Both of these methods, however, take a considerably longer time than the simple manipulation of the controller with the individual electric drive.

INFLUENCE OF RELATIVE COST. The question of whether group or individual drive is to be installed is a financial one, and each case must be properly analyzed. Individual drive necessarily means a larger investment, but in nearly all cases a much greater percentage income will be realized than if line-shaft drive were employed. With individual

drive the total horsepower rating of the motors installed in the plant will be considerably greater than with group drive, but the maximum power demand of the plant is approximately the same in either case. If power is purchased the price should be based on the actual maximum power demand and not, as sometimes is required, on the total connected horsepower capacity of the motors.

3. SELECTION OF MOTORS

GENERAL CONSIDERATIONS. The installation of a motor having too large a capacity should be avoided, unless an increase in the load is to be expected in the near future, because the efficiency of a motor is usually a maximum at its normal rated output. With a-c motors the effect of the power factor must furthermore be considered. This decreases rapidly below normal load, and on account of the penalty exacted by many public service companies for low power factor, and because of its bad effect on the regulation of the system, it should be kept as high as possible, which can only be done by operating the motors as nearly fully loaded as possible. Ordinarily, however, it is possible so to group the machinery that the motors may be operated near their rated output at all times. Too small a motor is naturally also very undesirable, as it would then in all probability be subject to overloads, which might result in overheating and a burn-out of the motor, causing a shutdown of the machinery which it drives. The operating conditions of the plant may furthermore be such, as for example in steel mills, that the failure of a single motor may necessitate the shutting down of the entire mill.

USE OF STANDARD MOTORS. The American Institute of Electrical Engineers has devised and promulgated standards on which the ratings of motors used by the most competent manufacturers are based. These are the best to use because of the standardized basis of comparison. In addition to this, many of the better motor manufacturers have been gradually changing the motor frames so as to conform with standardized motor mounting dimensions adopted under the guidance of the National Electrical Manufacturers Association (N.E.M.A). The interchangeability thus realized is obviously a great advantage because, among other things, the user is not committed to one make of motor. It is to be noted, further, that N.E.M.A. standards cover ratings, performance, and manufacture of motors in general.

TORQUE AND SPEED. Some machines will require motors with very heavy starting torque, although running under light load when up to speed; for others the requirements may be just the opposite. With a varying-speed motor the torque-speed characteristics should agree as nearly as possible with the load which the motor is to drive. For example, to start and accelerate the bridge of a crane requires a motor capable of developing a high starting torque, but after the bridge is accelerated comparatively little power is required to keep it in motion.

The condition of maximum torque must also be given due consideration. A motor driving a heavy punch may, in spite of the flywheel, develop insufficient torque to keep up the speed. As a rule, however, where the motor is large enough for starting and normal operation, but not large enough for the maximum overload required for perhaps only a second or two, the addition of a suitable flywheel will sometimes cut down the maximum torque required.

AVERAGE LOAD. The average load usually should be the determining factor, although under many conditions found in practice the starting load controls the size of the motor. The frequency of starting and the duration of the starting period, in addition to unusual starting current conditions, are necessarily of great importance in selecting the right motor. The required amount of power to drive a given machine can be ascertained from experience, but in any event it should be known as accurately as possible. See Section 14, Art 86, for current and voltage calculations, and tables of motor currents.

HIGH-SPEED MOTORS. It may be said that, in general, high-speed motors cost less and are more efficient from the operating standpoint than low-speed motors. It is, therefore, best to employ motors having a high normal speed unless it means the use of expensive mechanical transmission equipment where slow-moving machines are to be driven. Close speed regulation is required for machine tools and textile machinery, and under other conditions where the work must be kept running at substantially constant speed. On the other hand, where there are peak loads likely to damage the motor if it does not slow down automatically, or where the machine speed is partially governed by means of a flywheel, as with punch presses, wide speed regulation is necessary. For still other kinds of work calling for variable speed control by an operator it is necessary to use wound-rotor motors or d-c motors. In other words, the character of the drive must be fully taken into account in making the selection of a motor for any particular service.

GENERAL-PURPOSE MOTORS. Motors which are not designed for some special application are generally referred to as general-purpose motors. They are constant-speed motors but are so designed as to be able to carry reasonably varying loads above or below normal. They are made by most of the manufacturers in sizes up to 200 hp and with speeds of 450 rpm and higher. They meet most requirements, and their use is consequently so wide that the National Electrical Manufacturers Association has adopted a **service factor** for all general-purpose motors. This is applied to the normal horsepower rating and gives the overload at which a motor may be run with safety. It appears on the name plates of new motors and reads "Service Factor 1.15 at rated volts and cycles." In other words, if the rating of a motor is 50 hp the permissible loading will be $1.15 \times 50 = 57.5$ hp, provided the line voltage and frequency do not change. This means that if the load requirement should be 55 hp a 50-hp motor will be large enough.

INFLUENCE OF ENVIRONMENT. The physical environment in which the motor has to function should be given careful consideration. Many manufacturers make an effort to design motors for operation under almost every imaginable working condition such as heat, cold, moisture, dust, inflammable or corrosive gases, etc. The users should get the benefit of this by consulting with reliable makers, which costs nothing. The right motor may cost a little more, but it is poor economy to save in this way as it is almost sure to be at the sacrifice of quality and suitability and consequently at the expense of production.

There is no reason for installing d-c motors except where an adjustable-speed service is required, and in small plants where such a service is predominating the d-c system would naturally be the one to install. If a varying-speed feature is required only intermittently, the phase-wound induction motor may be used to advantage; but if the motor must run at reduced speed a considerable portion of the time, the varying-speed, brush-shifting motor should be given careful consideration. As a rule, a considerable part of industrial machinery will require a constant-speed service, for which the a-c motor is admirably adapted. The constant speed induction motor is adaptable to such a wide range of applications that this type covers the great majority of uses. It is, moreover, the least expensive, the most simple and rugged in design and the most economical from the standpoint of maintenance. Should direct current be required it can be obtained by installing a motor-generator set.

As a rule it may be said that the a-c system should be selected if possible, even for the isolated industrial plant, if for no other reason than that it permits of throwing over to a central-station service, in case it should be found that power could be more economically purchased from the central station than be generated on the premises, or in case emergency central-station current were needed.

Motors are of two classes: d-c and a-c according to the system from which they are to be operated. Their subclasses are given below.

Points to Consider in Selecting a D-c Motor

The d-c motors are subdivided into three types, namely, series, shunt, and compound motors.

SERIES MOTOR. This motor is used when a powerful starting torque and rapid acceleration are required, without an excessive instantaneous demand of energy. The torque is practically independent of the voltage and at low flux densities varies directly as the square of the current, but as the magnetization approaches saturation it becomes more nearly proportional to the first power of the current. The maximum torque exists at low speed, this being the most valuable feature of the series motor. Dangerously high speeds may be attained by the armature with very light loads, and for this reason series motors should be either geared or direct-connected to the load.

The Speed of a Series Motor on constant potential varies automatically with the load, increasing as the load decreases. The speed may be adjusted, however, if some means of varying the impressed voltage is provided. As the work required of a series motor is very often intermittent in character, the insertion of resistance in the armature circuit to reduce the speed is permissible from an economic standpoint in such cases. In others, where two or four motors are used, reduced voltage is most readily and economically obtained by connecting the motors in series or in series-parallel.

SHUNT MOTOR. This motor has good starting characteristics and a practically constant speed, varying only slightly with load changes. The speed can be adjusted, however, either by changing the emf impressed on the armature, or by changing the field flux.

Speed Adjustment by Armature-voltage Control, i.e., by changing the emf impressed on the armature, does not change the full-load torque which the motor is capable of

exerting, since the rated torque depends only upon field flux and rated armature current. These methods are therefore constant-torque methods and are properly adapted to loads in which the torque remains constant regardless of speed. The method most generally used for varying the impressed emf with a single-voltage system is by inserting resistance in series with the armature. The efficiency with this method is, of course, very low at slow speeds. The speed regulation with varying loads may also be very poor.

There are several systems of controlling motor speeds by applying different voltages, such as by the use of three-wire generators or two-wire generators with balancer sets or by the Ward-Leonard system. This latter system, which is the most practicable, consists of a constant-speed motor driving a generator which supplies current to the motor whose speed is to be adjusted. This arrangement is very satisfactory, but on account of the expense of providing three full-sized machines instead of one to perform the work, the cost may be prohibitive except with large individual motors, such as for hoists, etc.

Speed Adjustment by Shunt-field Control, i.e., by inserting resistance in the shunt-field circuit, is the simplest of all methods of speed variation, but with ordinary shunt motors, the range of speed variation by this means is small. Where a variation of more than from 20 to 30 per cent is desired, a motor of modified design and of a certain increased size is generally required because the field must be more powerful with respect to the armature than in standard single-speed motors. Varying or adjustable speed motors of the field-weakening type are not constant-torque, but constant-output motors, i.e., the torque falls proportionally as the speed increases.

As a rule, a speed variation up to 3 to 1 meets all requirements, and such motors can readily be obtained in commercial sizes. Should a greater speed variation be desired, say 4 to 1 or 5 to 1, it is possible to accomplish this by the commutating-pole shunt motor with field control only. A combined field and armature control, however, would be a better method.

COMPOUND MOTOR. This motor is provided with both a series and a shunt field. The two fields are usually connected so that they act in the same direction, in which case the motor is called a "cumulative" compound motor. "Differential" compound motors, with the two fields opposing, are sometimes employed for special services. The cumulative, or ordinary, compound motor combines the characteristics of the shunt and and series motors, having a speed not extremely variable under load changes, but developing a powerful starting torque and an increasing torque with decreasing load. Motors having a comparatively weak series field are employed extensively in shop practice where the motor may be required to start under heavy load but must maintain an approximately constant speed after starting, or when the load is removed. The heavily compounded motor is used where powerful starting torque and rapid acceleration are necessary, with a speed not varying too widely under load changes, such as for rolling mills, etc.

The speed control employed with compound motors may be any of the various methods explained in connection with the shunt motor. For certain service the control may be entirely rheostatic, the series winding being cut out after the motor has come up to speed.

Points to Consider in Selecting an A-c Motor

As a general thing, single-phase a-c motors are preferable in sizes of $^1/_2$ hp or less. They should also be used up to 5 hp in preference to polyphase motors when installed in places which are inaccessible or otherwise out of the way. This is because if a fuse blows on one phase of a polyphase motor, it has the effect of a heavy overload which causes excessive heating, and serious damage to the motor may result. If a fuse blows on a single-phase motor, the motor simply stops.

Except under these conditions two- or three-phase motors are preferable because of their simplicity, ruggedness, and fool-proof qualities.

SINGLE-PHASE INDUCTION MOTORS. These have their rotors wound for repulsion starting and provide for a starting torque of 2 to 4 times full-load torque. As the motor comes up to the speed at which it runs as an induction motor, a governor automatically short-circuits the rotor windings. The starting characteristics may be varied by shifting the brushes so that there will be an extra heavy torque when starting if the machine has a marked flywheel effect, or so that the greatest torque will come when the machine reaches full speed, as is required for such drives as blowers, centrifugal pumps, etc.

POLYPHASE MOTORS, SQUIRREL-CAGE TYPE. The following analysis of seven different types of squirrel-cage motors now on the market will form a basis of comparison for industrial applications. The type numbers refer to Table IV.

General-purpose Squirrel-cage Motors—with Normal Torque (Type 1) Standard squirrel-cage motors represent the simplest possible machines for converting electrical energy into mechanical work.

With rated voltage applied at the terminals, four-pole standard squirrel-cage motors develop a minimum starting torque of 150 per cent of full-load torque. (See Fig. 1 and Table 1.) The torque increases gradually until it reaches a maximum of from 250 to 300 per cent at about 75 per cent full-load speed. At no load, the speed is practically synchronous; as load is applied, speed falls off uniformly up to full load, where it is approximately 95 per cent of synchronous speed. Since these motors operate at nearly constant speed from no load to full load, they are often referred to as "constant-speed motors." These electrical characteristics qualify standard squirrel-cage motors for an almost unlimited variety of applications, as listed in Table III.

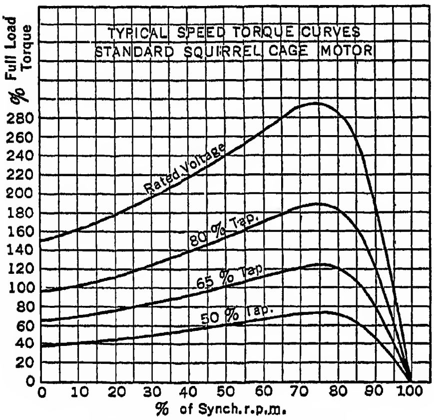

FIG. 1. Speed-torque Curves

Many power companies have established limitations on the amount of current motors may draw at starting, limitations usually based on N.E.L.A. 1923 (now E.E.I.) starting current recommendations, but in some cases higher or lower than those figures. The purpose is to reduce power fluctuations and prevent flickering of lights. The regulations apply to installations of a single polyphase motor of 1 hp and over; the larger the motor, the stricter the regulations. (See Table II.)

Table I. National Electric Manufacturers Association Minimum Starting Torques in Percentage of Full-load Torque, of Standard Squirrel-cage Motors, 25 to 60 Cycles, with Rated Voltage Applied, at the Instant of Starting from Rest

Poles	Torque	Poles	Torque	Poles	Torque	Poles	Torque
2	150	6	135	10	120	14	110
4	150	8	125	12	115	16	105

Where E.E.I. starting current recommendations have been accepted, or where even lower limits are the rule, standard squirrel-cage motors of 7 $^1/_2$ hp and larger cannot be thrown directly across the line. Their starting currents are higher than the E.E.I. recommendations shown in the table. Hence, current-reducing devices must be used to start these larger ratings when it is necessary to meet starting current limitations.

In localities where starting currents are limited, the application of standard squirrel-cage motors is limited to machines which do not require a heavy starting torque, such as fans and blowers, compressors, centrifugal pumps, line shafting, machine tools, etc. If the starting torque under reduced voltage is below that required, an across-the-line type motor should be used, as described below.

The data of Table II are from Appendix I, Revision of Motor Rules, N.E.L.A., April 16, 1923. The currents are the free rotor values, i.e., current values indicated by a well-damped ammeter located in the motor-circuit on the line side of the starter, if any, with the motor connected to its load and the starter in the position necessary to start the motor. These currents are three-fourths of the blocked rotor values and therefore will have to be increased one-third where the blocked rotor values govern.

Experience since 1923 has led to the conclusion that motor-starting current rules based not only on the capacity of the motor but also on that of the system, at a given point, would result in much more economical installations for consumers in the large majority of cases and would also prevent uneconomical demands for excessive starting currents at remote points. Where an installation consists of several motors, the diversity factor further extends the permissible starting current per motor. These considerations led the Electrical Apparatus Committee of N.E.L.A. in 1929 to withdraw their support from the 1923 Rules. Nevertheless, the Rules, although not followed rigorously, continue to be used as a general guide.

The initials E.E.I. will be used herein to designate the Edison Electric Institute or its predecessor, the N.E.L.A., and their respective committees. (See Edison Electric Institute Bulletin, July, 1934, page 251; July, 1935, page 271 and August, 1935, page 333.)

Tables of current at rated load data on overload protection and formulas for calculating wire sizes will be found in Section 14, Art. 86.

Low-torque across the Line Squirrel-cage Motors, 30 Hp and Smaller (Type 2). These motors are designed to develop starting torques approximately as given in Table I, and can be started directly across the line without exceeding E.E.I. starting-current recommendations shown below. No current-reducing starting devices are required; a simple hand-operated (manual) starting switch—or in case of remote-control, an across-the-line magnetic contactor operated by push-button or other pilot-circuit device—is all the starting equipment needed.

These motors are intended for installation where starting-current limitations require the use of compensators with type 1 motors, and where the reduction of voltage at starting lowers the starting torque of type 1 motors below that required.

These motors with across-the-line type starters cost considerably less than type 1 motors with compensators, as they require no compensators, are easier to install, and involve less maintenance. The cost of a 7 1/2-hp, 220-volt, 1800-rpm type 2 motor with push-button starter, for example, is 66 per cent of that of a type 1 motor of the same rating with compensator. That is not the only saving, however. The starting torque of a type 1 motor is greatly reduced by the compensator; the type 2 motor, on the other hand, starting at rated voltage, makes available the *full* inherent starting torque for " break-away " and acceleration. This feature makes it possible in many applications to use a type 2 motor of lower rating than would be necessary if a type 1 motor and compensator were used—reducing the initial investment still further.

Table II. E.E.I. (1923) Starting-current Recommendations—60 Cycles Only

Hp	Amperes per Phase (75 per cent of blocked rotor current)							
	220 volts		440 volts		550 volts		2200 volts	
	3 Ph.	2 Ph.	3 Ph.	2 Ph.	3 Ph.	2 Ph.	3 Ph.	2 Ph.
7 1/2	86	74	43	37	34	30	7 1/2	7 1/2
10	106	92	53	46	42	37	10	10
15	148	128	74	64	59	52	15	15
20	188	166	94	83	76	66	20	20
25	228	203	114	102	92	81	25	25
30	270	240	135	120	108	96	30	30
40	285	250	142	125	114	100	30	30
50	300	260	150	130	120	104	30	30
60	360	312	180	156	144	126	36	30
75	450	390	225	195	180	157.5	45	37.5
100	600	520	300	260	240	210	60	50

Low-torque across the Line Squirrel-cage Motors, 40 Hp, and Larger (Type 3). These large motors can be started directly across the line without exceeding E.E.I. starting-current recommendations. No current-reducing starting devices are required; a simple hand-operated (manual) starting switch—or in case of remote control, an across-the-line type magnetic motor switch operated by push button or other device—is all the starting equipment needed.

The starting torque of type 3 motors, is, however, somewhat lower than that of type 1 motors of 30 hp and below, the starting amperes per horsepower recommended by E.E.I. are high enough to permit E.E.I. starting torques. But above 30 hp the starting current allowed is so low that this starting torque cannot be developed. Designed to operate within E.E.I. limitations, type 3 motors develop a starting torque of about 80 to 100 per cent of full-load torque, and are therefore known as "low-torque " motors.

These low-torque motors are suitable for such applications as listed in Table III.

High-torque across the Line Double Squirrel-cage Motors, 30 Hp and Smaller (Type 4). Double squirrel-cage motors develop a starting torque of from 200 to 250 per cent of full-load torque, a starting torque from 1/3 to 2/3 higher than that of the standard squirrel-cage motors. Notwithstanding the high starting torque, the starting current is within E.E.I. recommendations, and the motors can therefore be thrown directly across the line without the use of current-reducing starting devices.

The absence of current-reducing starting devices and the high starting torque of these motors make them the preferred type for a wide variety of industrial applications. They are particularly suitable for such applications as listed in Table III, where heavy starting resistance must be overcome and starting current must be held down. As these motors can be started at rated voltage, they permit applying motors rated very closely to the actual horsepower requirements. Thus it is possible in applications requiring a high starting torque to install type 4 motors of considerably lower horsepower rating than

would be necessary if type 1 motors with compensators were installed, eliminating expensive overmotoring and assuring better power factor. The double squirrel-cage motor has what its name denotes: two separate squirrel cages, one of smaller dimensions inside the other, and both embedded in the same laminated iron field.

High Torque Double Squirrel-cage Motors, 40 Hp and Larger (Type 5). These motors are the same as type 4 motors, electrically and mechanically. They should, however, be treated as a separate group, as their starting currents exceed E.E.I. recommendations shown below—for which reason they involve the use of current-reducing starting devices wherever starting currents are regulated.

With full voltage applied, these motors develop the same high starting torques as the type 4 motors just described. When started on reduced voltage to meet E.E.I. starting-current limitations, their starting torques vary as the square of the voltage applied to the motor terminals. At 80 per cent rated voltage, the starting torque of a 4-pole type 5 motor is reduced to approximately 160 per cent (250×0.80^2—taking 250 per cent as the starting torque at rated voltage), which is naturally considerably higher than that of a type 1 motor started at the same reduced voltage. At 65 per cent rated voltage, the starting torque developed is approximately the same as that of the type 3 motors started on full voltage. See Figs. 2 and 3.

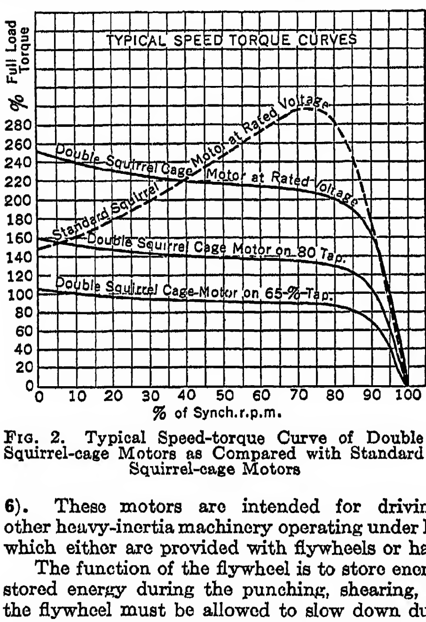

FIG. 2. Typical Speed-torque Curve of Double Squirrel-cage Motors as Compared with Standard Squirrel-cage Motors

The use of these motors is dependent upon starting-current regulations. Where full voltage can be applied, these motors are the logical selection for such applications as crushers, plunger-pumps, belt conveyors starting under load, large air compressors, and other machinery involving heavy inertia at starting. Where compensators are required and the starting torque obtained is insufficient to start a given load, the only alternative is the use of wound-rotor motors, such as the slip-ring and Fynn-Weichsel motors.

Ten Per Cent Slip Squirrel-cage Motors for Flywheel Applications (Type 6). These motors are intended for driving punch presses, shears, bulldozers, and other heavy-inertia machinery operating under heavy, fluctuating load conditions, machines which either are provided with flywheels or have flywheel effect.

The function of the flywheel is to store energy as the machine idles, and to deliver the stored energy during the punching, shearing, or other operation. In order to do this, the flywheel must be allowed to slow down during each operation, and must be quickly accelerated to full speed immediately after to prepare it for the next operation. The proper motor for such a service is one which has (1) high slip to allow the flywheel to release its stored energy, (2) high starting torque to overcome inertia of the heavy flywheel, (3) quick acceleration to bring the flywheel up to full speed at the start and after each operation.

These punch press motors have a slip high enough so that they slow down while the punch press releases stored-up energy. They develop a starting torque very much greater than that of standard squirrel-cage motors, accelerate quickly to full-load speed, and are designed for across-the-line starting. They are not suitable, however, for machinery not flywheel operated which requires motors of the standard, across-the-line, and double squirrel-cage types. On the other hand, these types are not suitable for flywheel machinery.

Standard squirrel-cage, double squirrel-cage and across-the-line motors are low-slip, constant-speed motors, inherently unable to slow down to let the flywheel do the work; they would attempt to keep the flywheel revolving at a *constant* speed, and would consequently create considerable line disturbance by drawing excessive current each time the machine is doing work. Furthermore, standard squirrel-cage and across-the-line motors have considerably lower starting torque than punch press motors, for which reason machines would have to be heavily overmotored to start the heavy flywheels.

High-torque Squirrel-cage Motors for Elevators, Small Hoists, etc. (Type 7). Elevator motors are intended for elevator service, or such similar applications as cranes and hoists requiring: (1) very high starting torque; (2) frequent starting, stopping, and reversing;

and (3) low starting current; and which do *not* require: (1) constant speed; (2) adjustable varying speed; or (3) long periods of operation.

A comparison between the type 7 elevator and standard squirrel-cage motors shows important differences in electrical characteristics, briefly stated as follows:

(*a*) Maximum torque of elevator motors occurs at the start rather than at $2/3$ full-load speed or thereabouts, as in standard squirrel-cage motors. This is necessary to overcome the inertia of machinery for which elevator motors are intended.

(*b*) Elevator motors have a slip of about 20 per cent as compared with 5 per cent or less for standard squirrel-cage motors. The high slip minimizes heavy jerking of the machinery, which would occur if low-slip motors were applied.

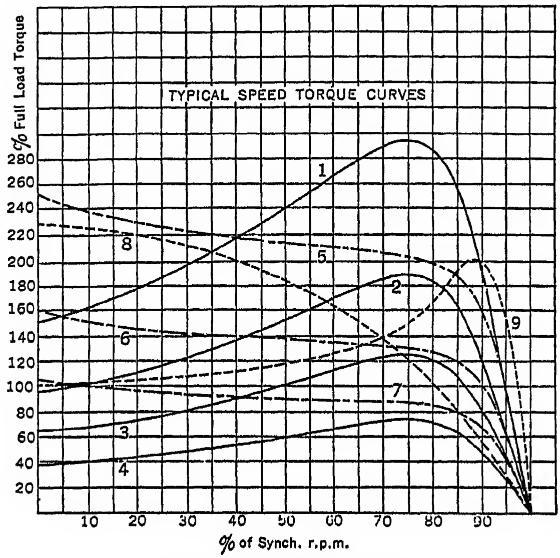

FIG. 3. Squirrel-cage Motors

Curve 1—Standard;	Rated Voltage	Curve 5—Double;	Rated Voltage
2— " ;	80% "	6— " ;	80% "
3— " ;	65% "	7— " ;	65% "
4— " ;	50% "	8—Elevator;	Rated "
		9—Low Torque;	" "

(*c*) Starting current drawn by elevator motors is much lower than that drawn by standard squirrel-cage motors, eliminating the need of current-reducing starting devices.

(*d*) Because of the high rotor resistance necessary to effect high starting torque, elevator motors are designed for intermittent loads only, and overheat when used for continuous service. They are intended for a maximum service of 30 minutes, over which period the temperature rise will not exceed 50 deg cent.

Multi-speed Squirrel-cage Motors. Both two- and four-speed squirrel-cage motors are now being used to a considerable extent and are available in the constant-torque, variable-torque, and constant-horsepower types. Multispeed, squirrel-cage motors are taking the place of the slip-ring variable-speed motor for many applications where only certain definite fixed speeds are required.

SLIP-RING INDUCTION MOTORS. The following discussion of the characteristics of slip-ring motors has been taken largely from bulletins of the Wagner Electric Corp. and tells why motors of this type are necessary for satisfactory service for certain industrial applications.

Mechanical and Electrical Characteristics. The outstanding difference between squirrel-cage and slip-ring motors is in the rotor winding. Since the rotor bars and end rings of squirrel-cage motors have fixed resistances, such characteristics as starting and pull-out torques, rate of acceleration, and full-load operating speed cannot be altered for a given squirrel-cage motor installation. In slip-ring motors, the ends of the windings are brought out to three collector rings, and the currents induced in the rotor are carried through the slip rings to external control equipment which inserts varying values of

Table III. Comparison between Seven Different Types of Squirrel-cage Motors with Average Characteristics and Typical Applications

Type	Standard Ratings (Single Speed)	Starting Current	Starting Torque	Approximate Full-load Slip	Mechanical Variations	Typical Applications
1	1/10 to 400 hp 3 or 2-phase 25 to 60 cycles 110 to 2200 volts	Above that permitted by most power companies for 10 hp and larger; hence, current-reducing starting devices ordinarily used.	Varies with the square of the voltage applied to the motor terminals: approximately 150% of full-load torque at rated voltage; 96% at 80% voltage; as low as 38% at 50% rated voltage.	4 to 5%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical.	Group or individual drives, in machine shops, on machine tools, fans and blowers, compressors, centrifugal pumps—on any application where normal torque motors are satisfactory.
2	7 1/2 to 30 hp 3 or 2-phase 60 cycles 110 to 2200 volts	Within E. E. I. starting-current recommendations, hence within most power companies' limitations, and therefore suitable for starting directly across the line.	Approximately same as type 1 motors. As these motors can be started across the line at *rated* voltage, they can start considerably more load than type 1 motors started under *reduced* voltage.	4 to 5%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical.	Same as standard squirrel-cage motors, type 1.
3	40 to 100 hp 3 or 2-phase 60 cycles 220 to 2200 volts	Within E. E. I. starting-current recommendations, hence within most power companies' limitations, and therefore suitable for starting directly across the line.	Centrifugal pump service does not require heavy starting torque. Therefore these motors have starting torque of 80 to 100% of full-load torque.	4 to 5%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical.	Centrifugal pumps, agitators, fans and blowers, generator sets, and other applications requiring low starting torque.
4	3 to 30 hp 3 or 2-phase 60 cycles 110 to 2200 volts	Within E. E. I. starting-current recommendations, hence within most power companies' limitations, and therefore suitable for starting directly across the line.	About 200 to 250% of full-load torque.	4 to 5%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical.	Crushers, plunger pumps, belt conveyors starting under load, large air compressors, large refrigerating machinery, mixers, and other applications requiring high starting torque.
5	40 to 100 hp 3 or 2-phase 60 cycles 220 to 2200 volts	These motors have starting currents above most power companies' limitations; hence, current-reducing starting devices ordinarily used.	Varies with the square of the voltage applied to the motor terminals: approximately 200 to 250% of full-load torque at rated voltage; 130 to 160% at 80% voltage; 85 to 106% at 65% rated voltage.	4 to 5%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical.	The logical motor to use for applications where the torque produced by type 1 motors is not sufficient. If the starting torque of type 5 motors under reduced voltage is too low for any application, slip-ring or Fynn-Weichsel motors should be used.
6	1 to 150 hp 3 or 2-phase 25 to 60 cycles 110 to 2200 volts	Low enough to start across the line.	About 350% of full-load torque.	10 to 13%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical	Punch presses, shears, bulldozers, metal-drawing operations, balers, and other machinery equipped with flywheels or having flywheel effect.
7	1 to 30 hp 3 or 2-phase 25 to 60 cycles 110 to 550 volts	Lower than any other type of squirrel-cage motor. No current-reducing starting devices used.	Approximately 250% of full-load torque.	15 to 17%	Sleeve or rolling bearings open or totally enclosed horizontal or vertical.	Elevators, cranes, hoists, dumbwaiters.

resistance in the rotor circuit, thus effecting (1) variation in starting torque and current, (2) smooth acceleration, and (3) variation in operating speed—depending, of course, entirely upon the resistors incorporated in the control equipment.

It also follows that, because the resistance of the rotor circuit is controlled externally and thus is subject to change at will, (1) a relatively large starting torque can be obtained with relatively low starting current, without affecting operating characteristics, and (2) the greater part of the heat developed during starting or reduced speed operation is dissipated in the external resistors rather than in the rotor.

These desirable characteristics of slip-ring motors not only assure more satisfactory service, but there are other advantages such as (*a*) prolonging the life of machinery and belts through smoother starting, (*b*) preventing overmotoring, and (*c*) reducing voltage fluctuations on distribution circuits.

Starting Heavy Loads. Slip-ring motors have the ability to start extremely heavy loads; hence they are suitable for (1) driving various types of machinery which require development of considerable starting torque to overcome friction, (2) accelerating extremely heavy loads which have flywheel effect or inertia, and (3) overcoming back-pressures set up by fluids and gases in the case of reciprocating pumps and compressors.

Double squirrel-cage motors are also applicable on many of the heavier machines involving the problems mentioned above. But if a considerable length of time is required to accelerate the load to full speed, double squirrel-cage rotors may burn out before full speed is attained—and for that reason slip-ring motors should be used instead. Frequent starting has the same effect of overheating double squirrel-cage motors—for which reason slip-ring motors should be used on machinery started frequently.

Variation in Operating Speed. Variations in operating speed are essential on many applications. It is often desirable to vary the operating speed of conveyors, compressors, pulverizers, stokers, and the like in order to meet varying production requirements. Slip-ring motors, because of their adjustable varying speeds, are ideally suited for such applications. However, if the torque required does not remain constant, the speed of the slip-ring motor will vary over wide limits—a characteristic constituting one of the serious objections to the use of slip-ring motors for obtaining reduced speeds. Another factor which must be taken into consideration when selecting slip-ring motors for reduced-speed operations is that of lowered motor efficiency.

When slip-ring motors are used for cranes, hoists, and elevators, machinery operated intermittently and not over long periods, poor speed regulation and loss in efficiency are of little consequence. However, if lowered speeds are required over longer periods, poor speed regulation and loss in efficiency may become prohibitive.

Smooth Starting. Through the use of external resistors in the slip-ring rotor windings, a wide variation in rotor resistance can be obtained with a resultant variation in acceleration characteristics. Thus a heavy load can be started as slowly as desired, without a jerk, and can be accelerated smoothly and uniformly to full speed. It is merely a matter of supplying the necessary auxiliary control equipment to insert sufficiently high resistance at start, and to reduce this resistance gradually as the motor picks up speed.

Low Starting Current. Many power companies have established limitations on the amount of current motors may draw at starting—limitations usually based on Edison Electric Institute starting-current recommendations, but in some cases higher or lower than those figures. The purpose is to reduce voltage fluctuations and prevent flickering of lights. Because of such limitations, the question of starting current is often the deciding factor in the choice of slip-ring motors instead of squirrel-cage motors.

Slip-ring motors with proper starting equipment develop a starting torque equal to 150 per cent of full-load torque with a starting current of approximately 150 per cent of full-load current—which compares very favorably with squirrel-cage motors, one type of which requires a starting current of as much as 600 per cent of full-load current to develop the same starting torque of 150 per cent.

Such a high starting current causes all but the smallest of squirrel-cage motors to exceed the E.E.I. recommendations, and such squirrel-cage motors must therefore be started with current-reducing devices to meet starting-current limitations established by the power companies. Any reduction, so obtained, in starting current of squirrel-cage motors involves a sacrifice in starting torque which frequently results in overmotoring in order to provide sufficient starting torque.

Types of Slip-ring Motors. Two types of slip-ring motors may be obtained, namely, type 1—continuous duty; type 2—intermittent duty. The two types are alike in practically every detail; the difference is in frame size for a given horsepower and rpm rating, the type 2 motors being built in smaller frames than the type 1. Type 2 is intended for elevator, crane, hoist, and like services requiring but short periods of motor operation, making a reduction in frame size permissible.

Type 1 can be subdivided into two classes: (1) constant speed; (2) adjustable varying speed.

In either case, the electrical differences are entirely in the control equipment, and principally the external resistor units. The motors themselves are the same. The starting devices used for both types of service are simple, but the control devices for adjustable varying speed are much larger in order to dissipate the greater amount of heat developed when the rotor resistances (determining operating speeds for a given torque) remain in the rotor circuit for a considerable period of time.

CONTROL EQUIPMENT FOR SLIP-RING MOTORS. Slip-ring motors have certain inherent speed-torque characteristics, which can be altered considerably by the secondary control equipment which introduces into the rotor circuit varying values of resistance. Since the control equipment has this ability to change the slip-ring motor characteristics, the following brief discussion should assist motor users to understand the various types of control apparatus needed with slip-ring motors.

Motor Starting Equipment. Standard manual starting equipment for slip-ring motors up to and including 20 hp consists of an enclosed primary magnetic contactor providing thermal overload and undervoltage protection, electrically interlocked with a secondary face plate starter with self-contained N.E.M.A.-15 starting duty resistors. For motors 25 hp and over, standard manual starting equipment consists of a primary magnetic contactor providing thermal overload and undervoltage protection, electrically interlocked with a non-reversing drum and externally mounted N.E.M.A.-35 starting duty resistors. For 2200-volt motors, an enclosed manually operated double-break, 3-pole, oil circuit breaker replaces the primary magnetic contactor employed on low-voltage circuits.

The electrical interlocking of the primary and secondary control circuits makes it always necessary to start the motor from the off position of the secondary controller, and assures that the motor is always started with the full resistor in the rotor circuit.

In the event that the starting duty requirements are quite severe, resistors built to N.E.M.A.-15 and N.E.M.A.-35 service classifications may not prove ample. In this case the proper service classification resistors listed in Table IV may be selected to correspond to the amount of starting torque required and the length of time the resistors will remain in the secondary circuit during the starting period. Cases may also arise where the starting service for motors 25 hp and under may require that a drum-type secondary starter be substituted for the standard face plate secondary with N.E.M.A.-15 resistors.

Should reverse rotation of the motor be required, this can be effected by means of a reversing drum controller in the secondary circuit similar to the non-reversing drum controller except that it is provided with a set of primary contacts which serve to reverse one phase of the primary or stator circuit.

Oftentimes it is desirable to start slip-ring motors entirely automatically. Standard non-reversing full magnetic remote-control slip-ring motor starters consist of a panel upon which is mounted a three-pole primary magnetic contactor with thermal overload relays, and secondary accelerating contactors governed by timing relays. The resistors (N.E.M.A.-36 for standard automatic starters) are mounted in the rear of the panel. A start and stop three-wire control push-button station completes the standard equipment.

Full magnetic slip-ring motor starters may also be entirely automatically operated from accessories such as float switches, thermostats, and pressure regulators.

Type 1 Motor Speed Regulating Equipment. Standard manual speed-regulating control equipment for slip-ring motors 15 hp and under consists of an enclosed primary magnetic contactor providing overload and undervoltage protection, electrically interlocked with a secondary face plate speed regulator with self-contained resistors designed for either fan or machine duty.

The interlocking of the primary and secondary control circuits makes it always necessary to start the unit from the off position of the controller, and assures that the motor is always started with full resistor in the rotor circuit of the motor.

Standard manual speed-regulating control equipment for slip-ring motors 20 hp and upwards consists of a primary magnetic contactor providing overload and undervoltage protection for low-voltage circuits. For 2200-volt circuits, an enclosed manually operated, double-break, 3-pole oil circuit breaker is used, electrically interlocked with a non-reversing drum controller and separately mounted fan-duty (N.E.M.A.-93), or machine-duty (N.E.M.A.-95) speed-regulating resistors.

A reversing drum controller can be supplied if reverse operation of the motor is required. Such a reversing drum has a set of primary contacts mounted in the drum which serves to reverse one phase of the primary (stator) circuit, thereby reversing the motor.

Upon the choice of the proper secondary resistors depends the success of any reduced or variable speed slip-ring motor installation since the speed and the torque are mutually

related. Great care should, therefore, be taken in determining the nature of the load as far as its torque requirements are concerned at reduced speeds.

Machine duty resistors (N.E.M.A.-95) are designed for constant-torque loads—that is, irrespective of speed, the *torque* required remains essentially the *same*. Machine-duty resistors are designed to reduce the motor speed 50 per cent with 80 per cent of normal current flowing. They are used with reciprocating pumps, positive pressure blowers, etc.

Fan-duty resistors (N.E.M.A.-93) are designed for loads where the torque decreases with the speed, and are designed to reduce the speed 50 per cent with approximately 40 per cent normal current flowing. They are used with ventilating fans, centrifugal pumps, etc. The characteristics of this type of load are such that the horsepower required to drive the load varies approximately as the cube of the speed.

Fan-duty and machine-duty resistors will perform satisfactorily only when employed with the type of load for which they are specifically designed.

MOTOR CONTROL EQUIPMENT. Since type 2 motors are intermittently rated motors used for crane, hoist, and elevator work (where the motor is under control of the operator, most, if not all of the time it is in operation), the standard manual control consists of a reversing drum controller with the proper separately mounted secondary resistors. A set of primary contacts in the drum serves to reverse one phase in the primary (stator) winding, thereby securing two directions of rotor rotation, or up and down travel of the driven load. Primary magnetic contactors are also employed with type 2 motor control in order to supply "limit protection" so as to insure that the load will not overtravel in the up and down, or back and forth directions.

Limit protection is provided by interlocking the primary magnetic contactor with limit or hatchway switches which open the pilot circuit of this primary magnetic contactor, thereby disconnecting the motor from the line. Overload relays may be included with this primary magnetic contactor to afford overload protection, but accurate overload protection is made difficult by the intermittent nature of the load.

In ordering control for type 2 motors, the service for which the apparatus is intended should be specified in all cases. If the resistors are to be designed for crane service, this should be stated; if for hoist service, full information should be given as to whether the resistors are to be used with a vertical or a slope hoist.

Brake Equipment. Type 2 motors for gear drive are generally furnished with a double extended shaft. One end of the shaft drives the load; the other is so arranged that a brake wheel can be mounted on it. A solenoid brake shoe of the spring-set or gravity-set type acts on the brake wheel. The solenoid coil of the brake is connected across the power supply, and as long as the motor is connected to the line the solenoid coil overcomes the tendency of the spring or gravity to set and seize the brake wheel.

Table IV. N.E.M.A. Resistor Service Classifications

Periodic Ratings

Approximate Percentage of Full-load Current on the First Point	15 Sec out of 4 Min	30 Sec out of 4 Min	45 Sec out of 4 Min	1 Min out of 4 Min	1 1/2 Min out of 4 Min	2 Min out of 4 Min	Continuous Duty
	Numbers						
25	11	31	41	51	61	71	91
50	12	32	42	52	62	72	92
75	13	33	43	53	63	73	93
100	14	34	44	54	64	74	94
150	15	35	45	55	65	75	95
200 or Over	16	36	46	56	66	76	96

NOTE: 15 sec out of 4 min means that the resistor will operate at its specified duty not more than a total of 15 sec during any 4 min period. Unless otherwise specified, Wagner furnishes a N.E.M.A.-35 starting duty resistor, which provides for 150 per cent torque on the first point of drum controllers, good for 30 sec starting duty. If the load is extremely hard to start and requires more that 30 sec to accelerate to full-load speed, a N.E.M.A.-55 (1 min duty out of every 4 min) or a N.E.M.A.-75 (2 min duty out of every 4 min) may be required. If the load is of such a nature that a 100 per cent starting torque is required, and if for the purpose of protecting the machinery from the shock of too rapid starting it is found necessary to consume 1 min in bringing the motor to full-load speed, a N.E.M.A.-54 starting duty resistor should be used as indicated in the above table. These same remarks apply to speed-regulating resistors as far as torque is concerned, as all speed-regulating resistors, whether for machine or fan duty, have a continuous duty rating. (See Continuous Duty column.)

The moment the motor is disconnected from the line the solenoid brake coil is de-energized and the brake sets, owing to the action of the spring, gravity, or both.

Type 2 motors for direct-connected drive are generally furnished with single shaft extension, the metal coupling between the motor and the driven load serving as the brake wheel, the rest of the solenoid brake mechanism being similar to that previously described.

SPLIT-PHASE MOTORS. This type of motor is going out of use because the excessive starting current causes flickering of lights fed from the same transformer. As a general thing, power companies are opposed to the use of these motors except in very small sizes ($^1/_4$ hp or less). Their application is practically entirely for domestic appliances and only very rarely industrial.

CONDENSER MOTORS. These are single-phase squirrel-cage motors with a condenser across one phase to correct power factor and provide starting torque for small sizes up to 5 hp, for appliances such as fans, unit heaters, domestic refrigerators, etc. The industrial uses, other than for unit heaters, have so far not been developed to any extent.

TOTALLY ENCLOSED AIR-JACKETED MOTORS. Several of the leading manufacturers are building motors which are totally enclosed and ventilated and fan cooled. They are designed for locations where dust, fumes, and moisture are present in sufficient quantity to clog, corrode, short-circuit, or wear out the open type or where inflammable dust or vapors are present in sufficient quantity to cause explosions or fires. In some cases enclosed motors should be used throughout the plant, and in others only in locations where conditions make them necessary. Obviously the use of such motors is more satisfactory in the long run than providing improvised unventilated boxes for their protection or placing them in a separate room or building.

Where Used. The following brief analysis gives an idea of the services to which motors of this type may be applied. It is worth bearing in mind that insurance rates in hazardous locations are lower where enclosed air-jacketed motors are used and that they are furthermore of advantage in that they act as a safeguard against loss of production, not covered by insurance, in atmospheres where there would be danger of fire or explosion with open-type motors, even when boxed or partitioned.

(*a*) *Abrasive Dust.* Any kind of dust of sufficient density to act as an abrasive—such as iron, glass, sand, rock, coke and coal—exerting wear on moving parts and windings, and shortening life of motor.	Steel mills and all other metal-working industries. Glass plants—especially plate glass works. Rock crushers. Foundries.
(*b*) *Conducting Dust.* Current-carrying substances, such as certain metals and their salts, which will short-circuit the motor windings.	Steel mills. Metal-working plants.
(*c*) *Explosive Dust.* Inflammable material present in sufficient quantity to ignite and explode—such as grain, feed, flour, coal, coke, lint, wood, fiber and starch.	Grain elevators. Flour and feed mills. Pulverized coal plants. Planing mills.
(*d*) *Corrosive Gases or Fumes.* Any alkaline or acid substance in gaseous state which will attack windings and corrode the motor—such as found in process industries, dipping and plating departments.	Gas plants. Chemical plants. Paint shops. Dipping and plating departments. Dye houses.
(*e*) *Steam and Moisture.* Free steam or any kind of vapor, splashes of water and other liquids, which will short-circuit or corrode the motor.	Laundries. Meat-packing plants. Paper and pulp industries. Glass factories. Any outdoor service.

DRIP-PROOF MOTORS. This type of motor has the upper halves of the heads closed so that materials, including liquids, cannot fall into it. They are used in locations where danger of this exists.

GEAR MOTORS. For many applications requiring reduction of speed, a type of motor with the reducing gears forming a part of it, has the advantage of compactness, quietness and low maintenance cost.

SYNCHRONOUS MOTOR. The speed of a synchronous motor is constant, being fixed by the number of poles and the frequency of the applied voltage. The single-phase

type is not self-starting, and the polyphase type has in itself a very low starting torque. They may, however, be made self-starting in the same manner as squirrel-cage induction motors, by the use of an amortisseur or cage winding, similar in construction to that used for induction motors. This is now the usual practice.

The speed-torque curve of a synchronous motor is similar to that of an induction motor except that the torque values are lower for a given resistance of rotor winding on account of the construction of the machine. The starting winding must be designed with both the load at start and the load at synchronous speed in mind, because too great a slip may cause the motor to shut down when the field is put on. It is seldom, however, that the same motor will be called upon to start a heavy load and at the same time synchronize a heavy load, as the load usually consists principally of either static friction, as in motor-generator sets, line shafting, etc., or it comes up with the speed as in a fan blower or centrifugal pump. The former case would be met by a high-resistance squirrel-cage winding, and the latter would require a low resistance.

FYNN-WEICHSEL MOTOR. The Fynn-Weichsel motor is designed to supply its own magnetizing current and supply it to the line for other motors so as to correct overall power factor. It starts as a slip-ring induction motor, and when reaching synchronous speed operates as a self-excited synchronous motor up to about 150 per cent of full-load torque, when it again resumes operation as an induction motor until the excessive overload has passed, when it automatically returns to synchronous operation. These characteristics make it widely applicable to industrial loads of considerable variety and irregularity.

Points to Consider in Selecting a Motor for a Given Application

1. Make allowance for manufacturing tolerances, difference in materials, etc., in the motor and the driven machine, bearing in mind that such differences exist in machines that are manufactured as exact duplicates.

2. Make certain that the normal rating of the motor is sufficient to handle the normal load properly. If the correct rating is selected for the normal load the reserve power will take care of all emergencies such as low voltage, tight bearings, congealed oil, line surges, etc.

3. Where a careful application test is desired on small machines it is preferable for the machine manufacturer to ship a complete machine to the motor manufacturer's plant where facilities for making tests of this nature are usually available.

4. Where a contract for a number of motors is involved and where it is impossible to send the machine, it is generally possible to have the motor manufacturer send an engineering representative to study conditions and make recommendations.

PULLEYS AND PINIONS. In connection with belted installations, select a pulley that is at least $1/4$ in. ($1/2$ in. preferable) wider than the belt. Belt speeds above 5000 ft per min should be avoided. Belt speeds of 3500 to 4500 ft per min are preferable. The following formula may be used for obtaining belt speeds where the diameter of the motor pulley and its speed in revolutions per minute are known.

$$\text{Belt speed in feet per minute} = .2618\, ds$$

where d equals the diameter of the pulley in inches and s the rated load speed of the motor in revolutions per minute.

Paper pulleys have a transmitting capacity approximately 65 per cent greater than that of iron pulleys and 30 per cent more than wood. For motors below 2 hp, and in case the belt contacts for both driving and driven pulleys is as much as approximately 170 deg of the pulley circumferences, the belt slippage is negligible, but where quantity is involved and it is important that the driven machine should run extremely close to a certain speed, it is well to put on a pulley of the calculated size and try it before deciding definitely as to correctness of size.

In order to calculate the proper pulley size use the following formula:

$$ds = DS$$

where ds represents diameter in inches and revolutions per minute respectively of motor pulley, and DS the diameter in inches and revolutions per minute of the driven pulley. For example, it is required to determine the diameter of a pulley for a 1725-rpm motor to drive an appliance having a 10-in. diameter pulley, and running 345 rpm. Substituting in the above formula:

$$1725\, d = 10 \times 345$$

$$d = 2 \text{ in.}$$

The direction of rotation should be such as to cause a pull on the bottom side of the belt.

POWER TRANSMITTED BY BELTS. The power a belt will transmit depends upon its width, its thickness, and the speed at which it travels, and the unit for measuring the capacity of belts is ordinarily taken as the speed in feet per minute required to transmit 1 hp with a belt 1 in. in width.

For single or light double belts, the value is 700 ft per min; for heavy double belts, 450 ft per min.

The formulas given below are intended to indicate the safe running load that can be transmitted. In selecting a belt, however, the buyer should be guided by the load required to start and the width of the pulley specified.

$$Hp = \frac{\text{Ft per min} \times W}{700} \text{ for single and light double belts}$$

$$Hp = \frac{\text{Ft per min} \times W}{450} \text{ for heavy double belts}$$

Hp represents horsepower and W represents belt width in inches.

GEAR DRIVE. In case gear drive is used, much care should be exercised when lining up the motor shaft pinion with the gear, so that no end thrust will occur on the motor bearings. Improper aligning causes excessive noise and undue wear. Where T and t represent the number of gear and pinion teeth respectively, and S and s speeds in revolutions per minute, of gear and pinion, respectively, one of these quantities can be determined if the other three are available by the use of the formula:

$$ts = TS$$

For example, it is required to determine the number of pinion teeth for a 1725-rpm motor necessary to drive a machine running 149 rpm and having 232 teeth in its gear. Substituting in the above formula:

$$t \times 1725 = 232 \times 149$$
$$t = 20$$

Tests

APPLICATION TEST DATA. It is impossible in the limited space available to outline the proper procedure in testing various kinds of appliances or machines. Each machine requires somewhat different treatment. However, certain general data can be supplied that will be of great assistance in determining the proper motor for the machine.

These data consist of the following:

1. Kind of machine to which the motor is to be applied.
2. Name of the manufacturer of the machine.
3. Serial number of the machine.
4. Type of drive to be used (whether belted or direct driven).
5. Size of driving and driven pulley, or gears (if the latter give the number of teeth in each).
6. Some idea as to the general location of the equipment after it is installed.
7. A blueprint or sketch showing just how the motor is to be mounted, and in what position.
8. The estimated horsepower required to drive the machine at normal load.
9. A general idea of the load characteristics. This includes information as to whether the motor will be called upon to carry normal operating load continuously or whether the service will be intermittent, and if the latter some idea of the frequency and duration of the load and rest periods.
10. The direction of rotation desired for the motor (whether clockwise or counter-clockwise when facing pulley end).
11. In case the machine is belt-driven, supply the distance between pulley centers.
12. Supply circular or catalog of the machine, if possible.

SPECIAL DATA. In some types or makes of machines there is some certain point in the cycle of operation where the starting conditions are more severe; therefore the starting period should be watched carefully to see that the motor will bring the machine up to speed under the very worst possible starting condition.

TESTS TO DETERMINE SIZE OF MOTOR. The test data given below are for the guidance of those users who desire to make tests or to obtain data that will enable the maker's engineers to give a definite motor recommendation.

One of the important phases of making the proper motor application is to secure wattage input tests under all conditions of load, especially during the starting and other periods of severe load.

There are many ways of making these tests, and the same results can be obtained by

various methods. The wiring diagrams illustrated here represent methods which have given good results.

It is of first importance to make sure that the various instruments used, which consist of a voltmeter, an ammeter, and one or more wattmeters, be properly connected into the supply line. Fig. 4 shows the correct way of connecting a voltmeter. Most voltmeters may be used on either a-c or d-c circuits, although there are some instruments made for either d-c or a-c use, but not for both. All modern voltmeters have separate binding posts marked 150 and 300 for use upon 110- or 220-volt circuits, respectively. The binding post marked ± is common to both voltages.

Fig. 4 represents the connection to be used for 110 volts, and by shifting the one voltmeter lead from the 150- to the 300-volt binding post it can be used to register on a 220-volt line. The main thing to remember in connecting a voltmeter is that the leads should be connected to opposite sides of the power supply line and as close to the motor terminals as is practicable. The voltmeter leads are generally clipped on the motor switch-blades by means of small clips made for that purpose.

Fig. 5 illustrates the proper ammeter connection. The ammeter is used to register the amount of current taken by the motor. Instead of being connected to opposite

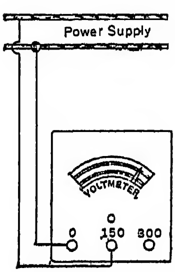

Fig. 4
Voltmeter

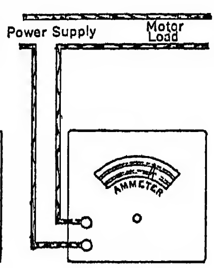

Fig. 5
Ammeter

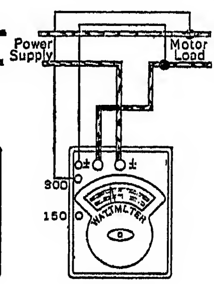

Fig. 6
Wattmeter

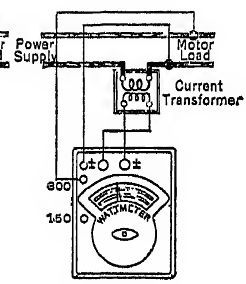

Fig. 7
Wattmeter

Wiring Diagrams for Test Instruments

sides of the supply line the ammeter leads are always connected in series with one side of the line, and when so connected the instrument registers the amount of current flowing through the line in which it is connected. On a two-wire circuit such as is used in direct current or single-phase alternating current it does not matter to which wire the ammeter is connected.

In connecting the ammeter for test, it is sometimes necessary to shift the ammeter leads at the ammeter binding posts until the current is flowing through the instrument in the proper direction. The ammeter coils inside the box are wound in such a way that when the current goes through the instrument in the wrong direction the needle will tend to go off the scale at the zero end and will not register. In case this happens when the ammeter is connected in the circuit just reverse the leads at the binding posts.

Fig. 6 represents a standard wattmeter connection. The wattmeter is a combination of voltmeter and ammeter, and this explains why the leads of the wattmeter are connected in exactly the same way as those of a standard voltmeter and ammeter. In connecting a wattmeter into the circuit it is well to remember that the voltage connection or the voltage leads should always be connected between the instrument and the motor load so that the true voltage across the terminals of the motor will be registered and the voltage drop across the wattmeter coils eliminated.

On motors of small size the average portable wattmeter can be used without any external equipment, but if the wattage input required by the motor is larger than that shown on the scale of the wattmeter it is then necessary to use a current transformer. The wattmeter connection with current transformer is shown in Fig. 7. Current transformers are made up in various ratios between the primary and secondary coils, and the wattmeter reading must always be multiplied by the correct ratio to obtain the true wattage input. For example, if the ratio of the primary to the secondary coil of the current transformer is 2 to 1, and the reading on the wattmeter scale is 100, the true reading would be 100 × 2, or 200 watts. If the current transformer ratio is 4 to 1 the true wattmeter reading would be 100 × 4 or 400 watts.

It will be noted that the wattmeter shown in Figs. 6 and 7 have three binding posts for the voltage connections, the same as a standard voltmeter, the maximum voltage

that can be used being 300 volts. In using a wattmeter of this type upon supply lines having voltages higher than 300 volts it will be necessary to use a potential transformer which would be connected into the voltage leads in exactly the same manner as the current transformer is connected into the current leads in Fig. 7. For example, let us suppose that a test is being made upon a 440-volt motor. This voltage is beyond the voltage range of the wattmeter shown. By the use of a potential transformer having a ratio of 2 to 1 the primary voltage of 440 is reduced to 220 volts, and the secondary leads of the potential transformer are then connected to the binding posts on the instrument marked respectively ± and 300.

When both potential and current transformers are used in the circuit the scale reading of the wattmeter must be multiplied by both the ratio of the current transformer and the ratio of the potential transformer. For example, assume the use of a potential and current transformer having a ratio of 2 to 1 and a wattmeter scale reading of 100. The actual number of watts consumed would then be the scale reading of the wattmeter multiplied by 2 (the ratio of the potential transformer) and further multiplied by 2 (the ratio of the primary and secondary clause of the current transformer) or $100 \times 2 \times 2 = 400$ watts.

The wiring diagrams shown in Figs. 8, 9, and 10 indicate a simple method of determining the wattage input to a motor driving an appliance or machine.

The heavy lines indicate that portion of the circuit represented by the permanent wiring; the light lines indicate the wire that has to be connected in to make the test.

The wiring diagram for d-c motors is shown in Fig. 8. It is not necessary to use a

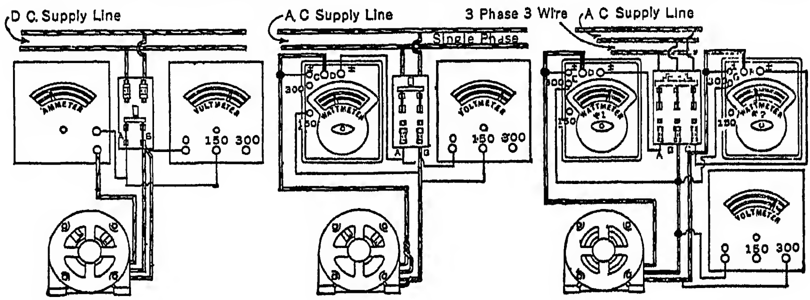

Fig. 8 Direct Current | Fig. 9 Single-phase | Fig. 10 Three-phase

Wiring Diagrams to Determine Power Input to Motors

wattmeter when measuring d-c power as the true wattage input to the motor will be the volts indicated by the voltmeter multiplied by the amperes indicated by the ammeter.

The wiring diagram shown in Fig. 9 is arranged for the test of a single-phase a-c motor operating on a 110-volt circuit. A 220-volt test can be made by changing the one voltage lead on voltmeter and wattmeter to the binding post marked 300.

Although the scale reading of the wattmeter is sufficient to give the wattage input to the motor, the voltmeter is also installed in a-c test circuits. Owing to the low-voltage conditions which exist in various localities and the effect which voltages below normal have upon the wattage input it is necessary to know the exact voltage condition prevailing at the time the wattmeter reading is taken. Note that the voltmeter is used also in the test of a three-phase a-c motor.

Fig. 10 indicates the correct wiring diagram to be used upon a three-phase squirrel-cage induction motor (three-wire supply circuit). It is possible in making a test of this kind to use a polyphase wattmeter in place of the two single-phase wattmeters shown.

The input to the motor in the circuit shown in Fig. 10 will be the arithmetical sum of the two wattmeter readings—providing the power factor of the motor is greater than 50 per cent. If the power factor is below 50 per cent the input delivered to the motor will be the arithmetical difference between the two wattmeter readings. For example, assume a scale reading on wattmeter 1 of 150, and on wattmeter 2 of 125. With the motor power factor above 50 per cent the total input to the motor would be 150 plus 125 or 275 watts. If the motor power factor is below 50 per cent the total input to the motor would be 150 less 125 or 25 watts.

Whether to add or subtract the readings can be determined as follows: If both of the scale pointers deflect toward the top of the scale add the reading; if one pointer deflects

toward the low part of the scale, reverse the current leads on the instrument and subtract the readings.

The diagram as shown is arranged for testing a 220-volt, three-phase motor. A 110-volt motor may be tested in the same manner by connecting the one voltage terminal of the two wattmeters and the voltmeter to the binding post marked 150.

Rating of Motors

See N.E.M.A. Motor and Generator Standards. These rules recommend that, with the exception of railway motors, all motor ratings shall be expressed in horsepower output.

It is also highly desirable that the motor ratings should closely conform to the actual service requirements, and for this reason the rules also recommend the following two kinds of ratings:

CONTINUOUS DUTY is a requirement of service which demands operation at substantially constant load for an unlimited period.

INTERMITTENT DUTY is a requirement of operation or service consisting of alternate periods of load and rest so apportioned and regulated that the temperature rise at no time exceeds that specified for the particular class of apparatus under consideration.

Speed Classification of Motors

Motors may, for industrial application, be classified with reference to their speed characteristics. The N.E.M.A. classification is as follows:

Constant-speed Motors, in which the speed is either constant or does not materially vary such as synchronous motors, induction motors with small slip, and ordinary d-c shunt-wound constant-voltage motors.

Multispeed Motor (change-speed motors), which can be operated at any one of several definite speeds, each being practically independent of the load; for example, a d-c motor with two armature windings, or an induction motor with a primary winding capable of various pole grouping.

Adjustable-speed Motors, in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load, such as shunt motors with resistance control, designed for a considerable range of speed adjustment.

Varying Speed Motors, in which the speed varies with the load, ordinarily decreasing when the load increases, such as series motors, compound-wound motors, and series-shunt motors.

Adjustable Varying Speed Motors, in which the speed can be varied over a considerable range but when once adjusted to a given load will vary in considerable degree with change in load.

4. SPECIFIC APPLICATIONS OF MOTORS

The preceding pages have covered motors in a general way in order that the reasons for the specific recommendations may be the more readily understood. The balance of this article is devoted to the discussion of specific applications of motors to a variety of those drives most commonly encountered in actual industrial practice. It is impossible within the limits of such a presentation as this to cover every conceivable case, but it is hoped that enough ground has been covered to indicate the type of motor which is applicable under ordinary circumstances.

Whenever there is any doubt as to what should be done the only reasonable procedure is to consult with one or more reliable motor manufacturers. In many instances certain builders of motors have specialized on particular types and their knowledge and experience should be utilized.

MACHINE TOOLS. The equipping of a machine tool with motor drive should be undertaken with the closest cooperation between the maker of the machine and the maker of the motor. If the user of the machine tool is changing from belt to individual drive he will in all probability ask some reliable motor manufacturer how his purpose can best be accomplished, or he may turn to the maker of his machine and ask the same question. Unless some past experience is being duplicated this is the most reasonable and safest course to pursue. If a machine is being purchased which is to be equipped for individual drive the buyer will naturally expect to be told what sort of motor he should provide; or if a special motor is required, one of proper design will be supplied or specified by the tool manufacturer.

There are some other equally important reasons for close cooperation between machine

tool makers and motor manufacturers. Among these is the desirability of so designing the machine tool that, wherever practicable, a standard motor and control apparatus can be used. Motor frames and control equipment are being standardized by most of the best-known makers, and it is generally possible to make provision in the design of the tool for mounting such standard equipment on or in it.

On the other hand, certain types of tools require special motors. Some tools are run at specified constant speeds; others require variable speeds; planers call for reversing motors; grinders must avoid vibrations; and the size of the machine, nature of the work, depth of cut, speed of feed, kind of metal, etc., are all factors on which the horsepower and design of the motor depend and whether intermittently rated or continuously rated motors must be supplied. Finally where machine tools are to be used for general manufacturing, rather than for one particular operation, the size of the motor will depend on the range of work which is likely to be performed. This applies especially to standard tools such as shapers, lathes, planers, etc., on which a wide variety of work may be done.

Shunt Motors are used in the following cases: when the work is of a fairly steady nature; when considerable range of adjustment of speed is required, as on lathes and boring mills, and on group and line-shaft drives, etc.

Compound-wound Motors are used where there are sudden calls for excessive power of short duration, as on belt-driven planers, punch pressers, etc. When a 50 per cent shunt, 50 per cent series, field is used, a motor is obtained which will develop nearly as much torque per ampere as a series motor with the advantage that light-load speed will not be greater than 150 per cent full-load speed.

Series Motors should be used where speed regulation is not essential and where excessive starting torque and slow starting speeds are required, as, for instance, in moving carriages of large lathes, in raising and lowering the cross rails of planers and boring mills, and for operating cranes.

When in doubt as to the choice of compound or series motors of small horsepower, the choice might be determined by the simplicity of control in favor of the series motor. Series motors, however, should never be used when the motor can run without load, as the speed would accelerate beyond the point of safety.

Induction Motor. The a-c motor of the squirrel-cage rotor type corresponds to the constant-speed, shunt, d-c motor, but with a high-resistance rotor it approaches more closely the characteristics of a compound motor. It is understood that the variable-speed machines, checked in Table V under the a-c squirrel-cage rotor column, have the necessary mechanical speed changes.

The slip-ring induction motor with external rotor resistance would be used for variable speed, but this must not be construed to mean that it corresponds to a d-c adjustable-speed motor, as it has the characteristics of a d-c shunt motor with armature control.

The self-contained, rotor-resistance type would be used for line-shaft drives, and for groups when of sufficient size.

Multi-speed A-c Motors are those giving a number of definite speeds, usually 600 and 1200 or 600, 900, 1200, and 1800 rpm, and are made for both constant horsepower and constant torque. These motors would be used where alternating current only was available, or direct current limited; and the speed range of the motor, together with one or two change gears, would give the required speeds.

Shaft Couplings. In connection with the selection of motors, standard shafts and shaft extensions should be chosen so that spare parts and interchanges may be made with the least cost and time.

Table of Motor Ratings. Table V will aid in the choice of the proper motor for machine tool application.

It must be kept in mind that various circumstances, such as size or roughness of work, flywheel capacity, etc., may call for radical departures in choice of motors, this list being compiled to meet average conditions.

Control Equipment. The choice of control, whether it be for old or new tools, in the majority of cases is fully as important as that of the motor. In selecting the control it is necessary to consider the nature of the work, the accessibility of the controller to the operator, the method of attaching it to the tool and in some cases its relative position to other tools; for instance, an open-type starting rheostat should not be exposed to danger of short circuit from flying chips.

When installing controllers, accessibility in case of accident should be kept in mind, even though of little importance as far as starting up is concerned. The starting apparatus should be placed where the motor or some of the moving parts can be seen by the operator. On individual motor-driven tools, where the motor is started and stopped many times a day or where the starting conditions are of a severe nature, or where tools are edged along, drum-type controllers with extra heavy starting resistance should be used. § Might be used for tire lathes as it allows slowing down when cutting hard spots.
¶ Small punch presses running at high speed can be driven by shunt motors.

adjustable speed motors, using the drum-type control, the field control should be through fingers making contact on segments of the controller drum and not by sliding contacts on a dial. Motors above 40 or 50 hp under these severe conditions are best operated by a master controller which operates contactors for cutting out steps of starting resistance, and if adjustable speed, the field control should be taken care of by fingers making contact on segments of the drum. This class of starting apparatus will stand any quantity of abuse and, by the addition of a simple current limit relay device, becomes practically a fool-proof protection for the motor. There are cases where it might be advantageous to use master controllers and contactors even with smaller motors. The controlling apparatus as well as the motor in the case of individual drives should be attached directly to the tool when possible. This arrangement allows moving the tool by simply disconnecting the leads and connecting them in the new position. In portable tools this, of course, is an absolute necessity.

Upon the convenient arrangement of the control depends, to a considerable degree, the output of the tool. The importance of the arrangement from the standpoint of the operator cannot be ignored, since the output of a tool will be materially increased when an operator can start and stop the tool and obtain at all times maximum cutting speeds by simply turning a handle. The controller must be placed in a safe position and should

be accessible for repairs, which very often means that some arrangement is necessary to bring the operating handle within easy access of the operator.

The convenience of control, which bears directly on production is ignored in the majority of tools where the control is of the greatest importance. A familiar illustration of the convenience of control is the arrangement so commonly seen on lathes, whereby the operating handle travels with the tool carriage and allows the operator at all times a complete control of his tool.

Application of Reversing Motors. One of the most interesting motor applications is the use of reversing motors for machine tools. The large increase in production due to this form of drive on planers is generally appreciated, but the application of the reversing motor drive in its various forms (which is almost unlimited) is not so well understood. This reversing drive is applicable not only to planers, new and old, but to screw, worm, and rack-driven slotters, keyseaters, turret lathes, wire and tube drawing machinery, grinder tables, lapping machines and boring mills, when machining projections which are short in comparison with the total travel of the mill or when machining surfaces where projections prevent a complete revolution.

The motors recommended for this service are of the commutating-pole type with a speed range usually of from 300 to 1200 rpm for the small sizes and 250 to 1000 rpm for the larger sizes. Other speeds can be obtained when required. The speeds given allow the motor, in the majority of cases, to be coupled direct to the driving shaft of the machine.

The requirements for reversing planer motors are ruggedness to withstand the strain of heavy service due to the reversing action and long armatures of small diameter to reduce the flywheel effect and facilitate reversal. Carefully made and insulated armature coils to withstand the mechanical and electrical strains of reversing, the windings designed to provide satisfactory commutation under quick reversing and to carry heavy currents at the time of reversal under heavy overload when extra deep cuts are being made, are further requirements for these motors.

Steel motor frames of extra-heavy mechanical strength to take care of the heavy stresses, and substantial feet, accurately machined for the direct connection of the motors, are also necessary. Because of the length and small diameter of the armature the frame is longer and lower than with standard general-purpose motors. Armature shafts are made of high-carbon steel of exceptional strength on account of the strains of reversing. Commutators should be liberal in size with deep wearing surfaces and have extra-thick mica insulation. Field coils of bobbin construction are used by many of the best manufacturers in order that they may be securely held in place under the vibration of the machine.

The control must automatically and very accurately control the operation of the planer at a number of different speeds. The cutting and return speeds must be separately adjustable—the former from 25 to 60 ft per min and the latter 50 to 100 ft per min, and in some cases up to 150 ft per min. The control equipment is the most vital part of this type of reversing motor drive. It is usually placed in a steel, dust-proof panel which may be mounted either on the machine or on the floor as is more convenient. It has two rheostat handles, one for controlling the cutting speed and the other for the return speed. The reversing contactors within the panel are generally carbon to copper to avoid the fusing of metal to metal. Some controllers are designed for reversing by "plugging" because this acts more quickly than dynamic braking. On the other hand, plugging takes more current than dynamic braking. The user will have to decide whether economy of time or economy of power is the more profitable. There are usually pendent push-button control stations with push buttons for "inching" the planer table while work is being set up, starting the machine and stopping it quickly by means of having the motor act as a self-excited generator and thus accomplishing dynamic braking.

The advantages of the reversing motor are (1) increased production due to the availability of the most economical cutting and return speeds, (2) decrease in cost of maintaining belts which wear quickly under the conditions of this service, (3) efficient setting up of jobs because of the easy control, or "inching," possible with direct motor drive and elimination of slipping of belts with their resultant losses.

Cross-rail and Tool Traverse Motors. Electrically driven cross-rail and tool traverse equipment is supplied by some of the motor manufacturers for mounting on boring mills, planers, and other machine tools where a rapid tool reverse is economical. They are the means, in many instances, of saving much time. The equipment consists of intermittently rated standard motors, either squirrel-cage or d-c motors, with heavily compounded windings to give high starting torque. Small enclosed drum controllers are used whereby the operator can easily start, stop, or reverse the motor.

Grinding Machine Motors. Grinding machine motors, where internal or external surface grinders for producing work of a high degree of accuracy are concerned, must meet special requirements to avoid vibrations. This is because vibrations set up by the

motor are communicated to the mirror finishes of the surfaces. For this reason a uniform air gap between rotor and stator is essential, for the variations in magnetic pull, where the gap is even only extremely slightly irregular, results in vibrations. Consequently it is preferable to have the bores of the motor stator ground. Ball bearings are necessary in order to keep the rotor accurately centered at all times, so as to reduce friction. For these reasons it probably will generally be best to let the machine tool builder supply the motor which he can have built according to the specific requirements of his machine.

PRINTING PRESSES. Owing to the great variety of work performed, printing machinery as a rule requires a certain degree of speed variation in order that, with a given equipment and operating force, the maximum of high-grade production may be turned out.

Individual drive is particularly applicable to printing establishments, as in this class of service the ratio is small between the power required to drive the machines running idle and when performing actual productive work. With group drive the ratio between average and connected load is high, owing to the large and constant character of the friction losses. The economy in power consumption is, therefore, in favor of separately driven units, which may be shut down when not operating productively.

Many motor manufacturers have specialized on printing press motors, and it is strongly recommended that prospective buyers consult with such manufacturers in order that they may secure motors which are adapted to their particular requirements. It is frequently practicable to get motors which may be mounted on a given machine with minimum waste of floor space or other inconvenience.

Job Presses. Job presses are the smallest type and require motors of $1/4$ to $1\ 1/2$ hp in either a-c or d-c types. The following table taken from one of the bulletins of the Cline Electric Manufacturing Co. gives an idea of the different sizes of motors applicable to different-sized presses.

Table VI

Hp	Maximum Rpm	Suitable for Press Size		
		Hand Feed	With Peerless or Miller Feeder	With Brandtjen and Kluge Feeder
1/4	1800	8 × 12	......	.....
1/4	1200	8 × 12	......	.....
1/3	1800	10 × 15	......	.....
1/3	1200	10 × 15	......	.....
1/2	1800	12 × 18	8 × 12	.....
1/2	1200	12 × 18	8 × 12	.....
3/4	1800	Craftsman	10 × 15 & 12 × 18	10 × 15
3/4	1200	Craftsman	10 × 15 & 12 × 18	10 × 15
1	1800	14 1/2 × 22	Craftsman	12 × 18
1	1200	14 1/2 × 22	Craftsman	12 × 18
1 1/2	1800	.....	......	Craftsman
1 1/2	1200	.....	......	Craftsman

High-speed Presses. For most of the high-speed automatic presses single-phase, polyphase, or d-c motors may be used. With d-c motors speed control is secured by shunt field or armature control. Dynamic braking stops the machine quickly and is also used with the a-c motors. With single-phase motors the speeds are obtained by varying the voltage. Motors of this type giving 12 speeds are on the market, and two- or three-phase slip-ring motors with 18 speeds.

Offset presses, small rotary presses, and cylinder presses where the service is alternating current require motors providing a strong starting torque and low starting current because of the heavy inertia and friction they must overcome in starting up the presses. They must do this with minimum loss of time and without causing line disturbances. The motors must be of the slip-ring type on account of the speed-control features. When d-c service is available shunt-wound motors are used with shunt field control. Special attention should be given to securing sparkless commutation in order to avoid unnecessary fire hazard.

Unit-type Presses. On unit-type presses it is generally desirable to have an individual motor for each printing unit and folder because of the comparative simplicity and lower cost of the drives and the more satisfactory speed control of each motor. When the speed has been set for each unit the whole group of motors driving the press is controlled by means of a single controller so that all start simultaneously and with equal pull on each web.

ELEVATORS. Elevators may be divided in two general classes, freight and passenger. The former may be divided into (1) slow-speed elevators (75 ft per min or less), (2) infrequent-duty elevators, and (3) high-speed (250 ft per min or less) material-handling elevators provided with accurate means for landing so as to accommodate wheel vehicles. The latter may be divided into local service (450 ft per min and less), which requires rapid rates of acceleration and accurate landing; and high-speed express (600 ft per min and more) which requires smooth acceleration and efficient landing. These express elevators sometimes must be operated as local elevators for a few floors at the top of the building and are often of the two-speed type.

Power Required. The horsepower of an elevator motor depends on the load to be raised, the speed of travel, and the elevator efficiency, that is, the combined efficiency of the motor, the gear, and the drive. It is customary to counterbalance the weight of the cage, and if it is under or overbalanced this amount must be added to or deducted from the live load to get the actual load.

$$\text{Horsepower} = \frac{(\text{Unbalanced load in lb}) \times (\text{Speed of elevator in ft per min})}{33{,}000 \times (\text{Efficiency})}$$

An efficiency of 0.50 is generally used in problems of this kind.

As the load is intermittent the motors are generally rated on the basis of 55 deg cent rise, with full load for one-half hour. The starting torque should be from 2 to 2 1/2 times full-load torque.

D-c and A-c Systems are both in general use for elevator service. On a-c systems the induction motor, either of the squirrel-cage or wound-rotor type, is used. These motors may be either single-speed or multispeed, depending upon the kind of service.

Single-speed, Slip-ring Elevator Motors are applicable to passenger and freight elevators where the speeds, not exceeding 200 ft per min, are within the limits of satisfactory mechanical braking. By inserting resistance in series with the rotor windings it is possible to obtain a starting torque of 2 1/2 times full-load torque with low starting current. With this type of motor, also, the heat generated is dissipated from the external resistance and the regulation is good. This type is particularly well adapted to the operation of heavy elevators calling for motors larger than 25 hp.

Two-speed Squirrel-cage Motors have given good results in elevator operation because the elevator can be started on the slow-speed winding. As the motor accelerates the resistance in series with this winding automatically cuts out until it is running at full voltage. It is then switched on to the high-speed winding with its set of resistors in series which are switched out as the elevator reaches full speed. All this switching takes place automatically after the operator moves the switch handle from "off" to "full speed." There is an intermediate position for the switch handle used when the car is to travel only short distances and which permits use of only the low-speed winding. When stopping the elevator the slow-speed winding has a braking action. For speeds over 250 ft per min reactor coils placed in the line circuit smooth out sudden changes of current and provide for correspondingly smooth changes in the speed of the elevator.

D-c Motors are, of course, the ideal for elevator service so far as accurate speed control and low-speed operation without gears is concerned. For passenger service exceeding 250 ft per min shunt-wound motors are used. Compound motors are used for low and moderate single-speed elevators. When the motor comes up to speed the series field is short-circuited and the motor runs as a shunt motor.

Variable-voltage Control Motors for High Buildings. The following summary of a paper by Edgar Bouton, presented at the Midwinter Convention of the A.I.E.E. at Philadelphia, Feb. 4–8, 1924, will give an excellent idea of the application and advantages of variable-voltage control for elevators used in high buildings.

Low-speed electric elevators, using d-c motors, came into use about 1890. Later, a-c motors were employed, but on account of the difficulty of speed control could not be used for the high speeds necessary in tall buildings. Since the height of buildings is dependent upon the elevator system, and in many districts only alternating current is available, the need for high-speed equipments that can be operated from alternating current is evident. A solution to the problem is found in the variable-voltage system of control.

In this system each elevator motor is supplied by an individual generator driven by a motor operating from the a-c or d-c supply voltage. The generator's voltage, and hence the elevator motor's speed, are controlled by varying the field of the generator.

The apparatus consists of:

1. An ordinary shunt-wound d-c elevator motor.
2. A d-c generator of special design for the elevator motor.
3. Control panel for the generator and elevator motor.

4. An a-c or d-c motor to drive the generator.
5. A starting device for the driving motor.
And if the supply is alternating current:
6. A direct-connected exciter for the field, brake, and control circuits.

The control panel (1) makes the proper connections for up and down motion of the car; (2) releases, or sets, the brake; (3) controls the speed; (4) discharges the generator field during retardation, and on stopping; (5) demagnetizes the generator; and (6) opens the circuit between the armature of the generator and the armature of the elevator motor.

From the tests the following conclusions in favor of the variable-voltage over the rheostatic control system are drawn:

1. High-speed installations are now possible for any commercial a-c voltage and frequency.

2. The rate of acceleration increases gradually to about half speed, then decreases uniformly until full speed is reached. The time and power required for acceleration are less than with rheostatic control. The time remains practically the same for all loads. The higher rate of acceleration and retardation permits higher speeds, and the smoothness, besides reducing wear and tear on the machinery, makes riding entirely comfortable to passengers. The impression of falling which is often given, under rheostatic control, by a heavily loaded car when descending, is inherently avoided, since the car follows the generator voltage which at no time changes suddenly.

3. The speed regulation remains flat at as low as one-tenth full speed. Consequently it is easier to make an accurate landing, fewer false stops are made, and the car may be "inched" easily and quickly. In stopping, regenerative braking is set up which brings the car quickly but smoothly to a low speed before the friction brake is applied. Positive speed control enables the limit stops to be made in less time and shorter distances, and without overtravel.

4. Less power is required in acceleration and retardation. This saving of power over the rheostatic control is greatest when the number of starts and stops is large. Power is returned to the line while making the limit stops. Power consumption is not increased in making small movements of the car or in running at low speed. During idle periods standby losses may be eliminated by shutting down the motor-generator set.

5. Since the switching of major currents is eliminated and they are controlled indirectly, the number of arc rupturing contacts is reduced to a minimum, the control as a whole is simpler, less adjustments are necessary, and maintenance costs are lowered.

6. Inherent safety features make higher speeds possible. Limit stops are made accurately and positively. A second independent means is provided for stopping the car in emergencies. On failure of power a dynamic braking circuit closes and a field is maintained, on the elevator motor, making certain the stopping of the car. An overspeed contact on the motor-generator set opens the safety circuit independently of the speed governor.

Energy Consumption. The use of power increases in proportion to the number of starts and stops. This is a natural result of the use of the electric motor, in which the largest part of the energy is required for the process of acceleration, the next largest for electrical and mechanical retardation, and a lesser amount for the actual running, with a small proportion devoted to the continuous excitation of the field. It therefore follows that the main part of the consumption of power is directly related to the number of stops and starts which result from the number of persons carried.

POWER SHOVELS. The operating cycle of an electrically operated shovel is about 20 sec, the component times being: hoist 8 to 10 sec, thrust 10 sec, and swing 10 to 12 sec, the thrust being in operation at the same time as the hoist and swing are operating. The motors to meet these requirements must have a sufficiently low armature inertia to permit of rapid acceleration under small power, and are therefore generally of the crane or mill-type construction.

Hoist Motors. In the case of the hoist, considerable advantage may be gained in this respect by using two motors of one-half the capacity each instead of one motor of the full capacity, as the power required for accelerating is much less. For example: Assume a shovel that requires a 225-hp, 514-rpm motor for the hoisting operation. Such a motor requires 144-hp-sec for bringing up to full speed, whereas if two 115-hp, 600-rpm motors are substituted in its place, each motor requiring 63.5 hp-sec or both 127 hp-sec to bring up to speed, there would be a saving of about 12 per cent in the power required to accelerate the motor alone. On the other hand, such an arrangement may require the use of bevel gears and additional shafting.

Swing Motor. This motor, although not subject to the severe overloads and shocks encountered on the hoist motors, is subject to frequent reversals, and, as rapid acceleration is required, a motor of similar design as for the hoist should be used.

Thrust Motor. This motor differs somewhat in its operation in that it is practically stalled during the digging operation, although it may revolve or overhaul according to conditions, and is operated at full speed only after the hoist operation is completed. Its duty is to keep the dipper against the bank, and it must therefore stand still and exert torque most of the time. For this reason its design should be very rugged, and the motor should be able to develop a heavy torque for short intervals of time while standing still, or rotating very slowly.

Location of Motors. The hoist and swinging motors are as a rule located on the car and are geared to the drums through suitable reducing gears, while the thrust motor as a rule is mounted directly on the boom and communicates its motion to the bucket staff through reducing gears connected to a pinion engaging a rack on the staff.

Type and Size of Motors. It is possible to obtain successful operation with a-c induction motors but it can be done only at the expense of larger capacities and increased power consumption, owing to the characteristic of the motor, which radically differs from that of the steam engine ordinarily used on shovels and from the d-c series motor.

A careful analysis of the typical steam-shovel engine reveals a characteristic which is not unlike that of the series d-c motor in that it speeds up under light loads, slows down under heavy loads, and possesses a certain elasticity in operation which minimizes mechanical strains on the shovels. Because of these facts it is not only desirable but advisable to adhere to the d-c series motor on the electric shovel. Practically all large power supplies are alternating current, but the smaller capacities in d-c series motors permit the use of a synchronous motor-generator set mounted on the shovel at practically the same cost as the a-c induction motors with transformers, with the advantages in operating characteristics and power consumption all favorable to the d-c equipment.

Variable-voltage System. The variable-voltage system is the latest development and makes possible simple and flexible control. Each d-c motor is supplied by its separate d-c generator, the particular motion in question being controlled by varying the voltage of the generator. These generators are the differentially compound-wound type. There is a separately excited shunt winding, a self-excited shunt winding, and a differential series winding. The main driving motor which drives the d-c generators is either a squirrel-cage induction motor, on the smaller shovels, or a synchronous motor for the large shovels. Mill-type motors are used for driving the different motions, ventilated for the hoist and swing motions and totally enclosed for the thrust. Different manufacturers use different field windings, including shunt, compound, and series windings, depending in part on the service for which the shovel is intended and in part on its design.

Control Equipment. With the variable-voltage shovels, the practice is to use small drum controllers with series resistors in circuit with the separately excited shunt fields.

Brakes for the different shovel motions are generally of the air-brake type, a small air compressor being provided on the shovel for this purpose.

WOODWORKING INDUSTRY. The cutting heads of woodworking machinery generally operate at high speeds, and in order to eliminate high-speed belts, save floor space, decrease maintenance and fire hazard, and secure a safe compact machine there is a distinct advantage in using high-speed direct-connected motors. When there are several cutting heads, each having its individual motor, the group of motors is interlocked electrically so that the stopping of one stops all.

Motor Requirements. The motors recommended for this service by one of the important manufacturers are of squirrel-cage construction made in sizes up to 35 hp and with speeds from 3600 to 10,000 rpm and even as high as 20,000 rpm when used in conjunction with a frequency changer. Double-end ventilation is preferable, but single-end will suffice if mounting conditions make this necessary. Multispeed, generally two- or four-speed depending on the nature of the work, motors are applied to the feed mechanism. The controls of all motors are located conveniently so that the operator can control both feed and cutting.

TEXTILE MACHINERY. Individual drive is largely used for pickers, spinning, roving frames, twisting frames, cotton cards, looms, and other machines, especially on new installations. In mills where a change is being made from mechanical to electrical drive two or four frames are frequently driven from one motor to reduce first cost.

Motors have been specially designed for these services, or certain types are particularly well adapted, as outlined below:

Roving, Spinning and Twisting Frames—Two and Four Frame Drive.

(*a*) Motor has shaft extending on each end and two frames can be belt driven from each end, motor mounted on ceiling.

(*b*) Motor has long extension on one end of shaft only for use where aisle space between driving ends of frames is limited.

(*c*) There are squirrel-cage motors treated to resist moisture from the humidity of

the mill. There are no screens, and the openings in the brackets are large to permit of easy cleaning with compressed air. Air deflectors are omitted to reduce the amount of lint and dirt drawn in.

Spinning, Roving and Twisting Frames, Pickers, Cone Winders, etc.—Individual Drive. (*a*) Squirrel-cage motors with screens to prevent entrance of lint into interior because the motor is mounted on the machine.

(*b*) Specially treated motors to resist moisture of mill.

(*c*) Dust-proof waste-packed bearings to exclude foreign material.

Carding Machines—Individual Drive. High starting torque motor required to take care of inertia of heavy cylinder. Starter with means for reversing the cylinder for grinding.

Looms. Individual Drive. Totally enclosed induction motor.

PAPER INDUSTRY. The following analysis will give an idea of the motors applicable to the various machines used in the making of paper:

BEATERS. Wound rotor induction motors are applicable where the starting conditions are severe and where the starting current must be kept low. Squirrel-cage motors, because of their simplicity, should be used when starting conditions permit. Synchronous motors, where desirable to improve power factor, may be used provided starting torque requirements may be met by overmotoring or by the use of a slip belt or a magnetic clutch.

Paper Machine.—Single Motor Drive. D-c variable speed.

Paper Machines.—Sectional Drive. Many advantages in economy of operation are claimed for driving each section of a paper machine by its individual motor.

Super-calenders. There are three principal methods of driving these, namely, single motor, two motors, and single motor dual frequency.

(*a*) With single motor drive the wound rotor type of motor is used and the various speeds are obtained by means of gears and clutches.

(*b*) With two motor drive a large wound rotor motor is used for driving the super-calender at "production" speed, and for "threading-in speed" a small squirrel-cage motor, both operating through gears.

(*c*) The dual frequency motor has a wound rotor designed to operate at two frequencies, one frequency being that of the power system and the other obtained from a frequency changer. The low frequency is used for the threading in and the high frequency for production speed. This system has several advantages over the others such as increased flexibility, less noise, less fire hazard, greater safety and cleanliness, and less floor space.

(*d*) D-c motors are in many ways preferable for super-calender drives on account of the greater facility of speed control. The most usual methods are the single motor, two motor, and the Ward-Leonard system. Either shunt or compound wound motors may be used in either of the first two systems. With the Ward-Leonard system only one motor with shunt wound characteristics is necessary and presents substantially the same advantages as the dual frequency a-c arrangement.

Super-calender Reel Stand. Squirrel-cage motors are generally used for this drive.

Sheet Calenders. Wound rotor motors for a-c service or shunt wound motors for direct current are the usual practice.

Platers. High torque and low flywheel characteristics are called for. With a-c operation wound rotor motors with a permanent resistance across the rotor circuit give satisfactory service because with this arrangement maximum starting torque is available at any time and excessive heating takes place in the resistance outside the motor. With d-c service compound-wound motors with small flywheel effect are used.

Rewinders. D-c or a-c motors or Ward-Leonard system.

Cutters. Wound rotor motors, with variable resistance in the rotor circuit to secure speed changes, are used. With d-c service the speed is regulated by shunt field control.

Trimmers. When d-c drive is employed the shunt-wound motor is required, and for alternating current a motor with high slip characteristics is desirable so that the shock of the cutting stroke will be taken by the flywheel.

SUGAR MILLS. Cane Crushers and Rolls. These call for close speed control, and as alternating current is commonly used motor secondaries are required.

Pumps and Auxiliaries. Squirrel-cage motors are applicable where constant speed is called for and where there is no objection to high starting current, or wound rotor motors where variable speed is required for hoists, car dumps, etc., and where it is desired to keep the starting current not much in excess of full-load current when starting at full-load torque.

Centrifugals. Squirrel-cage motors designed to be thrown directly on the line by a drum controller are generally used.

OIL FIELDS. Well Drilling, Pumping, etc. Two-speed wound rotor induction motors have a wide application in the oil fields. They are made in open and air-jacketed enclosed types, the latter for use in outdoor locations. The low speed is used for pumping. Other operations, such as pulling, cleaning, swabbing, bailing, and redrilling, are done at the high speed. Enclosed standard controls are used. The same motors are applicable to cable tool drilling, in which case twin motors are used. Motors are of proper size for pumping the well after it is drilled, provided that two motors of such size are large enough to do the drilling. When the well has been brought in, one of the motors is left on the job for pumping, etc. Single motor drilling is practicable with this type of motor for depths of about 4000 ft. The size of motor for drilling equipment for various depths is given in Table VII.

Table VII

Equipment	Maximum Band Wheel Speeds, rpm	Maximum Recommended Depth, ft
15–35 hp twin-motor equipment	70–80	2500
20–50 hp twin-motor equipment	70–80	4000
25–65 hp twin-motor equipment	60–90	7000
35–75 hp twin-motor equipment	60–90	9000
25–65 hp single motor with auxiliary control	55–80	4000
35–75 hp single motor with auxiliary control	55–80	4500
75 hp single motor equipment	55–80	4000

Pipe Line Pumping. Squirrel-cage motors have the widest application because of their low first cost and simplicity, and the fact that constant speed is generally all that is called for. Of course, where variable speeds are required the slip-ring motor is the next best thing. Synchronous motors are entirely applicable to this service and should be used where low power factor is penalized. The size of motor required may be figured by means of the following formula:

$$Hp = \frac{1.7 \times Q \times P}{\text{Eff.}}$$

where P = pressure in hundreds of pounds per square inch or static head plus friction head on pipe line.
Q = thousands of barrels of output per day.
Eff. = 65–75 per cent for centrifugal pumps and 85–95 per cent for plunger pumps.

Rotary Drilling. Motors for this service have been specially designed to provide for continuous carrying of rated load and several hundred per cent overload for short periods due to the meeting of sudden unexpected obstructions. Wide speed range is also required because at light load for making and breaking pipe, circulating, fishing, etc.

Band Wheel Drive. For this a standard two-speed oil well motor is usually the most satisfactory drive. A reduction gear is mounted on the same bed plate as the motor.

Slush Pumps are generally driven by single-speed, wound rotor motors.

COAL MINES. Most of the operations in coal mining have been electrified in one way or another. Some of the electrified equipment, such as cutters and locomotives, have motors which form an integral part of each unit, and there is seldom, if ever, any occasion for the mine operator to consider what type of motor is needed. On the other hand, there are a number of drives, such as for tipples and breakers, ventilation, pumping, and dumping, and hoisting, where data concerning the type of motor which should be used are frequently needed. A further point of importance is that, in gaseous mines, all motors and controls must be fully enclosed so that there will be no danger of sparks setting off an explosion. Motors specially designed for this service are on the market.

Tipples and Breakers. For tipple and breaker drives either d-c or a-c motors may be used. For reasons of economy and simplicity of operation squirrel-cage and wound rotor motors are used to the greatest extent. Synchronous motors are also installed where power-factor correction is an item of consideration.

Ventilation of coal mines is of course of particular importance. Squirrel-cage, wound rotor and synchronous motors are applicable.

Pumping. In mine pumping the motor must withstand severe service conditions. The locations are usually very damp, there is likely to be a good deal of sweating, and sulfuric acid in the water causes corrosion. Consequently, enclosed air-jacketed motors and tightly sealed bearings are very necessary. The squirrel-cage motor or, if it is desired to run at half speed part of the time, a two-speed squirrel-cage motor is generally the most economical and satisfactory. In some instances wider speed ranges are called for,

and then the wound rotor type is needed. Synchronous motors are coming into use to an increasing extent and are applicable to either centrifugal or plunger pumps.

Hoisting. For hoisting either a-c or d-c motors may be used. Variable-voltage d-c hoisting motors, supplied from a flywheel motor-generator set, have advantages in that they give fast acceleration and high speed economically and safely.

CRANES. Cranes may be divided into six general types, namely, overhead traveling cranes, gantry cranes, locomotive cranes, jib cranes, shipbuilding cranes, and wharf cranes. As a general thing the crane builder takes care of the selection of the proper motors for their use, and it is assumed that a clear and unmistakable picture has been given of the service which is to be required. The electrical equipment is about the same for all of them. For instance, the overhead traveling cranes and gantry cranes usually have three motors. One is for the hoist, the second for the travel of the trolley, and the third for the bridge travel. Sometimes a crane has two trolleys, and not infrequently there are two hoists for a single trolley to handle loads of different size.

Motor Data. It is essential, of course, that the motors for crane service be strong and rugged, have high starting torque, large short-time overload capacity, large shafts and bearings, armatures of small diameter to reduce the power for quick acceleration and braking, and other consistent characteristics. Control may be magnetic or manual, with drum-controllers. The Westinghouse Electric and Manufacturing Co. has devised the following table covering the types of motors to be used in crane service:

Motors		Control		Brakes	
D-c	A-c	D-c	A-c	D-c	A-c
Type HK	Type CI	Type S Drum	Type FA Drum	Type HB	Type A
Type K	....	Type C Magnetic	Type F Magnetic	Type KT	....
Type MC	....	....	....	Type B	....

Coal and Ore Bridges. These are actually special kinds of gantry cranes with exceptionally long bridges. The selection of the proper motors for the drives is highly specialized, and as a general thing the purchaser of the handling equipment buys it complete with the necessary motors. This is in fact the safest and most satisfactory procedure to follow ordinarily. Either a-c or d-c motors can be used for the bridge travel, trolley, and hoist.

Coal Towers. These are another variation of crane service as they consist of a boom with a trolley, equipped with a hoist. Ordinarily wound rotor motors are used, although for very high-speed operation d-c motors with variable-voltage control are generally more economical.

CONVEYORS. Conveyors for the mechanical handling of materials are very widely used in industry. There are many types which may be divided into two general classes, namely, conveyors for handling packages and conveyors for handling loose, bulk material.

Package Conveyors. All package conveyors consist essentially of one or two parallel endless chains or cables or of endless belts. The ordinary chain conveyor may be used for horizontal travel or steep inclines. Sometimes these consist of single chains, sometimes of a pair of chains with cross-bars; they are used mainly for handling heavy materials, and provision may be made for suspending slings between the cross-bars. The well-known automobile assembly line is a form of chain conveyor. Belt conveyors are so well known as not to call for any special description. In addition to this there is the continuous overhead conveyor made of a chain or cable supported by rollers. A single exception to the endless chain or belt system is the roller conveyor which is made up of a series of horizontal rollers all driven simultaneously in the same direction. These are used for moving steel ingots in rolling mills and elsewhere, logs in sawmills, etc. In some cases the rotation of the rolls must be reversed to return the ingot or log for further operations.

Bulk Conveyors. Bulk material conveyors embrace bucket conveyors, belt conveyors, including portable car loading conveyors and the like, pan conveyors, and drag conveyors, all dependent on the endless-line principle. In addition there are screw conveyors, shaking conveyors, and pneumatic conveyors.

Application of Motors. The application of motors is fairly simple. Generally the conveyors are run at constant speed so that induction motors may be used. Where starting is heavy and reduced speed operation is desirable the wound rotor type should be selected as it may be brought up to full speed by short-circuiting the external resistor through the controller. Where the starting torque is low the squirrel-cage type of motor is

permissible and preferable because of its simplicity. It is also advantageous under operating conditions involving dust and dirt and danger of explosions.

D-c motors, either constant or variable speed, are suitable for these conveyor services. Enclosed types should be used where operating conditions may make this necessary or desirable.

Where exposed to the weather the appropriate type of motor should be used.

Aerial Tramways. Aerial tramways are used for the handling of materials of many kinds, sometimes for distances of several miles. It is in general an economical method of transportation, especially over rough country, for the output of quarries and mines, etc. Aerial tramways are also used for short hauls for the disposal of waste from industrial plants. Motors are wound rotor with magnetic control.

DREDGES. Dredges have many of the characteristics of shovels. They may be supplied with electrical power either by means of a submarine cable or more often from their own power plants. Diesel engines direct-connected with the generator or steam turbines direct-connected are used. With Diesel engine drive there are usually several generating units which make possible variable-voltage d-c control. With such arrangements some of the generators are constant voltage for constant-speed drives, and others have variable voltage for the variable-speed drives. A-c motors are also used with success. In any event, each motor performs one distinct duty so that several are used per dredge. One of the very large harbor dredges has four Diesel engine d-c generator units, a 2700-hp motor for the pump, plus twenty-five other motors between 5 and 250 hp.

CAR DUMPERS. Car dumpers are designed for the dumping of open top railroad cars, from small mine cars to full-size gondola cars. D-c series motors are preferred, but in some cases wound-rotor a-c motors are applicable. In selecting motors for this it is safest to draw on the experience of the manufacturer of the dumping equipment as to just what type of motor is likely to give satisfactory results.

TRUCKS, TRACTORS, ROAD TRUCKS, LOCOMOTIVES, AND LORRY CARS. These pieces of handling equipment are supplied by their manufacturers complete with motors installed. For details concerning the selection of the proper unit for particular service see discussion under the respective headings.

LAUNDRY MACHINERY. The machines found in laundries which are individually motorized in up-to-date installations consist of washers, drying tumblers, centrifugal extractors, and ironers.

Washing Machines and Drying Tumblers call for reversing motors. Reversal is automatic, by means of the reversing switch. With a-c motors this is accomplished by throwing it across the line. A low-torque motor is used so as to cause it to start gradually and smoothly on reversal. These motors must also be so designed as not to overheat even when reversed as many as six times per minute. When the service is direct current compound-wound motors are used. The automatic control does not permit the starting voltage to be applied for reversal until the machine has been stopped by means of dynamic braking. Bearings which are proof against the entrance of moisture, lint, etc., and the leakage of oil are essential for these applications.

Centrifugal Extractors. For centrifugal extractors the motor bearings must also be closely sealed for the same reasons, and splash-proof covers for the ends are necessary to keep out water and clothes which might become entangled in the motor. The motors should also be well impregnated to protect the winding against moisture. Low starting current motors, both alternating and direct current, which bring the basket up to speed smoothly and quickly, have been especially designed for this application.

Ironers. For the ironers either of two types of standard a-c motors may be applied. One of these is the squirrel-cage induction motor for constant-speed machines, and the other, for large flatwork ironers, a four-speed motor with push-button starter and drum controller. Standard shunt-wound motors with either constant or adjustable speed are used where the service is direct current.

RUBBER MILLS AND CALENDERS. Rubber mills are used for the various steps in producing commercial rubber compounds from the raw rubber. They may be driven either by wound rotor or synchronous motors. In those applications where the motors operate at the speed of the mill line, synchronous motors are generally preferable because they cost less and perform more satisfactorily than induction motors. With geared drive the principal advantage of synchronous motors is due to their corrective effect on the plant power factor. So far as actual running of the mills is concerned, experience has shown that either type of motor will give satisfactory performance. When the synchronous motor is run at the comparatively low speed of the mill it is brought up to speed with the clutch thrown out so that the stored energy in rotor will make up for the lower starting torque as compared to the induction motor. For geared drives where the motor runs at something like 600 rpm it has been found that the starting torque is sufficient.

Quick Stopping. In order to obtain quick stoppage as a safety measure the wound rotor motor drives and synchronous motor direct drives should be equipped with clutch brakes. With synchronous motor geared drives where the clutch is eliminated, quick stopping is secured by disconnecting the motor armature from the a-c source and connecting it to a proper resistance, leaving the field energized at full-load value.*

Rubber Calenders are used for the final treatments of the previously prepared rubber compound. A great deal of speed adjustment is called for, and because of this the best results from electrical operation can usually be obtained by means of adjustable-speed d-c motors. Either single- or double-voltage motors may be used; magnetic-type controllers are supplied for either single- or double-voltage equipments. Speed variation with the former is by means of a field rheostat, and with the latter, with a drum-type master switch. Wound rotor induction motors can be used for rubber calender drives, but as the speed regulation is very limited, the different kinds of rubber compound that can be calendered and the rate of production are correspondingly limited.

Ratings for Rubber Calender Motors. The ratings in Table VIII, taken from the bulletin Electric Drive for Rubber Calenders, of the Westinghouse Electric and Manufacturing Co., apply to d-c rubber calender motors for operating on single- and double-voltage circuits:

Table VIII

Horsepower at Maximum Speed	Single Voltage		Horsepower at Maximum Speed	Double Voltage	
	Volts	RPM		Volts	RPM
25	230	300-1200	50	115-230	287-575-1150
35	230	300-1200	60	115-230	237-475- 950
50	230	300-1200	75	115-230	237-475- 950
60	230	300-1200	90	115-230	237-475- 950
75	230	300- 900	100	115-230	225-450- 900
75	230	300-1200	100	115-230	175-350- 700
75	230	225- 900	125	115-230	225-450- 900
100	230	300- 900	150	115-230	225-450- 900
100	230	300-1200	200	115-230	200-400- 800
125	230	300- 900	250	115-230	175-350- 700

All motors are rated at 50 deg on a constant-torque basis. The single voltage motors are good for 80 per cent rating at 600 rpm. The double-voltage motors are good for 80 per cent of full-load rating at high voltage and half speed.

LOGGING AND SAWMILLS. Electrical drive has been very completely applied in this industry; instead of discussing each machine separately, primary details of the motors required are given in Table IX taken from the Westinghouse bulletin entitled "From Log to Lumber by Electric Power."

CHEMICAL INDUSTRIES. Most of the applications in the chemical industries can be made with a-c squirrel-cage motors. They are particularly desirable because many of the operations are continuous and very frequently the service conditions are severe in other ways. That is, there are very likely to be fumes, dust, and moisture. The simple construction of squirrel-cage motors with no small parts and no sliding contacts makes them peculiarly well adapted for this service. Motors must be strongly constructed, and they should be of the air-jacketed enclosed type to keep out oil, fumes, and moisture, and as a protection against deterioration from dusty chemicals. Motors should be selected with tight, dust-proof bearings, automatic oiling, and of a design which will not permit accumulated dust to interfere with proper ventilation.

Dusty Locations. For very dusty locations, as in cement mills and potash, fertilizer, and other factories where there is a great deal of dust, the motors should be enclosed.

Variable Speeds. Where variable speeds or especially strong starting torque is called for, wound rotor motors must be used for a-c service.

D-c Applications. About the only usual application of d-c motors in the chemical and electrochemical industries is for the operation of cranes, hoists, and other material-handling equipment requiring a wide range of speed adjustment.

HEATING AND VENTILATION OF BUILDINGS. In the heating and ventilating of buildings electric drive for the fans circulating the air are of extreme importance. Two types of fans are generally used, the propeller or disk fan and the centrifugal fan. The former are best adapted for exhausting air from rooms and for use with unit heaters. Centrifugal fans should be used with duct systems of ventilation and with certain kinds

* For further details see Synchronous motor drive for rubber mills, by C. W. Drake, a paper presented at Spring Convention of the A.I.E.E., St. Louis, April 13-17, 1925.

of unit heaters. Great care must be exercised in selecting the proper fan for the work to be done and in choosing the right motor to go with it. Consultation with reliable fan manufacturers is strongly recommended.

* Where motors are direct connected, flexible couplings are recommended.
† Solenoid brake generally supplied. ‡ These motors are of the high starting torque type.

Selection of Motor. The selection of the motor will depend on several service conditions, which include the speed variation desired, available voltage and space, and the horsepower necessary. The following equation for determining the required horsepower for estimating purposes is taken from an electrical manufacturer's bulletin, but accurate figures should be obtained from the manufacturer's curves:

$$Bhp = \frac{QI}{6356 \times \text{Eff.}}$$

Q = cubic feet of air required per minute; I = water gage pressure in inches; Eff. = blower efficiency in decimals (usually from 50 to 60 per cent); pressure in pounds per square foot = 5.2 × water gage in inches; pressure in ounces per square inch = water gage in inches ÷ 1.73. The pressure I should be measured at the fan. The amount of air required (Q) varies under different circumstances and should be substantially as given in Table X.

D-c Motor Applications. D-c motors of the shunt-wound type furnish satisfactory drives for fans and blowers where variable speed is required. The greatest flexibility is realizable with variable voltage control as explained under elevator and hoist drives. Where the fan or blower is to be operated with low-speed direct drive, d-c motors are particularly satisfactory because they operate at high efficiency at all speeds. The benefits of this higher efficiency are so marked that where slow-speed direct drives are required in localities where direct current is not available it may be worth while to install a motor-generator set. This holds particularly if the fan is to run more or less continuously.

Table X. Air Required

Cubic feet of new air per person per minute

	Without Humidification or Recirculation	With Humidification but without Recirculation	With Humidification and Recirculation	Number Air Changes per Hour

Squirrel-cage Motors. Squirrel-cage motors should be used for constant-speed drives, or where, by having two- or four-pole combinations providing wide steps in speed, regulation will be satisfactory.

Slip-ring Motors. Wound rotor or slip-ring motors should be used where speed regulation is required in small steps. Synchronous motors are well adapted for slow-speed operation, but unless large units are involved the power is too small for this type.

STEEL MILLS. The application of electric motors to steel mill service may be divided in two general classes: (1) that dealing with the application of motor drive to the main rolls, that is, to those rolls in which the ingot or billet is reduced in section; and (2) that dealing with the problems of electrifying the numerous other auxiliary machines and devices, such as tables, screw-downs, charging machines, etc.

Main-roll Application. The term "mill" is sometimes used to designate a single stand or group of stands, and sometimes to include the main rolls and all auxiliaries involved in the production of a given class of materials. The stands are generally classified according to the arrangement of rolls and method of operation, that is, two-high or three-high, the two-high being either reversing or non-reversing.

Continuous Mills. Continuous mills should also be included in which a number of stands are placed in series, the metal from the rolls of one stand passing directly to the rolls of the next. The stands are operated at such speed as to take care of the increased length. The speed of successive stands is accurately controlled to prevent the formation of loops or the stretching of the metal between passes.

Reversing and Non-reversing Mills. The great majority of rolling mills in this country are of the non-reversing type where the rolls run continuously in one direction. The large flywheel effect of the motors used for this class of service, together with the great capacity of the electrical supply systems at the present time, renders the use of separate flywheels unnecessary in most cases, in spite of the heavy peak loads encountered.

For reversing mill duty d-c motors are used in connection with flywheel motor-generator sets. The motors of such motor-generator sets are of the slip-ring type with either a constant resistance in series with the rotor, to increase the motor slip and enable the flywheel to give up its stored energy during peaks, or with a liquid slip regulator to perform the same function with a more definite limit on the motor input. To reduce the flywheel effect of the d-c reversing motors they are usually built with two armatures mounted on the same shaft.

Non-reversing Mills. For non-reversing mills rolling to definite sizes where no variation in speed is required, slip-ring induction motors are used, and more recently synchronous motors. Although the latter do not possess as good starting characteristics their effect on the power factor of the system in many cases more than offsets the disadvantages as regards starting torque.

Variable Conditions. Where mills are called upon to roll a variety of sections, and also in continuous mills where it is essential to adjust the speeds of successive stands to take up the increased length due to reduction of cross-section, the use of d-c motors having field control is now standard practice. They are used in connection with large motor-generator sets.

Speed Control. The use of the Kraemer and Scherlius systems of speed control for large slip-ring a-c motors has largely been given up in favor of d-c adjustable-speed motors. These are now built in capacities up to 7000 hp with a speed range from 50 to 120 rpm.

Power Required. Rolling mill loads are irregular in the extreme owing to the inter-

mittent character of the process. For any particular ingot the motor load consists of periods of heavy duty increasing in length with the length of the metal in the pass, interspersed with periods of friction load only. With a given mill the load varies widely with the difference in the section rolled, differences in temperatures of metal, personal equation of the operator, etc. The practical determination of the power required to roll steel is a matter of elaborate and extensive tests under widely varying conditions. The information for predetermining the sizes of motor and flywheel for an installation must cover the following points:

Type of mill; rail, plate, etc.
Diameter and speed of rolls.
Weight of ingot.
Initial and final section.
Number of passes.
Time between passes.
Elongation in each pass and total.
Initial length.
Average and maximum rate of rolling.
Temperature of metal.
Character of metal.

Auxiliary Motor Applications. Electric motors have been used for a long time for auxiliary steel-mill machinery. The nature of this service is unusually severe and has led to the development of the mill-type motor for both d-c and a-c service. These motors are designed to withstand heavy overloads and abnormally rapid acceleration. Their insulation consists of mica and asbestos (class B insulation) to withstand the high temperatures encountered.

All A-c versus Mixed System. It is to be assumed that power will primarily be alternating current, as the transmission distances ordinarily preclude the use of d-c generators. It might therefore seem to be simplest and most efficient to step down to a suitable voltage through static transformers and use a-c motors. But, with many of the auxiliaries, such as screw-downs, live-roll tables, etc., the advantages in favor of d-c motors are so great that they are almost universally adopted. This system involves additional expense for motor-generator sets and entails considerable power loss due to the low efficiency of conversion with intermittent loads. On the other hand, d-c motors of this type are lower in first cost than corresponding induction motors, and a higher power factor is maintained on the entire system where they are used. An increase in power factor is effected by eliminating the lagging current of the induction motors, and, in addition, the motor-generator sets can be equipped with synchronous motors which will take a leading current from the line and offset part of the lagging current on the rest of the system. The increase in power factor enables a reduction to be made in the size and cost of transformers and generators, and also increases their efficiency owing to the lower currents which they are required to handle and to the decreased excitation required by the generators.

ELECTRIC RAILWAYS

By H. A. Currie and Robt. S. Rhodes

1. TRACTION SYSTEMS

APPLICATIONS OF ELECTRIC TRACTION. There are certain well-defined fields in which electric traction is superior to other methods, the most important of which are the following:

1. Where the frequency of stops is so great as to require a high rate of acceleration in order to make a good schedule speed. Motor buses are replacing trolley lines to an increasing extent for such service. If the service requires trains of several cars, any desired number of these cars can be made motor cars and thus a sufficient weight on the driving wheels can be economically secured to give the required adhesion and tractive effort.

2. Where local conditions prohibit the nuisance of the smoke, exhaust gases, and noise of steam locomotives, as in cities, tunnels, and mines.

3. In heavy trunk-line service where the density of traffic is so great that a high load factor can be obtained with respect to both the power house and distribution system. The *operating* cost of an electric train is always less than the operating cost of a steam train but the *fixed* charges (interest on investment and depreciation) of the electric system are high, for the first cost for the electric equipment, viz., locomotives, motor-car equipment, distribution system, and power house, is much greater than the first cost of steam locomotives, and their accessory equipment. If there are sufficient trains in a system so that the pro rata share of the fixed charges for each train is less than its share of the difference between the operating cost of an equivalent steam equipment and the operating cost of the total electric equipment then electric traction is advantageous even in the absence of the secondary and intangible advantages which usually exist.

4. Where cheap electric power is available and fuel is expensive.

SYSTEMS. Three different types of motors are in use for electric traction, the d-c motor, the single-phase commutator motor, and the three-phase induction motor; see chapter on Motors. The operating voltages (i.e., volts between trolley and track rails or between third rail and track rails or, in double-trolley roads, between the two contact wires) and the motor voltages employed are as follows:

D-c Systems. Trolley or third-rail voltages of 600, 750, 1200, 1500, 2400, and 3000 are in use. The motors for the 600- and 750-volt systems are designed for operation at full trolley voltage. For all the other systems, two motors are usually connected permanently in series electrically, each designed for half the trolley voltage, but insulated for the full voltage.

Single-phase Systems. Trolley voltages (third rails are not used) of from 3000 to 11,000 volts and frequencies of 15 and 25 cycles per second are in use. In the United States 11,000-volt single-phase 25 cycles is standard, and in Europe 15,000-volt 15 or 16 2/3 cycles. The trolley voltage is stepped down to values suitable for direct application to the motors, from 200 to 1150 volts.

Three-phase Systems. Two trolley wires for each track are required, the two wires and the track forming the necessary three conductors for the three-phase distribution. This system is extensively used in Italy.

The voltages used between the two contact wires and between each contact wire and track range from 3700 to 10,000, and the frequency is 15, 16 2/3, and 45 cycles. A few installations have also been made in Switzerland, Spain, and Austria using 25 and 40 cycles, and as low as 750 volts. Voltage is stepped down for the motors as in the single-phase system.

Comparison of the Various Systems. For ordinary street railway service the 600-volt d-c system is almost universally employed, but for interurban and trunk-line service there has been much difference of opinion as to which of the various systems is the most economical when all the factors are taken into account. The factors which must be considered in comparing the three systems in any particular case are the following:

1. For a given weight and length of trolley or third rail the per cent power loss for a

given amount of power transmitted varies inversely as the square of the trolley or third-rail voltage.

2. The higher the trolley or third-rail voltage the smaller is the number of substations required for the same efficiency of distribution and weight of conductor.

3. The higher the trolley or third-rail voltage the more costly is the insulation and supporting structure, and also the greater is the cost of maintenance of the distribution system.

4. Both the first cost and the annual expense of the substations are less for the a-c systems than for the d-c systems, since for the former static transformers only are required whereas for the latter mercury-arc rectifiers or rotating machinery must be used for conversion.

5. The less-than-unity power factor of a-c motors (90 to 95 per cent) as well as of the line (due to the reactance of the trolley wire and track return) gives rise to a greater power loss in the a-c distribution system for the same power delivered than in the d-c system, and makes necessary generating apparatus of greater kv-a capacity.

6. The high-voltage d-c motor, for the same horsepower rating and speed, costs more, weighs more, and occupies more space than the 600-volt d-c type or the modern a-c motor.

7. With the a-c motors transformers are required on the locomotive or car, which adds to the cost and weight of the equipment.

8. The 600-volt d-c motor costs less to maintain and is liable to fewer operating troubles than any of the other motors.

9. With the commutating type of a-c motor the power lost in the control equipment is practically negligible, since the "potential" type of control can be used. For both the d-c motor and the induction motor a resistance control is necessary, with consequent loss in power (see Art. 5, Control Systems for Railway Motors).

10. The induction motor is inherently a constant-speed machine, and consequently the power input varies directly as the opposing resistance. The d-c motor and the a-c commutator motor are inherently variable-speed machines, and the power input varies approximately as the square root of the opposing resistance, the speed at the same time falling off.

11. The three-phase induction motor, when kept connected electrically to the source of power, automatically operates as a generator when the train is going down grade at a speed greater than the synchronous speed of the motor, the motor thus returning power to the line and at the same time acting as a brake preventing any considerable increase in speed. "Regeneration," as this action is called, can also be obtained with the other types of motors but only at increased expense for the additional control equipment required.

Examples of the Use of the Various Systems. Tables I and II list the most notable examples of electrified steam railroads.

ANALYSIS OF AN ELECTRIC RAILWAY PROJECT. In the analysis of a particular problem the general line of procedure indicated below is followed, referring to Art. 2 for methods of calculation.

1. Determine the number and capacity of cars to supply the service desired.

2. Determine the power and energy required to propel these cars at the schedule speed desired.

3. Select the motors to correspond to the power determined in 2.

4. Lay out distribution of cars, by train diagrams if necessary.

5. Calculate the capacity of the low-potential distribution system and of the substations.

6. Determine the capacity of the generating stations and transmission system.

7. Estimate the first cost of the system.

8. Estimate the cost of operation.

9. Estimate the earning power of the system.

A. In the case of a new road the earning power must exceed the sum of the operating cost and fixed charges by an amount sufficient to pay dividends.

B. In the case of the electrification of a steam road it must be possible to show either: (1) that the result of electrification has been to reduce the operating charges by an amount more than sufficient to pay the fixed charges on the electrical apparatus, or, (2) that the result of electrification will increase the capacity of the road or attract sufficient new business so that the increased earning power will more than balance the increased fixed charges.

C. The study should include other traction systems, such as internal-combustion engine systems.

2. ENERGY REQUIREMENTS AND MOTOR EQUIPMENT

By W. A. Del Mar

From a consideration of the forces acting on a moving train it is possible to determine the motor capacity and energy required to operate it when the profile and contour of the road, the time table, and the characteristics of the available motors are known.

UNITS AND ABBREVIATIONS. Throughout this article the various quantities employed will be expressed in the following units unless specifically stated otherwise: distances in feet, weights in tons of 2000 lb, forces in pounds, speeds in miles per hour (abbreviated mph), accelerations in miles per hour per second (abbreviated mphps), mechanical power in horsepower, energy in watthours.

FORCES ACTING ON A TRAIN. The forces tending to accelerate a train are the tractive effort developed by the motors and the component of the weight along the track on down grades. The forces which retard the motion of the train are the various frictional forces and the component of the weight along the track on up-grades; also in braking, the frictional force due to the brakes. All the various frictional forces, except the braking resistance, such as track friction, journal friction, air friction, etc., which oppose the motion of a train on a straight track are usually considered together and are referred to as the "train resistance." The extra friction due to track curvature is usually considered as an equivalent up-grade.

Tractive Effort and Draw-bar Pull. The tractive effort of a motor is the force exerted by the motor at the rim of the driving wheel to which the motor is geared. The tractive effort of a locomotive is the force exerted by the locomotive at the rim of the drivers. The draw-bar pull of a locomotive is the force transmitted through the draw-bar of the locomotive,* and is less than its tractive effort by an amount equal to the resistance due to the rolling friction of the locomotive wheels on the track and the air resistance of the locomotive.

D-c motors deliver a uniform tractive effort for a given current; the tractive effort of a-c motors pulsates to some extent with the alternations of the current; the tractive effort of a steam locomotive varies from 28 to 50 per cent above and below its average value during each revolution of the drivers.

Train Resistance. The total train resistance may be expressed as the sum of four terms, described as follows by W. J. Davis, Jr., in the *General Electric Review*, 1926. It is now usual to add 10 per cent to the values obtained from these equations.

The first two terms of the equations represent journal friction almost entirely. They have been derived from dynamometer and coasting tests on standard freight and passenger cars and electric locomotives and are based on oil lubrication with average temperature conditions. Journal friction may be increased 20 to 40 per cent at temperatures below freezing.

The third term comprises resistances due to flange friction, concussion, swaying, and miscellaneous frictions proportional to the speed. The factor for this element is decreased by increase in length of truck wheel base and increased by poor roadbed conditions and inferior riding qualities of motor cars.

The last term gives air resistance for average weight of car or locomotive in pounds per ton for standard types of equipment. No allowance is made for head winds or strong side winds.

Locomotive resistance represents tractive effort delivered to driving axles and does not include friction losses in gears, motor bearings, or other parts of the driving equipment, as these are usually covered in the motive power efficiency.

The formulas in Table III are based on tests taken under mild weather conditions. Values obtained from them may be used as modified above in calculations relating to electric distributing systems, substations, energy consumption, and power demand. In the determination of electric motor characteristics and gear reductions to meet particular speed requirements, however, it may be desirable to add a small percentage to the required speed as a protection against unusual conditions.

The accuracy of these formulas at very high speeds is unconfirmed.

Train Resistance at Starting. The formulas given above are not applicable to speeds below about 10 mph. The New York Central tests on electric trains show that the train resistance decreases with decrease in speed to 10 mph, but that as the speed still further

* In the case of a steam locomotive, the draw-bar pull usually refers to the force transmitted through the coupling between the tender and train; i.e., the tender is considered as a part of the locomotive.

Table III

Symbols

R = Tractive resistance in pounds per ton (2000 lb) on tangent level track.
A = Area in square feet of cross-section of locomotive or car body and trucks.
V = Speed in miles per hour.
n = Number of axles per car.
w = Average weight per axle in tons.
wn = Average weight of locomotive or car.

Values of A

Locomotives: 50 tons	105	sq ft
" 70 tons	110	"
" 100 tons and over	120	"
Freight cars	85–90	"
Passenger cars	120	"
Multiple-unit cars	100–110	"
Motor cars: 2 trucks	80–100	"
" " 1 truck	70–75	"

Where Used		Usual Formulas Recommended for convenience in calculation. Approved for axle weights in excess of 5 tons.	General Formulas Applicable to all axle weights. To be used when axle weights are less than 5 tons
Locomotives		$R=1.3+\frac{29}{w}+0.03\,V+\frac{0.0024\,AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.03V+\frac{0.0024AV^2}{wn}$
Freight cars		$R=1.3+\frac{29}{w}+0.045\,V+\frac{0.0005\,AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.0005AV^2}{wn}$
Passenger cars (vestibuled)		$R=1.3+\frac{29}{w}+0.03\,V+\frac{0.00034A\,V^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.03V+\frac{0.00034\,AV^2}{wn}$
Multiple-unit trains	Leading car. (vestibuled)	$R=1.3+\frac{29}{w}+0.045\,V+\frac{0.0024\,AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.0024AV^2}{wn}$
	trailing cars	$R=1.3+\frac{29}{w}+0.045\,V+\frac{0.00034\,AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.00034\,AV^2}{wn}$
Motor cars		$R=1.3+\frac{29}{w}+0.09\,V+\frac{0.0024\,AV^2}{wn}$	$R=\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.09V+\frac{0.0024AV^2}{wn}$

decreases the resistance per ton increases. The resistance at starting may be from 6 to 18 lb per ton, depending upon the condition of the bearings, track, etc., and upon the duration of the stop preceding the starting. These figures also apply to freight trains. Tests on the Rock Island system showed that in a train which had stood overnight in cold weather (i.e., which had become " frozen up "), the starting resistance was 30 lb per ton. The slack in the car couplings, however, renders it unnecessary for a locomotive to exert sufficient effort to start all the cars at once.

Grades and Curvature. An actual up-grade of G per cent produces a retarding force of 20 G pounds per ton, and a down-grade of G per cent produces an accelerating force of 20 G pounds per ton. A curve gives rise to a retarding force which may be represented by the formula:

$$r = 0.058\,SC \tag{1}$$

where r = (excess) curve resistance in pounds per ton.
S = speed, miles per hour.
C = degree of curvature.

(E. C. Schmidt and H. H. Dunn, Univ. of Illinois, Bulletin 92.)

Note that for angles of curvature up to 12 deg the angle in degrees may be taken equal to 5730 ÷ R where R is the radius of curvature in feet.

ACCELERATION AND BRAKING. The permissible rate of acceleration depends upon a number of factors.

1. The rating of the motors; the larger the motors the higher the tractive effort they can develop and therefore the greater the acceleration.
2. The weight on the driving wheels of the car or locomotive; the maximum tractive effort that a motor car can exert without slipping the wheels is from 15 to 20 per cent of the weight on the drivers (see below under Adhesion Coefficient).
3. The comfort of the passengers. This also depends to some extent upon the uniformity of the acceleration.
4. To make a given schedule speed with the least amount of energy the acceleration rate should be as high as possible. Very high rates of acceleration, however, are not in general justified on this score, as the increase in the size of the motors required may more than offset the saving of energy.

The rates of acceleration in Table IV represent common practice:

Table IV. Acceleration Rates

Service	Miles per hour per second
Steam locomotive, freight service...........	0.1 to 0.2
Steam locomotive, passenger service.........	0.2 to 0.5
Electric locomotive, passenger service........	0.3 to 0.6
Electric motor cars, interurban service.......	1.0 to 1.5
Electric motor cars, city service.............	2.0 to 4.75
Electric motor cars, rapid transit service.....	1.5 to 2.0
Highest practical rate, service conditions.....	2.5 to 4.75
Highest practical rate, emergency...........	7 to 8

Braking. The maximum retardation in braking is limited by the comfort of the passengers, and injury to equipment, a retardation of 1.5 mphps being the usual practical limit for electric or steam passenger trains, although 2.5 mphps is sometimes attained. For freight trains the braking retardation is from 0.7 to 8.0 mphps. The higher the rate of braking the less the energy consumption for a given schedule speed.

The tractive effort required to give to 1 ton (2000 lb) a linear acceleration of 1 mphps is 91.2 lb. To accelerate a train of W tons requires a tractive effort of 91.2 aW lb to produce a linear acceleration of a miles per hour per second, but on account of the accompanying angular acceleration of the rotating parts an additional force is required. This additional force is proportional to the linear acceleration a and also depends upon the radius of gyration (see Vol. I, Fund. of Eng.) of all rotating parts, and upon the gear ratio of the motors (i.e., ratio of number of teeth in gear to number of teeth in pinion). The effect of the moment of inertia may be looked upon either as increasing the effective weight W or as increasing the acceleration constant, the acceleration constant being defined as the quotient of total accelerating force divided by the product of weight and linear acceleration.

The increase in effective weight (in tons) due to any rotating axle or wheel is $\dfrac{M}{2000}\left(\dfrac{K}{r}\right)^2$ where M is the weight in pounds of the part in question, K its radius of gyration, and r its actual radius, both in feet. Each motor armature adds to the effective weight $\dfrac{M}{2000}\left(\dfrac{\rho K}{r}\right)^2$ tons, where M is the weight of the armature in pounds, K the radius of gyration of the armature in feet, r the radius in feet of the wheel to which it is geared, and ρ is the gear ratio. The total additional weight W_r is the sum of the above items for all the rotating parts. The total force in pounds required to produce the acceleration of a miles per hour per second is then CaW, where W is the actual weight of the train in tons and $C = 91.2\left(1 + \dfrac{W_r}{W}\right)$. This quantity C is the **corrected acceleration constant** and this corrected value should be used in all calculations.

The acceleration constant is raised by the flywheel effect discussed above by about 5 per cent (i.e., $W_r/W = 0.05$) for heavy cars and locomotives, and between 5 per cent and 10 per cent for light low-speed cars, 8 per cent being an average figure. However, C is usually taken as 100, correspondence to an increase in effective weight of about 10 per cent. A given linear acceleration of a miles per hour per second then requires an accelerating force of 100 a pounds per ton.

TRACTIVE EFFORT REQUIRED.

Let F = tractive effort, in pounds per ton, exerted by motors.
G = per cent actual grade (+for up-grade).
g = degrees of curvature.
r = train resistance, in pounds per ton.
a = acceleration in miles per hour per second (−for retardation).

Then the tractive effort required per ton of total train weight is

$$F = 100\,a + r + 20\,G + g \tag{2}$$

Example. Given a train of three 45-ton cars moving with a speed of 20 mph and accelerating at a rate of 1.5 mphps up a 1 per cent grade on a straight track; what is the total tractive effort required?

Answer: $(100 \times 1.5 + 7.8 + 20 \times 1)3 \times 45 = 24{,}000$ lb

GEAR RATIO AND SPEED. By gear ratio is meant the ratio of the number of teeth in the gear on the wheel axle to the number of teeth in the pinion on the motor shaft. A gear ratio greater than 6 : 1 is seldom used for railway motors. For a given torque developed by the driving motor, the tractive effort at the wheel rim and the linear speed for a given current depend upon the gear ratio and wheel diameter. Let D = the diameter of the wheel in inches, K = the gear ratio, F = the tractive effort for a given current

input; then the tractive effort F_1 for this same current input but for a wheel diameter D_1 and gear ratio K_1 is

$$F_1 = \frac{DK_1}{D_1 K} F$$

If V is the speed corresponding to the tractive effort F for a given motor voltage, then the speed V_1 corresponding to the tractive effort F_1 for the same motor voltage and current is

$$V_1 = \frac{D_1 K}{DK_1} V$$

If the gear ratio is low, the maximum speed will be high and the rate of acceleration low; if the gear ratio is high, the maximum speed will be low and the rate of acceleration high.

For a given motor equipment, train weight, schedule, and profile the energy consumption and temperature rise of the motors depend upon the gear ratio selected, since this in turn determines the amount of coasting; see below on Importance of Coasting. The proper gear ratio can be found only by trial calculation, plotting speed-time and distance-time curves from motor curves based upon different gear ratios, and calculating the energy consumption and temperature rise in the motors as described below.

MAXIMUM POSSIBLE TRACTIVE EFFORT—ADHESION COEFFICIENT. The adhesion or "tractive" coefficient is the quotient (expressed usually as per cent) of the tractive effort in pounds which will slip the drivers, divided by the weight in pounds on the drivers. Burch gives the values in Table V. The maximum possible tractive effort is the product of the adhesion coefficient (as a decimal fraction) by the weight (in pounds) on the drivers.

Table V. Adhesion Coefficients

Condition of Track	Without Sand	With Sand
Most favorable condition	35	40
Clean, dry rail	28	30
Thoroughly wet rail	18	24
Greasy moist rail	15	25
Sleet-covered rail	15	20
Dry-snow-covered rail	11	15

Maximum Grade Train Can Ascend.

Let W = total weight of train in tons.
W_d = total weight on all drivers in tons.
p = adhesion coefficient in per cent
r = train resistance in pounds per ton of total weight.
G = per cent grade.
g = degree of curvature.
a = acceleration in miles per hour per second.

Then the maximum tractive effort which the drivers can exert is 20 pW_d pounds, and therefore $(r + 20\,G + g + 100\,a)\,W$ must be less than 20 pW_d, or the maximum per cent grade which the train can ascend is *

$$G = \frac{pW_d}{W} - \frac{(r + g + 100\,a)}{20} \tag{3}$$

This grade is greater the less the acceleration, or the greater the retardation. The greater the speed before the train strikes the grade, the greater may the retardation be without bringing the train to rest on the grade, and therefore the steeper the grade it may ascend.

Example. Assume no acceleration or retardation and no curvature, a train resistance of 8 lb per ton, an adhesive coefficient of 15 per cent, and 25 per cent of total weight of train on drivers. Then the maximum grade the train can ascend is $G = 15 \times 0.25 - 8/20 = 3.35$ per cent.

The highest permissible grade is when all the weight is on the drivers, e.g., single cars or trains of motor cars with all axles equipped with motors. On steam freight roads the maximum grade seldom exceeds 2 per cent, and is usually considerably less, except in very mountainous country.

Weight of Locomotive. The weight of locomotive required to accelerate a train weighing W tons at the rate of a miles per hour per second up a grade of G per cent on a g degree curve against a frictional resistance of r pounds per ton, when the q per cent of the

* To be exact W_d should be multiplied by $\sqrt{1 - (G/100)^2}$, but except for very heavy grades this correction is negligible.

weight is on the drivers and the coefficient of adhesion is p per cent, is given by the following formula:

$$\text{Weight of locomotive} = \frac{5\,W}{pq}(100\,a + r + 20\,G + g)$$

Example. What weight of locomotive is required to accelerate a 400-ton train at the rate of 0.5 mphps up a 0.1 per cent grade against a frictional resistance of 8 lb per ton, when 80 per cent of the weight is on the drivers and the coefficient of adhesion is 20 per cent.

$$\text{Weight of locomotive} = \frac{5 \times 400}{20 \times 80}(50 + 8 + 2) = 75 \text{ tons.}$$

POWER REQUIRED AT GIVEN SPEED.

Let r = train resistance in pounds per ton of total train weight.
G = per cent grade.
g = degree of curvature.
a = acceleration in miles per hour per second.
v = speed in miles per hour.
W = total weight of train in tons.

Then the power required *at the rims of the drivers* is $1.99\,v(r + 20\,G + g + 100\,a)$ watts per ton, or $p_0 = 2.67 \times 10^{-3}\,vW(r + 20\,G + g + 100\,a)$ horsepower, total. (4)

The *power input* p_i to the car or locomotive is equal to the power at the rims of the drivers divided by the over-all efficiency ϵ of the controller, motors and gears, i.e.,

$$p_i = \frac{1.99\,Wv(r + 20\,G + g + 100\,a)}{1000\,\epsilon} \quad \text{kilowatts} \tag{5}$$

Efficiency of Motors. The overall efficiency of the motors and gears when the motor is operating at full line voltage does not vary considerably for loads ranging from 50 to 150 per cent of rated load. The maximum efficiency is usually at about rated load, and has the values given in Table VI. At 50 and 150 per cent load, the efficiency may be from 3 to 10 per cent less, depending upon the design and the type of motor. The variation in efficiency with load is usually greater with a-c series than with d-c motors.

Table VI. Maximum Overall Efficiency of Motors and Gears at Rated Voltage

Horsepower, 1-hr rating	Kind of Motor	Maximum Efficiency per cent
30–100	D-c single-reduction spur geared...	83–88
30–100	D-c single reduction worm geared..	79–83
30–100	D-c double reduction spur geared..	82–86
100–250	D-c geared.....................	88–89
250–500	D-c gearless....................	91–93
50–200	A-c series geared................	70–80*
200–500	3-phase induction geared.........	85–89

* Including step-down transformers.

Average Over-all Efficiency During Controller Period. The overall efficiency of the motors and controller depends upon the type of control employed and upon the resistance inserted or the connections made by the controller. Most modern controllers for interurban cars are provided with a current-limiting device which limits the current to a given value, usually the value of the current corresponding to the 1-hr rating of the motor. Under these conditions the *average* overall efficiency of the motors and controller over the whole of the *controller period* (i.e., from time of starting until full line voltage is established across each motor or until all resistance is cut out) may be expressed as follows, on the assumption (which is very nearly exact) that the speed of the motor varies directly as the voltage impressed across its terminals:

Let ϵ = the overall efficiency of the motors and gears at end of controller period. Then for straight resistance control with d-c or induction motors the average efficiency during the controller period is $\epsilon/2$; for series-parallel control with 2 d-c motors the average efficiency during the controller period is $2\,\epsilon/3$; with 4 d-c motors first all in series, then 2 series sets in parallel, and then all 4 motors in parallel the average efficiency during the controller period is $8\,\epsilon/11$; for a-c series motors with voltage control the average efficiency during the controller period (including losses in step-down transformers) is about 0.90ϵ. Hence for a motor having an 85 per cent efficiency at the 1-hr rating and the starting current limited to the corresponding current rating, the average overall efficiency of the controller, motors, and gear during the controller period is

For straight resistance control................. 43 per cent
For series-parallel control, d-c motors.......... 57 per cent
For series-series-parallel control, d-c motors..... 62 per cent

Example. Given a train of three 45-ton cars each car equipped with two 200-hp d-c motors. What is the input to each motor if the speed is 30 mph and the train is accelerating at 1.0 mphps up a 2-per-cent grade, the track being straight, and full line voltage being across each motor?

Answer: From Table III the train resistance is $r = 10.5$, and from eq. (4) the total power output is

$$p_0 = 2.67 \times 10^{-3} \times 30 \times 135(10.5 + 20 \times 2 + 100 \times 1)$$
$$= 1627 \text{ hp}$$

or $1627/6 = 271$ hp per motor. Assuming an efficiency of 87 per cent, the input to each motor is $271 \times 0.746/0.87 = 232$ kw, and the total input to the train $6 \times 232 = 1392$ kw.

If the train accelerates at this same rate from rest to a speed of 30 mph at the end of the controller period (series multiple control) the grade being 2 per cent throughout, the average output of the motor would be the output corresponding to half speed or 15 mph, or 136 hp per motor, requiring an average input of $136 \times 0.746/0.57 = 178$ kw, and the average input to the train during the controller period would be $6 \times 178 = 1068$ kw.

SPEED-TIME AND DISTANCE-TIME CURVES. To determine the energy required to propel a car or train a given distance over a given track in a given time requires the consideration of a number of factors which can best be taken into account by the construction of various kinds of time curves. Such curves may be constructed with practically

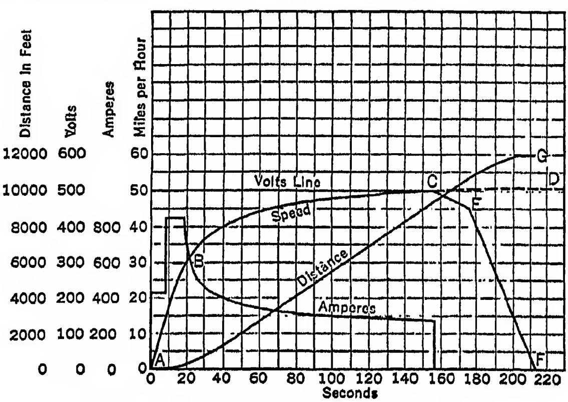

Fig. 1. Speed, Distance, and Current Curves

any degree of accuracy desired when the profile of the track, the weight of the train, the various resistances, schedule speed, time of stops, etc., are accurately known. Such data are, however, seldom known with any great precision, and consequently elaborate methods of plotting and calculation are seldom justified. Below will be given (1) some results of actual tests, (2) a rough but simple method of approximating the energy requirements, (3) a step-by-step method, which, though tedious in application, is capable of any degree of accuracy desired, provided the given data are accurately known, and (4) an outline of an analytical method by which the effect of changes in the time of coasting, rates of acceleration and braking, etc., may be predetermined.

The following terminology will be employed:

Speed-time Curve. A curve showing the speed (in miles per hour) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve *ABCEF* in Fig. 1. A speed-time curve may be conveniently divided into four parts, namely:

Controller Period. The period from starting until full line voltage is established across each motor; i.e., the portion *AB* of the curve in Fig. 1.

Motor-curve Period. The period during which the motor is operating on full line voltage; i.e., the portion *BC* in Fig. 1. The relation between speed and tractive effort during this portion of the run is fixed by the motor characteristics, specifically by the speed-torque curve of the motor and the gear ratio.

Coasting Period. The period during which the car or train is coasting; i.e., the portion *CE* in Fig. 1.

Braking Period. The period during which the brakes are applied; i.e., the portion *EF* in Fig. 1.

Distance-time Curve. A curve showing the distance covered (in feet) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve AG in Fig. 1.

Current-time Curve. A curve showing the line current (in amperes) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve marked "Amperes" in Fig. 1.

Voltage-time and Power-time Curves. Curves showing respectively the voltage per motor (or the line voltage) and the power input to the motor (or train) plotted as ordinates against elapsed time (in seconds) as abscissas.

Average Speed and Schedule Speed. The average speed V is the total distance run L' (in miles) divided by the time (in hours) the train is actually running. The schedule speed S is the total distance run (in miles) divided by the total time (in hours) of the run from one end of the road to the other, including time of all stops at intermediate stations. If the *total* time of all the *intermediate* stops is T_s' seconds, then

$$V = \frac{S}{1 - \dfrac{T_s' S}{3600 L'}} \tag{6}$$

where V and S are in miles per hour and L' is the *total* length of route in *miles*.

Duration and Frequency of Station Stops. The duration of each stop for surface cars ranges from 5 to 10 sec. for elevated and subway trains from 10 to 30 sec. for interurban trains from 10 to 40 sec. The stops per mile are the reciprocal of the average distance in miles between stops. For the six most important elevated and subway lines in Europe and America, the stops per mile average 2.5.

Average Equivalent Grade (G). Grades may be taken into consideration by calculating the sum H_1 of all the rises on up-grades and the sum H_2 of all the drops on down-grades, and taking for the average "equivalent" up-grade in percentage

$$G = \frac{100(H_1 - 0.5\,H_2)}{L} \tag{7}$$

where H_1 and H_2 are in feet and L is the total length of the route in feet. On a round trip $H_1 = H_2$, and the "equivalent" grade in per cent is

$$G = \frac{50\,H_1}{L}$$

This method of dealing with grades is equivalent to assuming that half the kinetic energy stored in the train on down-grades is utilized in taking the train up the following up-grade. The amount of energy thus rendered available of course will depend upon the amount of braking necessary on down-grades to prevent excessive speeds and also upon the location of the stops with respect to the grades. The figure $^1/_2$ is taken as an approximate average; it may be varied as seems reasonable in view of the actual profile.

Average Angle of Curvature (g). Curves may be taken into account by finding the average curvature, i.e., finding for each curve the product of the degree of curvature by the length of the curve, adding all these products, and dividing by the length of the route.

ENERGY CONSUMPTION FROM TESTS. Table VII gives the energy consumption, as found by tests, for a number of typical services. This table will be found useful as a

rough check on any calculations made for a specific service. Methods of making such calculations are given below.

APPROXIMATE METHOD OF CALCULATING ENERGY CONSUMPTION. The following method is based upon simple kinetic principles, and, if certain characteristics of the run are known, gives the actual energy output at the wheel rims. This fact makes the method useful, not only for rough calculations, but also to check calculations made by the step-by-step method.

When the method is applied to checking purposes, the column of Table VIII headed "Actual Energy Output" should be used, and the input calculated from the known efficiencies. When applied to rough calculations, the column headed "Approximate Electrical Energy Input" should be used. In the latter case the maximum speed and length of run with power on are not known, but it is possible to assume certain values, based upon experience, which will give a rough approximation to the energy required.

Table VIII. Output at Wheel Rim and Input to Car in Watthours per Ton-mile

Energy for	Actual Energy Output at Wheel Rims of Cars	Approximate Electrical Energy Input to Cars
Acceleration	$\dfrac{V^2_m}{36.2L}$	$\dfrac{K^2 n V^2}{25}$
Train resistance	$\dfrac{1.99\, rL_p}{L}$	$\dfrac{2.9\, r}{Q}$
Grades	$\dfrac{39.8\, GL_p}{L}$	$\dfrac{57\, G}{Q}$
Curves	$\dfrac{1.99\, gL_p}{L}$	$\dfrac{2.9\, g}{Q}$
Total	Sum	Sum

Let V = average running speed in miles per hour.
V_m = maximum speed in miles per hour.
L = length of run in miles.
L_p = distance traveled, with power on, in miles.
n = $1/L$ = number of stops per mile including one terminus.
r = average train resistance, in pounds per ton. (Say that corresponding to a speed from 10 to 20 per cent greater than the average speed.)
G = average equivalent grade, in per cent.
g = average curvature in degrees.

$$K = \frac{V_m}{V} = \text{ratio of maximum to average speed; see Table IX.}$$

$$Q = \frac{L}{L_p} = \text{ratio of length of run to distance traveled with power on; see Table VIII.}$$

NOTE: $25 = 36.2\,\epsilon$, $57 = 39.8 \div \epsilon$, and $2.9 = 1.99 \div \epsilon$, where ϵ is the efficiency, taken as 0.7. The formula for energy due to curves assumes each degree of curvature to be equivalent to a train resistance of 1 lb per ton, which is probably high.

Table IX. Values of K and Q

(D. C. Woodbury and W. A. Del Mar)

Stops per Mile n	K: Locomotive Passenger Trains	K: Single Cars, Multiple-unit Trains and Freight Trains	Q: All Trains	Stops per Mile n	K: Locomotive Passenger Trains	K: Single Cars, Multiple-unit Trains and Freight Trains	Q: All Trains
0	1.00	1.00	1.00	1.4	1.93	1.59	2.34

1.2	1.93	1.56	2.24				

Example. A multiple-unit train has a speed (excluding stops) of 25 mph and makes 0.8 stop per mile. It ascends an average grade of 0.143 per cent. What will be its energy consumption in watthours per ton-mile?

From Table IX we find for $n = 0.8$, that $K = 1.47$ and $Q = 1.99$. Then using the formulas in Table VIII, the results in Table X are obtained, assuming 6.5 lb per ton for friction.

Table X

Energy for	Watthours per Ton-mile	
Acceleration	$\frac{1.47^2 \times 0.9 \times 25^2}{25} =$	48.5
Train resistance	$\frac{2.9 \times 6.5}{1.99} =$	9.5
Grades	$\frac{57 \times 0.143}{1.99} =$	4.1
Total		62.1

Efficiency of Run. The formulas given above enable one to judge the effect, upon the energy consumption, of altering any of the principal physical elements upon which the run is based.

From the formulas for kinetic energy it is obvious that a low value of K means a low energy consumption. A low value of K, however, means a "square" speed-time curve; i.e., for low energy consumption the controller, acceleration, and braking periods should be as short as possible, or in other words, the rate of acceleration and braking should be as great as practicable.

The quantitative effect of changing any of these variables may be estimated by the analytical method outlined on p. 22.

This example worked out by the step-by-step method gave 60.5 whr per ton-mile.

STEP-BY-STEP METHOD OF PLOTTING SPEED-TIME CURVES. There is no way of exactly predetermining a speed-time curve except by a number of successive trials. That is to say, the time the current is kept on, the time of coasting, and the time of braking must each be guessed, and it is usually necessary to make a number of trials, by varying the proportion of motor run, coasting, and braking, before the given distance is traversed in the desired time.

If the characteristics of the train and its equipment are expressed numerically, the principles of mechanics enable such trial runs to be plotted on paper and the proper proportion of motor run, coasting, and braking selected to make the train travel the desired distance in the given time. For a given motor equipment on a given route it is possible to plot by a step-by-step method these speed-time curves, and then from these curves and the characteristic curves of the motors the various characteristics, such as energy consumption, root-mean-square current, etc., may be determined. The accuracy of this method depends solely upon the accuracy with which the assumed data are known. The necessary data are:

Profile and alignment of road.
Characteristic curves of the motors.

W = total weight of train in tons.
T = the time of run in seconds between successive stops.
I_0 = the permissible starting current, or
a = the acceleration in miles per hour per second during the controller period.
b = the braking rate in miles per hour per second.
r = the train resistance in pounds per ton at any speed.

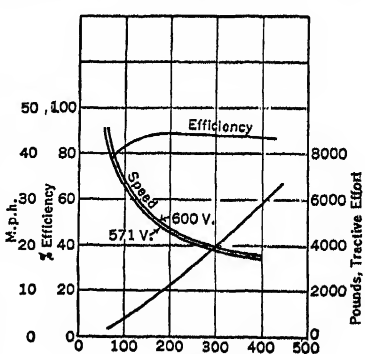

Fig. 2

Determination of Acceleration and Retardation Rates. From the motor characteristics, which are usually given in the form indicated in Fig. 2, determine the tractive effort and speed corresponding to the permissible starting current. This is usually taken as the current corresponding to the 1-hr rating; in the case of the motor whose characteristics are shown in Fig. 2, this current is 315 amp, the speed 19.6 mph, and the tractive effort 4300 lb. If each car is equipped with two motors, the weight corresponding to each motor is half the weight of the car. If the cars weigh 44 tons each, then the tractive effort per ton developed by the motors at this speed is 4300/22 = 195 lb per ton. At the point where the motors are changed from series to parallel the speed will be approximately one-half the speed at rated voltage or 9.8 mph. If the average line voltage is less than the

rated voltage, these speeds should be reduced in proportion to the ratio of the actual to the rated voltage. In the case selected the average line voltage is 571 volts; hence the speeds corresponding to the parallel and series points are 18.6 and 9.3 mph respectively. These speeds and the corresponding tractive efforts are entered into Table XI.

Table XI. Acceleration Rates

Speed, mph		Motor Tractive Effort, lb per ton	Train Resistance, lb per ton	Acceleration rates, mphps, = a						
				Per Cent Equivalent Grade Given in First Line						
	v	f	r	+3	+2	+1	0	−1	−2	−3

Retarding, power on	40	18	18	−0.60	−0.40	−0.20	......	......	......	......
	35	27	15	−0.48	−0.28	−0.08	......	......	......	......
	30	45	13	−0.28	−0.08	......	......	......	......	......
Coasting, no power	50	0	34	−0.94	−0.74	−0.54	−0.34	−0.14	+0.06	+0.26
	45	0	31	−0.91	−0.71	−0.51	−0.31	−0.11	+0.09	+0.29
	40	0	28	−0.88	−0.68	−0.48	−0.28	−0.08	+0.12	+0.32
	35	0	25	−0.85	−0.65	−0.45	−0.25	−0.05	+0.15	+0.35
	30	0	23	−0.83	−0.63	−0.43	−0.23	−0.03	+0.17	+0.37
	25	0	21	−0.81	−0.61	−0.41	−0.21	−0.01	+0.19	+0.39
	20	0	19	−0.79	−0.59	−0.39	−0.19	+0.01	+0.21	+0.41

NOTE. The train resistance is assumed to be 6 lb per ton from zero speed to 9.3 mph.

From the motor characteristics determine the tractive effort (f) in pounds per ton and the corresponding speeds (v), corrected for line voltage, up to the maximum permissible speed, and enter these in Table XI. Also enter in this table the train resistance corresponding to the various speeds. In the table given, the train resistance is calculated from Burch's formula for three 44-ton cars, the cross-section of each car being 120 sq ft, and the constant K is taken equal to 0.0050 (subway service). The formula is then

$$r = 4.0 + 0.13\,v + 0.0055\,v^2$$

where v is the speed in miles per hour.

The available tractive effort in pounds per ton for acceleration on any grade is then $f - r - 20\,G'$, and the acceleration rate is (assuming an acceleration constant of 100)

$$a = \frac{f - r - 20\,G'}{100}$$

where G' is the "equivalent" grade (including curvature, see above), in per cent. The value of a is calculated for grades of 0, 1, 2, 3, etc., per cent, both up and down, including the largest up- and down-grade. These values are entered in Table XI. The maximum speeds are the speeds for which the acceleration becomes zero. These can be obtained by plotting the accelerations against speed, and finding the speed at which the curves cross the speed axis.

Similar calculations should also be made for the retardation on up-grades when the train strikes such a grade, with power on, at a higher speed than the free running speed on the grade, and also for the coasting period when no power is on. When power is on, the friction of the gears and motors is allowed for in the motor tractive effort curve, the tractive effort curve being the gross tractive effort less these losses. The friction of the gears and motors may be taken as approximately 5 per cent of the rated tractive effort, which, in the special case under consideration, is $0.05 \times 195 = 10$ lb per ton. The total train resistance in coasting is then the normal train resistance plus the resistance of gears and motors.

In the tables a + acceleration signifies an actual increase in velocity, a − acceleration a retardation, or decrease in velocity.

The braking rate is assumed constant, usually $b = 1.5$ mphps.

Construction of Acceleration and Retardation Time Curves. The next step is to con-

struct a set of acceleration speed-time and distance-time curves, a set of coasting speed-time and distance-time curves, and a braking speed-time and distance-time curve. The construction of these curves is based on the following relations:

Let v_1 = the speed in miles per hour at time t_1.
v_2 = the speed in miles per hour at time t_2.
$v = \dfrac{v_1 + v_2}{2}$ = average speed during the interval $t_2 - t_1$.
a_1 = the acceleration in miles per hour per second at time t_1.
a_2 = the acceleration in miles per hour per second at time t_2.
$a = \dfrac{a_1 + a_2}{2}$ = average acceleration during the interval $t_2 - t_1$ (for the first step take a speed corresponding to half the speed at end of controller period).
x_1 = the distance in feet from the starting point at time t_1.
x_2 = the distance in feet from the starting point at time t_2.

Then, for a small change in speed,

$$t_2 - t_1 = \frac{v_2 - v_1}{a} \quad \text{seconds} \tag{8}$$

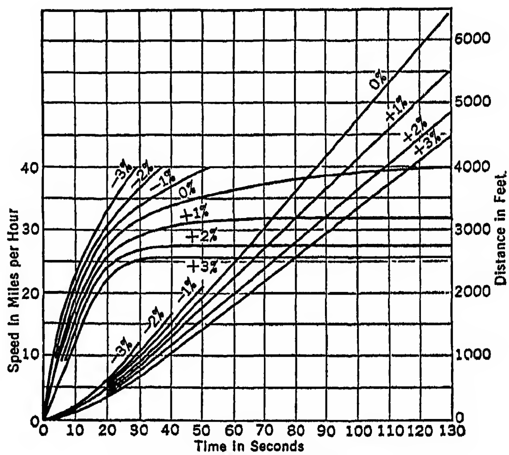

FIG. 3. Accelerating Curves

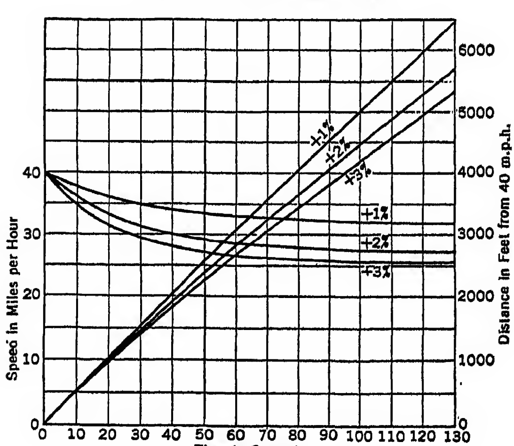

FIG. 4. Retarding. Power On

and the distance covered in this interval is

$$x_2 - x_1 = 1.466\, v(t_2 - t_1) \qquad \text{feet} \tag{9}$$

or, when the speed is plotted against time,

$$x_2 - x_1 = 1.466 \times (\text{Area of speed-time curve between } t_2 \text{ and } t\,) \tag{10}$$

From eq. (8), using the values of a given in Table XI, the time at which any speed is reached may be calculated. The results of such calculations for the special case under consideration are given in Table XII, and are plotted in Figs. 3, 4, and 5. The distance-time curves are found by planimetering the speed-time curves and multiplying by 1.466 (see eq. 9), and are also plotted in Figs. 3, 4, and 5.

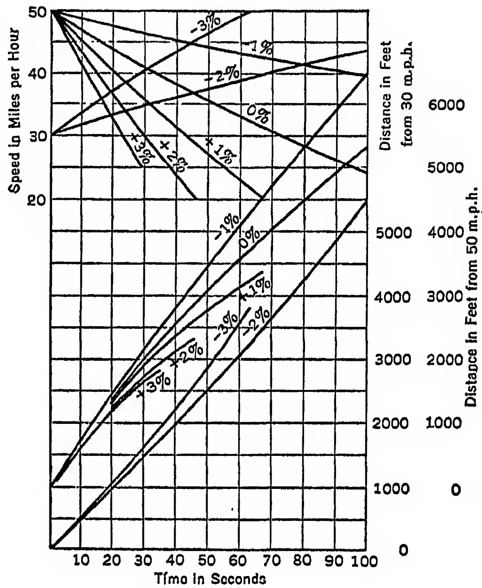

FIG. 5. Retarding, Power Off

The speed during the braking period t seconds *before* the train stops is $v = bt$, and the distance to travel to come to rest is $x = {}^1/_2\, bt^2$.

In the special case of a braking rate of 1.5 mphps,

$$v = 1.5\, t \text{ miles per hour}$$

and the distance to travel to come to rest is

$$x = \frac{1.466 \times 1.5\, t^2}{2}$$

The corresponding curves are given in Fig. 6.

Time Curves for Given Profile and Alignment. With these four sets of curves the speed-time curve for any given run with this particular equipment may be rapidly constructed. For intermediate grades interpolation may be readily made. In Fig. 7 is given a profile and alignment between two stops. The first step is to make up a table like Table XIII, dividing the route into sections such that the " equivalent " grade (= actual grade plus, say, 0.05 per cent for each degree of curvature, assuming a resistance of 1 lb per ton per degree of curvature) is the same throughout each section.

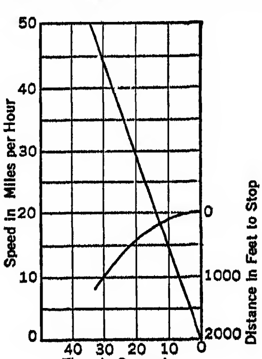

Fig. 6. Braking

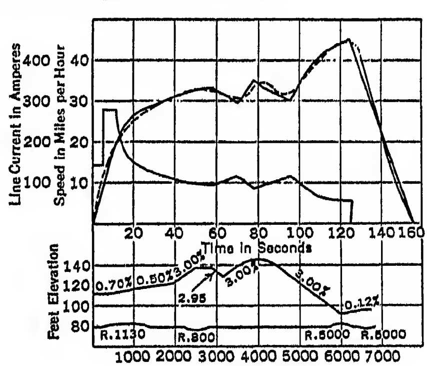

FIG. 7

For a complete round trip over the entire route the time curves must be plotted for the entire route in both directions. The run in one direction between two stations only will be considered in the numerical calculations given below.

Next lay off on a piece of tracing cloth, see upper part of Fig. 7, a distance equal to

Table XII. Data for Accelerating, Coasting, and Retarding Speed-time Curves

the time of run between the two stations (156 sec in the example), to the same scale as Figs. 3 to 6. The braking speed-time curve can be laid off directly at the far end of the run by placing Fig. 6 under the tracing cloth and tracing the curve. Similarly, by placing Figs. 3 and 4 under the tracing cloth and tracing for the proper distance the curve corresponding to the proper grade, an acceleration curve can be built up until this curve intersects the braking curve. If the total distance, as read off from the corresponding distance-time curve, is greater than the actual distance, it will be necessary to introduce a coasting period of proper duration to make the total distance as read off from the distance-time

curves equal to the actual distance. This can be done by placing Fig. 5 under the tracing cloth, and by cut and try finding the proper amount of coasting.

If there are curves or crossovers, requiring a reduction in speed at certain points, these reductions should be allowed for in plotting the speed-time curve. A rough rule for the permissible speeds on properly constructed curves is that

$$\text{Speed on curve} = \sqrt{\text{Radius of curve}},$$

where the radius is in feet and the speed in miles per hour.

The dotted curve in Fig. 7 was obtained from test.

Current-time Curve. The motor current for any speed may be taken directly from the speed-time curve and motor characteristics. From the motor currents the line current is readily found by multiplying by *half* the number of motors during the *series* portion of the controller period and by the total number of motors during the rest of the time power is on. Current-time curves (line current) for the various grades may also be drawn once for all in the same manner as the speed-time curves in Fig. 3. The curve with the square shoulder in Fig. 7 is the current-time curve for the example considered.

Watthours per Ton-mile. During the first half of the controller period the input per motor is equal to the product of the current per motor by approximately one-half the line voltage (series-parallel control assumed); during the rest of the time that power is on, the input per motor is equal to the product of the motor current by the line voltage. Hence, calling A the area of the current-time curve from the start until power is shut off, and I_0 the starting current, E the average line voltage, T_1 the seconds' duration of the controller period, L the length of the run in miles, M the number of motors, and W the weight of the train in tons, then to a fair approximation,

$$\text{Watthours per ton-mile} = \frac{EM(A - 0.25\, I_0\, T_1)}{3600\, WL}$$

A more accurate, but tedious, method is to plot a power-time curve by multiplying the total current per train at successive intervals of time by the average line voltage during this interval, and then integrating this curve to find the total watt-seconds. This area, in watt-seconds, divided by (3600 WL) will give the watthours per ton-mile. In making such a calculation note that during the series part of the controller period the current per train is equal to the current per motor multiplied by *half* the number of motors.

Root-mean-square Current per Motor. This may be found by squaring the ordinates of the current-time curve (current per *motor*), plotted as described above, and dividing by the time of run including stops and taking the square root of the quotient. Or the current-time curve may be plotted in polar coordinates, taking time in seconds as the angle in degrees and current in amperes as the radius vector. See Fig. 8. Calling B the area of this curve, the unit of area being the square whose side has a length corresponding to 1 amp, then the root-mean-square current is

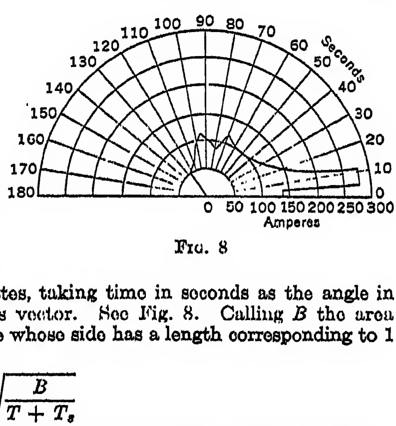

FIG. 8

$$I_e = 10.7\sqrt{\frac{B}{T + T_s}}$$

where T is the time that the train is moving and T_s the standing time, both in seconds.

Average Motor Voltage. For a simple run, such as shown in Fig. 1, average motor voltage during the controller period is equal to approximately 55 per cent of the line voltage, assuming 10 per cent of line voltage across the motors at the instant of starting.

Let E = average line voltage.
T_1 = time of controller period, from speed-time curve.
T_2 = time motor is running on full line voltage.
T = total time that the train is moving.
T_s = total standing time.

Then average motor voltage for the entire run is

$$E_m = \frac{0.55\, ET_1 + ET_2}{T + T_s}$$

For a complex run, where the controller is shut off and put on again during the run, a voltage-time curve may be plotted and the average ordinate obtained by integration.

MOTOR CAPACITY. A railway motor is usually rated in terms of the output in kilowatts or horsepower which it will give when run for 1 hr at rated voltage with a temperature rise above the surrounding air not exceeding 75 deg cent in any part of the motor, other than the commutator. (See Standards of the A.I.E.E.)

The size of motor required for any particular service (i.e., for a given route, schedule, weight of car, line voltage, and per cent coasting) depends upon two factors: (1) the motor must be of such a size that the maximum current required will not produce harmful sparking at the brushes or dangerous mechanical stresses in any part of the motor, and (2) the temperature must not rise to a value which will cause the insulation to deteriorate.

Size of Motor Limited by Commutation and Mechanical Stresses. The maximum current is usually that required at starting, and since the starting current remains practically constant up to the point where full line voltage is impressed across the motor, the corresponding maximum horsepower output of the motor can be calculated directly from eq. (5), when v is taken as the speed at the end of the controller period and W as the weight of the train per motor, i.e., W is taken equal to the total weight of train divided by the number of motors. A safe rule for non-interpole motors in single-car or multiple-unit service is to limit the starting current to a value equal to the rated current. For interpole motors in like service the starting current may safely be 25 to 50 per cent in excess of the rated current.

In locomotive work a heavier starting current is sometimes demanded, and due to the low acceleration rate during the starting period the motor must carry this current for a longer interval than in single-car or multiple-unit service. In selecting a motor for such service, information should be obtained from the manufacturer as to the maximum current which the motor can safely carry during a limited period, say for 5 min. This maximum current may be limited by sparking at the commutator, by mechanical stresses, or by local heating of the windings. See also Size of Motor Limited by Short-time Heating.

Size of Motor Limited by Heating. The heat developed in a railway motor is carried partly by conduction through the several parts and partly by convection through the air to the motor frame, whence it is distributed to the outside air. As the temperature of the several parts is thus dependent not only upon their own internal losses, but also upon the temperature of the neighboring parts, it becomes necessary to determine the actual value and distribution of losses in a railway motor for a given service in order to determine with precision what the temperature rise will be; or, vice versa, to determine what size of motor will be required to avoid too great a temperature rise.

For ordinary electric railway calculations, however, in view of the other uncertain elements which enter, it is usually sufficiently accurate to assume that the *relative* temperatures in the different parts of the motor are independent of the *relative* values of the copper and core losses. The copper loss, i.e., the rate at which heat is developed in the windings, is proportioned to the square of the current, and the core loss, i.e., the rate at which heat is developed in the core, due to hysteresis and eddy currents, may be taken as proportional to the first power of the voltage across the motor terminals (this latter relation being approximate only). When the motor reaches a constant temperature under a constant load, the temperature of any part will then be proportional (approximately) to the total power (kilowatts) lost in the windings and core. Similarly, under a fluctuating load continuing over a long period during which there are no excessively long breaks or excessive overloads, the temperature becomes fairly constant and the rise is proportional to the average power (kilowatts) lost during this period. There will be times at which the temperature rise will exceed this average and times at which it will be less, but on account of the heat-storage capacity (or thermal capacity) of the materials of which the motor is made the fluctuations in temperature will be very much less than the fluctuations in the load.

Size of Motor Limited by Average Temperature Rise. The manufacturers supply information as to the current which any motor will carry continuously (on stand test) without overheating, at various voltages from one-half to full voltage; see Table XIV. From this information, making the assumptions noted in the preceding paragraph, it is possible to determine the approximate temperature of the motor for any given run or series of runs. The process is to calculate the root-mean-square current per motor and the average motor voltage for the particular service contemplated, using the methods given above in the paragraph headed Root-Mean-Square Current per Motor and Average Motor Voltage. Call these values of the rms service current and average motor voltage, I_s and E_m respectively. Let I_c be the continuous-current capacity at a given voltage E_c, as given by the manufacturer (see Table XIV), and let T_c be temperature rise corresponding to this continuous rating. (Motors having ordinary fibrous insulation are rated on the basis of a 75 deg cent temperature rise on stand test, which corresponds to about 65 deg cent rise in actual service, due to better ventilation; see Standards of the A.I.E.E.; hence for

‡ 1500/3000-volt motor—rating at 1500 volts rated amperes and at 750 and 1125 volts continuous.

ordinary motors T_c is 65 deg cent). Let J_c be the corresponding core loss and K_c the corresponding copper loss and $L_c = J_c + K_c$ be the corresponding total electrical losses. Then the total electrical losses corresponding to the average load are

$$L_a = \frac{E_m}{E_c} J_c + \left(\frac{I_c}{I_c}\right)^2 K_c$$

and the average temperature attained by the motor in service will be approximately

$$T_a = \frac{L_a}{L_c} \cdot T_c$$

For safe operation the average temperature rise T_a should never exceed the value T_c, which for motors with ordinary fibrous insulation is 65 deg cent.

Approximate Values of J_c and K_c. When the core loss and copper loss are not given separately, a rough estimate of J_c and K_c may be made by assuming that at rated load (1-hr rating and line voltage) the core loss is, say, one-fourth of the total electrical losses.

The total electrical losses L_r in kilowatts at rated load may be found from the characteristic curves of the motor by using the formula

$$L_r = P\left(\frac{0.97}{\varepsilon} - 1\right)$$

where P is the 1-hr rating in kilowatts, ε the efficiency of the motor with gears, and the 0.97 takes into account the frictional losses in the motor and the gears. Let I_r be the rated current and E_r the rated voltage; then

$$J_c = \frac{L_r}{4}\frac{E_c}{E_r} \qquad \text{and} \qquad K_c = \frac{3\,L_r}{4}\left(\frac{I_c}{I_r}\right)^2$$

Size of Motor Limited by Short-time Temperature Rise. When the service is such that the motor must take a heavy current for a comparatively long interval (e.g., a long starting period or a heavy grade for a considerable distance) followed by a like period of light load or no load, the average temperature for the run, as calculated above, may be within the required limits, but the short-time temperature rise may be excessive. This short-time temperature rise depends upon the heat-storage capacity of the motor, i.e., upon the energy loss (number of kilowatthours of heat developed in it) required to raise its temperature 1 deg, say, assuming no radiation of heat from its surface. The 1-hr rating of a motor is an indirect measure of this heat-storage or thermal capacity.

The temperature-time curve during the first hour's application of a load is practically a straight line whose slope is proportional to the load. The rise in temperature of the motor due to a short-time load may then be assumed to be proportional to the *energy* (kilowatthour) input during this time, and the factor of proportionality may be obtained from the 1-hr rating as follows: Let T_r = the temperature rise at the end of 1 hr due to a load equal to the 1-hr rating of the motor (rated current and rated voltage), L_r = the total electrical losses in kilowatts corresponding to the rated load, L_a = the total electrical losses in kilowatts corresponding to the average load in service (L_r and L_a may be estimated by the method given in the preceding section), L_p = the total electrical losses in kilowatts corresponding to any given short-time or peak load, t_p = the number of minutes' duration of this peak load. Then during this interval t_p the rise of temperature above the average value T_a, is

$$T_p - T_a = \frac{t_p\,T_r}{60\,L_r}\cdot(L_p - L_a)$$

T_p as calculated from this formula gives approximately the maximum temperature rise during the run. For safe operation this maximum temperature rise T_p should not exceed the safe limit stated by the manufacturer. For motors with ordinary fibrous insulation T_p should not exceed 75 deg cent.

Final Choice of Motor. No motor should be employed for a given service which does not meet the above requirements regarding the maximum current and heating limits. A larger motor than that fixed by these requirements may prove the cheaper in the long run, if by using such a motor the energy consumption can be materially reduced by increasing the amount of coasting during the run. In any event the motor should be of sufficient capacity to permit of a reasonable amount of coasting under normal conditions, so that there will be a sufficient margin in which to make up for lost time, due to unexpected slow-downs or extra stops.

ANALYTICAL METHOD OF PREDETERMINING ENERGY AND MOTOR EQUIPMENT. A useful analytical method was developed by Cary T. Hutchinson, in two papers in the *A.I.E.E. Trans.*, Vol. 19, p. 129, 1902, and Vol. 22, p. 657, 1903. In the method a speed-time curve similar in shape to the curve *ABCEF* in Fig. 1 is assumed. That is, the acceleration during the controller period, the train resistance, and the braking retardation are all assumed constant, but a "motor-curve" period (*BC* in Fig. 1) is also taken into account, this last constituting the essential difference between this method and and the "straight-line" speed-time curve method frequently employed for approximate calculations. The introduction of this motor-curve period in the calculations enables one to approximate much more closely actual working conditions, and the results are much more accurate. In addition this method enables one to predetermine, without choosing any particular equipment, the effect of rate of acceleration, rate of braking, per cent of coasting, etc. Where extensive calculations are to be carried out, it would be well worth while to master the above references and apply this method.

Importance of Coasting and Selection of Gear Ratio. A study of Fig. 9 shows that a much less energy consumption would be required for a coasting period of 50 per cent instead of the actual coasting period of 10 per cent, namely 72 watt-hr instead of 88 watt-hr. The starting current required in order to obtain this higher coasting time is 406 instead of 345 amp, or an increase in the starting current of 18 per cent. If no change in the size of

motor were made, this would require approximately the same percentage increase in the gear ratio. The root-mean-square current would increase from 131 to 150, but the average motor voltage would drop from 350 to 170. The motor could therefore probably operate at this higher gear ratio without seriously overheating, but it would be safer to use a larger motor, particularly as the starting current of 406 amperes is also close to the safe commutating limit.

TRAIN AND LOAD DIAGRAMS. The current-time curve for a train making a number of stops may be represented as shown by (*a*) in Fig. 9. On a railway line where there are several trains, the total current may be obtained by placing the current curve for each train at its proper place in the time scale, and adding the ordinates of the curves. Such a process is very tedious and unnecessary where there is a large number of trains. In such cases the high and low parts of the curves become staggered with respect to one another more or less according to the laws of chance, so that each current curve may be replaced by a rectangle of the same area but with a base extending over the entire running

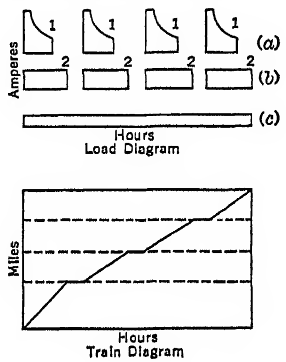

Fig. 9

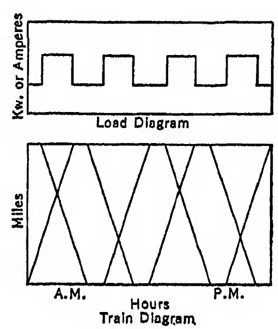

Fig. 10

time as shown by (*b*) in Fig. 9. When this is done the kilowatts and amperes per train are derived from the watthours per ton-mile by the following formulas:

$$\text{Kilowatts} = \frac{WV}{1000} \times \text{(Watthours per ton-mile)}$$

$$\text{Amperes} = \frac{WV}{E} \times \text{(Watthours per ton-mile)}$$

where W = weight of train in tons.
V = average running speed (excluding stops) in miles per hour.
E = line voltage.

The time when the current is cut off is indicated by 1, and that when the train stops, by 2, in Fig. 9.

Another approximation, which is even more often used, is to replace the series of rectangles shown at *b*, by a single rectangle as shown at *c* in Fig. 9. The area of this rectangle will be equal to the sum of the areas of the smaller rectangles or current curves. Using this approximation, kilowatts or amperes may be obtained from the above formulas, taking, however, V to be the schedule speed (i.e., speed including stops). The procedure is to plot a train diagram showing when each train comes on and off the line, neglecting intermediate stops, as shown for a simple case in Fig. 10. Each time a train comes on or off, the corresponding kilowatts or amperes are added to, or subtracted from, the load diagram.

Power Required for Car Heating and Lighting. In addition to the energy required for propelling the

Table XV. Heating and Lighting of Cars

Length of Car, ft	Average* Kilowatts for Lighting	Average† Kilowatts for Heating	
		Average Conditions	Severe Conditions
14–20	0.25	3.5	4
20–28	0.35	4.5	5.5
28–34	0.55	5.5	7.5
34–40	0.70	7.5	10.5

* During the hours lights are on, using tungsten lamps.
† During the time car is in service.

cars, a very appreciable amount is also required in the winter, for heating them, and a small amount at night for lighting. In making up a load diagram this energy should be included.

The average power for car heating varies, of course, with the climate and time of year. The figures in Table XV represent usual requirements in the northern parts of the United States.

Substation and Power-station Loads. The load diagram obtained as described above gives the total load at the trains. To obtain the load at a substation, the kilowatts or amperes must be increased by a suitable amount to allow for the losses in the distribution system. The load diagram of the power station should allow for all transmission and distribution losses between the power house and substation and also for all auxiliary power, such as that required for station lighting, shop machinery, etc.

3. ELECTRIC LOCOMOTIVES

By H. A. Currie and Robt. S. Rhodes

For many years a new type of electric locomotive was designed for nearly every new proposition. This was due in part to the wide diversity in the conditions to be fulfilled. However, with the very numerous applications of electric locomotives of from 30 to 80 tons weight for slow freight and switching service on interurban roads and in terminals, the double-truck bogie type finally demonstrated its superior fitness and came to be adopted almost universally in America for all work involving speeds less than 45 mph. For higher speeds special provision must be made for guiding the locomotive around curves by the addition of guiding trucks or axles, for placing as much of the weight of the motors as possible on springs and for raising the center of gravity to a reasonable height (5 ft or over). With a low center of gravity every sidewise movement of the mass of the locomotive strikes a blow sidewise on the track, but with a high center of gravity a side swaying is transformed into a downward thrust on the track. As the track is not usually designed to withstand great side thrusts it is better to avoid a low center of gravity in high-speed locomotives. For higher capacities, the cab underframe must be relieved of the draft forces by articulating the trucks with a hinge joint, and mounting the draft gear on the truck frame.

The coefficient of adhesion which can be relied upon in electric locomotives at running speeds is from 18 to 22 per cent, tending to decrease at higher speeds. It is higher for electric than for steam locomotives on account of the uniform torque of the electric motor, while the steam locomotive has the advantage of coupled drivers which minimizes the effect of local slippery spots on the rail. The coefficient at starting is usually taken at 25 per cent, and with clean dry rails may at low speeds be as high as from 30 to 40 per cent.

CLASSIFICATION. Locomotives are usually classified by the arrangement of their wheels and the subdivision of the wheels into driving wheels and guiding wheels. The Whyte classification for steam locomotives has been applied to electric locomotives to some extent, but a distinct system, which distinguishes more clearly between driving and idle axles, has come into use both in the United States and abroad. Numerals are used to represent the number of idle axles, either in a guiding truck or simple weight-bearing axles in a driving truck. The number of adjacent drivers in one truck or driving wheel-base is indicated by the letters A, B, C, D, etc., for one, two, three, and four axles respectively. For example, the symbol 2 – D – 2 represents an electric locomotive which, in the Whyte classification, would be designated as 4 – 8 – 4. If two driving wheel-bases are used, two letters are required separated by a minus sign in case of a non-articulated unit (transmitting the tractive force through the truck center pins and the cab underframe) or a plus sign in case of an articulated arrangement. For example, 2 – C + C – 2 would represent two "ten wheeler" or 4 – 6 – 0 wheel arrangements coupled back to back with an articulated joint or hinge.

TYPES OF MOTORS. Locomotives are built with various types of motors and operate from various systems of electrical distribution, e.g.,

(*a*) D-c System. D-c series motors operating from 600,- 750,- 1200,- 1500,- 2400-, or 3000-volt trolleys. In all cases each motor must be insulated for full trolley voltage, but on the higher voltages, two or more motors are operated in series.

(*b*) A-c System.

1. A-c series motors fed from transformer secondaries at approximately 250 volts at 25 cycles. The contact line may be 3300, 6600, 11,000, or 22,000 volts, though 11,000 is by far the most common. Freedom from the restriction of inconvenient high trolley potential on the motor commutator is a strong point in favor of the a-c system.

2. D-c series motors fed from a motor-generator carried in the locomotive cab. This

makes available the advantages of the high-voltage, a-c distribution and the ruggedness of the d-c series motor. Economical use of this type of unit is confined to heavy-drag, slow-speed service.

3. Three-phase induction motors fed from a single-phase trolley through a Scott-connected transformer and phase converter. Acceleration is secured by inserting resistance, usually by means of a liquid rheostat, in the rotor circuits.

4. Three-phase induction motors fed through a transformer, from a three-phase trolley system. This system is widely used in Italy, but the only installation of its sort in the United States has been superseded. The complexity of the three-phase distribution is a great handicap to this system.

CONTROL SYSTEMS. The control of all modern electric locomotives is by some form of remotely operated power control, as the currents required are too large or the voltage too high for a hand-operated control. Many locomotives are equipped with multiple unit control, one engineman operating and controlling two or three locomotive units at the same time.

TYPES OF ELECTRIC LOCOMOTIVES. The simplest form of locomotive is a two-truck car ballasted to provide greater adhesion. Freight and baggage cars are frequently so used on interurban roads. In general, the ordinary car motors are not suited to locomotive service, being wound for too high speed.

The type of locomotive used for light haulage and terminal switching consists of a cab containing the control equipment and supported by two four-wheeled trucks with two axle-hung motors each. The tractive forces are transmitted through the cab underframe. Such units range in weight up to 100 tons and a horsepower of 1850. They are well adapted to switching purposes in terminal freight yards, and in smaller units to hauling freight trains on interurban electric railways.

A further development of this type of unit is exemplified in the Detroit River Tunnel locomotives of the Michigan Central Railroad. The heaviest of these units weigh 126 tons. They are similar to the type described above except that the two trucks are fastened together by an articulated coupling. The draft gear is carried at the ends of the truck frames, thereby relieving the cab underframe of all tractive and buffing forces.

A still further step is illustrated by the West Side freight locomotives of the New York Central Railroad which have two three-axle articulated trucks to obtain greater motor capacity and to subdivide the load sufficiently to keep the axle loading within limits.

The Cleveland Union Terminal passenger locomotives have a two-axle truck for guiding purposes at each end of a wheel-base similar to the New York Central units just described.

While the above types have been evolving by steps from the street-car prototype, another type has been developing, designed especially for high-speed railway service. Several earlier attempts have contributed features. The New York, New Haven and Hartford Railroad, in 1906, purchased 41 passenger locomotives having a number of new features. In addition to being the first a-c installation of considerable size, these locomotives introduced the quill drive. To relieve the dead weight on the axle, attendant upon an axle-hung motor, the motor armature was mounted on a quill which was frame-supported while surrounding the axle and driving through flexible spring elements. In 1912 the New Haven again advanced the art by introducing the twin motor. A gear was mounted on the quill which was supported in bearings below a frame-mounted twin motor, both pinions meshing with the gear.

Meanwhile the Pennsylvania was using locomotives patterned closely after the steam locomotive, driving from one or two large motors by means of side rods. Their most recent development, in connection with the most comprehensive electrification yet attempted, abandons the side rod in favor of the individually powered quill-drive axle mounted in a frame with integral cab similar to a steam locomotive. Their latest passenger unit has a $2 - C + C - 2$ wheel arrangement, each of the six driving axles having a twin motor and quill drive.

Table XVI gives data on a number of electric locomotives.

SPECIFICATION FOR ELECTRIC LOCOMOTIVE. The following memoranda are intended to assist in writing specifications. See also article on Specifications.

On important high-speed systems it is usual for the design of the locomotive to be worked out by the purchaser and manufacturer working in collaboration, and the design is usually specified in detail. In other cases, it is more usual to specify the operating characteristics and leave the design to the manufacturer. The following memoranda are to assist in the preparation of a specification of the latter type.

General Description of Service. Whether for direct or alternating current, single-phase or three-phase, freight or passenger hauling, overhead trolley or third rail. Line voltage, etc.

Specific Details of Work To Be Performed by Locomotive. Weight of cars loaded

4. ELECTRIC CARS AND TROLLEY BUSES

The cars used on electric railways are of both single- and double-truck types, closed bodies with fully enclosed platforms or vestibules being now almost universally used. The cross-bench continuous step open car, and the open platform car, long the standard, have been largely made obsolete in order to eliminate the accident hazard and to permit the same car to be used the year around, relieving railway companies of the burden of maintaining distinct summer and winter equipments.

SINGLE-TRUCK CARS. Single-truck cars were used extensively in the early days of electric railways, but were very generally replaced by the larger-capacity double-truck car; about 1914 the single-truck one-man safety car was developed, and many hundreds were placed in service. The characteristics of a typical single-truck safety car are given in Table XVII.

Table XVII

Item	Dimension
Length overall	27 ft 10 in.
Truck wheel-base	8 ft 0 in.
Seating capacity	32
Maximum capacity	65
Weight complete unloaded	16,000 lb
Weight complete with maximum load	25,100 lb
Maximum speed	25 mph
Schedule speed	10 mph
Number of motors	2
Motor capacity, total	70 hp

These cars are of light weight and economical construction and are equipped with motors, control, and air brake of such characteristics as permit them to meet the growing competition of buses and automobiles. The safety car makes possible faster and more frequent service at lower labor cost than the buses. Safety devices interlocking with the air-operated doors and air brakes are also included in the equipment to permit operation of cars by one man, who combines the duties of motorman and conductor.

TROLLEY BUSES. The trackless trolley or trolley bus has been in limited use for twenty years in many parts of the world. Large installations have been made recently, notably in Chicago. The modern buses have street-car-type bodies mounted on automotive chassis, with conventional bus wheels and tires, steering gears, air and hand brakes and axles, except that the rear axle is adapted for drive by two motors each driving one wheel only, without the usual differential. Electrical equipment comprises two 50-hp motors with automatic acceleration controller carried in a compartment at rear of bus, and a master controller actuated by pedal. A similar pedal mechanism operates the air brake valve thus duplicating driving conditions on gasoline buses including acceleration, steering, and braking. The characteristics of a typical trolley bus are given in Table XVIII.

Table XVIII. Trolley Bus

Item	Dimension
Length overall	32 ft 0 in.
Wheel-base	16 ft 0 in.
Seating capacity	40
Maximum capacity	80
Weight complete (unloaded)	17,500 lb
Weight complete with maximum load	29,500 lb
Maximum speed	35 mph
Schedule speed	12 mph
Number of motors	2
Motor capacity, total	100 hp

DOUBLE-TRUCK CARS. Electric railway cars are now almost entirely of double-truck type and range in size from 42 ft 0 in. overall length, with seating capacity of 42 passengers and maximum speed of 35 mph for city service, to 80 ft 0 in. overall length, seating capacity of 121 passengers, and maximum speed of 75 mph for interurban and electrified steam railroad suburban service.

The body of these cars is supported by two bolsters, each having a lubricated pivot bearing, and two bearing plates located about 2 ft 6 in. each side of longitudinal center line of car. These bearings rest upon similar bearings on the truck, body and trucks being held together by a large king pin. This arrangement permits the truck to swivel through a large angle in running on curves as sharp as 30-ft radius.

Construction of Trucks. The truck consists of a rigid frame of either structural steel, pressed steel, or cast steel, or a combination of all three, having vertical guides at all four corners in which slide journal boxes equipped with either plain babbitt-lined bronze bearings or anti-friction bearings. The journal boxes rest upon journals on the axles, which are of carbon or alloy steel, in some cases heat treated. The wheels and motor gears of wrought steel are pressed on and generally no keys are used, the torque of the motors being transmitted through the press fit. The car body is supported on truck bolsters which are carried on springs, either full elliptic, semi-elliptic, helical, or some combination of these, which rest on seats hung by swing hangers from the main cross-members of truck frame known as transoms, the seats being connected together across the truck, and the swing hangers permitting the bolster, springs, and seats to swing transversely when the car enters a curve. The truck frames are supported on springs resting on the journal boxes, or on equalizer beams spanning both journal boxes. Special wheel and axle arrangements such as radial axles and "maximum traction" trucks (having large wheels on one axle and smaller wheels on the other, and one motor per truck) are now seldom built. Trucks may be of motor or trailer types, arranged for either one or two motors. Wheels are from 22-in. diameter for city service to 42-in. maximum diameter for electrified suburban service, and wheel-bases are from 5 ft 2 in. to 8 ft 4 in. Truck weights for motor trucks range from 13,500 lb per pair to 56,250 lb per pair complete with motors.

Suspension of Motors. Motors, until recently, have been almost universally mounted by the nose suspension method with motors located between truck transoms and axles. Motor frames have two split bronze bushed bearings which bear on the axle, and a nose which bears on the transom, with wear plates and springs between nose and transom. Power is transmitted by single reduction spur gears, sometimes with helical teeth. Some experimental special drives with completely spring-borne high-speed motors have been applied, one embodying an application of automotive type axle and worm drive with armature shafts longitudinal, others using double reduction spur gears.

CAR BODIES. Most cars now have fully enclosed bodies, convertible, semi-convertible, and open bodies being now practically obsolete. The arrangement and dimensions of car bodies have become fairly well standardized according to the service for which they are designed, and of four general types: city, interurban, rapid transit (subway and elevated) and suburban. The following describes typical cars of each type.

City car bodies are of two different sizes, the smaller usually arranged for double-end operation and having exit and entrance doors at both ends, with an average seating capacity of 46, about two-thirds of the seats being of the transverse type. The larger type is arranged for single-end operation, has front entrance and center exit doors, seating capacity about 54, two-thirds of which is also transverse and located in rear of car to provide a large standing space in front portion of car and to facilitate free circulation of passengers entering and leaving. This type is used largely in the larger cities. Both types of city car bodies are equipped with deep spring-cushioned seats upholstered generally in leather.

Interurban car bodies are usually provided with front entrance and rear exit doors on both sides, but some have been built with a single entrance door at front for single-end operation by one man. Seating capacity is from 45 to 50, practically all transverse seats of the reclining type upholstered in various fabrics.

Rapid-transit car bodies are built with two, three, or four doors per side to facilitate loading and unloading from station platforms level with the car floor. Seats are provided for 50 to 65 passengers and are usually all longitudinal and upholstered in rattan.

Suburban car bodies for electrified steam railroad service are generally duplicates of steam road practice, modified by restrictions of weight and clearance. Enclosed vestibules are provided, with covered connecting doorways in some cases, for passing between cars. Seating capacity is from 82 to 120. Nearly all seats are transverse, upholstered in rattan or imitation leather.

Construction of Car Bodies. Car bodies are built entirely of metal except floors of city cars, which are usually of wood, and roofs, which are of wood, covered with canvas. Some of the recent designs of bodies have had very low weight per seated passenger,

achieved in some cases by the use of strong aluminum alloys and in others by careful design and arrangement.

DIMENSIONS AND WEIGHTS OF TYPICAL EQUIPMENTS. Table XIX gives the principal data for electric cars operated in various typical services.

5. CONTROL SYSTEMS FOR RAILWAY MOTORS

The function of the control equipment is to regulate the speed and direction of the motors by certain definite systematic changes in connections. The speed of d-c railway motors is controlled in two ways: (1) by connecting suitable resistances in series with the motors, which will reduce the voltage across the motors and thereby the current which they will take; (2) by changing the connection of the motors so that they will be connected at first in series, thereby applying half of the line voltage to each motor, and then in parallel across full line voltage. In most control equipments a combination of both methods is used. For the speed control of a-c railway motors an auto-transformer, or compensator, is used instead of the resistances.

The direction of rotation of the motors, d-c or a-c, is changed by changing the direction of the current in either the fields or the armatures; it is customary to connect the terminals of each field coil to a reversing switch in order to accomplish this effect.

TERMINOLOGY. The following terms are in general use.

Cylinder or Drum Control or Direct Control are names commonly applied to an equipment in which all the connections are made by contacts on a cylinder or drum which is manually operated by the motorman and located on the platform. This may, therefore, be called direct control.

Multiple-unit, Indirect, Remote Control or Train Control are names applied to an equipment in which the changes in connection of the main power circuit are made by switches called "contactors," usually located underneath the floor of the car, and controlled by electric circuits coming from a small master controller on the platform. Two systems of multiple-unit control are in use in this country, viz.:

Magnetic Contactor System. In this system the contactors are closed by electromagnets which force a plunger against a spring, which normally holds the switch open.

Pneumatic Contactor System. In this system the contactors are closed by compressed air, from the air-brake system, the air valves at the switches being controlled electrically from the master controller.

Non-Automatic Control is a term applied to that method of control in which the motorman has it in his power to regulate the current to any value he pleases by moving the controller handle, the change in connections depending only upon the motion of the handle.

Automatic Control, as distinguished from non-automatic, is a type of control in which certain automatic devices prevent the motorman from causing the motors to take a cur-

rent greater than a predetermined value. With this method the motors start with a definite current and as soon as the current has decreased to a specified value a change in the connections is automatically made. Thus the rate of acceleration and the current are kept practically uniform throughout the period of control. It is nearly always used in connection with multiple-unit control.

Rheostatic Control consists in connecting a resistance in series with the motor and short-circuiting consecutively parts of this resistance. It is seldom used at present, except on mining locomotives and for single-motor operation.

Series-parallel Control, which is used on practically all railway equipments, includes the feature of connecting two motors and their resistances in series on the first step, then short-circuiting portions of the resistance consecutively until all resistance is cut out, under which condition the motors will operate efficiently at approximately half speed. On the next step of the controller the two motors with resistance in series are connected in parallel and subjected to full line voltage. There are three methods of accomplishing the change from series to parallel.

Transition with Power Off. In the so-called type L controller power is entirely cut off from both motors while the change in connection is being made. This was formerly used for large motors and locomotives but is not at present much used.

Transition with Series Resistance. During the transition from series to parallel a resistance is placed in series with one motor and the other motor is first short-circuited, then disconnected from the main circuit, and finally, placed in parallel with the other motor. This method is in general use in equipments of small motors with the so-called type K controller.

Bridge Transition. The so-called " bridge " method consists in grouping the motors and their resistances like the arms of a Wheatstone bridge, so that after the two motors are in full-series position the resistances may be placed in circuit again in parallel with the motors, without opening the circuit; the two motors are then connected in parallel with each other and each in series with its own resistance.

Series-parallel Control with Four-motor Equipment. Whereas the three methods just described apply particularly to two-motor equipments, they are equally applicable to four-motor equipments by connecting two motors permanently in parallel and treating them as a unit.

DRUM CONTROLLERS. The type of control as well as the construction of the controllers for ordinary single-car equipments have been practically standardized in this country, the chief manufacturers supplying control equipments which are practically identical. Railway drum controllers are designated by the type letters K, B, R, and L with appropriate subnumbers and subletters to distinguish smaller variations. The most common form is the K controller. On the first notch this controller connects the motors in series with each other and with the starting resistance. The resistance is then cut out by steps until the motors alone are in series. Transition is then effected from series to parallel connection of motors with resistance in the circuit. The resistance is then again cut out in steps until the motors are connected directly across the line. B controllers in addition to the starting steps include a certain number of braking steps. They find little use in the United States where air brakes are nearly universal. L controllers have connections similar to those of K controllers except that transition from series to parallel is made by completely opening the series circuit and then applying the parallel circuit; they are practically obsolete. R controllers provide resistance steps only, without series-parallel connection of motors. Applications of R controllers are largely confined to single-motor equipments and to very small locomotives where simplicity is desirable.

Railway drum controllers generally include two drums held in a cast frame. A cover of insulating material encloses the front and sides and when removed gives access to all working parts. The main drum, which makes the resistance and transition connections, consists of an insulated shaft carrying a set of contacts. Fingers press on these contacts to make the proper connections. Between fingers are barriers of arc-resisting material. A magnetic blowout operates between these barriers to assist in extinguishing arcs. The second drum is used to reverse the direction of motion of the motors. It consists of a wooden drum with copper contacts with fingers pressing on the contacts. It is mechanically interlocked with the main drum so that it cannot be moved with power applied.

Railway drum controllers find their widest application on cars used on city streets. Except in special cases they are not applied to equipments of an aggregate motor capacity of more than about 260 hp.

Where type K controllers are used for motors aggregating more than about 100 hp, they are sometimes adapted with a modification of the remote control by the addition of an electrically operated line breaker, placed underneath the floor of the car, the function of which is to open the main power circuit every time it is necessary that it should be

opened and thus remove all flashing and arcing from the controller. This expedient makes it possible to use a smaller controller for a given capacity of motors and obviates all danger to the passengers from fire and fright. The scheme is accomplished by substituting for the main power circuit on the controller an auxiliary circuit carrying only a fraction of an ampere, and every time this auxiliary circuit is opened in the main controller the line breaker underneath the car opens the power circuit. When the auxiliary circuit is closed the line breaker closes the main circuit. By means of an overload trip operated by a coil in the main circuit this breaker is also used as a circuit breaker, and if the current taken by the car exceeds a certain value a relay opens the auxiliary circuit which in turn causes the line breaker to open.

Capacity and Weight of Type K Controllers. The more usual forms of type K controllers and the capacity in motors for which they are adapted are as shown in Table XX.

Table XX. Type K Controllers

Type	No. of Motors	Maximum Allowable Capacity, each Motor, Hourly Rating Hp at 600 Volts	Number of Points		Approximate Weight, lb

* For metallic-return circuit. † For tapped-field motors.

Method of Operation of the Type K Control. The principle of the type K control for small and moderate-size motors is shown in Fig. 11. The controller has an operating handle which moves the main cylinder and thereby changes the connections, and also a reversing handle which moves the reversing cylinder. The latter merely changes the direction of the current through the fields of all the motors with respect to the armature. These two handles or cylinders are interlocked so that the reversing handle can be moved only when the operating handle is in the off-position, thus preventing reversal with voltage on the motors.

One terminal of one of the motors is grounded throughout. The first three points are known as accelerating steps. As resistance is in circuit for each of these points the controller should not be left on any of them for a considerable length of time, for there is a considerable power loss in the rheostats and they are not designed for continuous operation. The fourth step, full series, is an efficient "running point," giving about half normal speed. The next two steps are transition steps and are not marked as points on the controller as they must be passed over rapidly. During this period one terminal of the second motor is grounded, thus short-circuiting the motor, which has one terminal grounded initially; the connection between the two motors is then opened; finally the

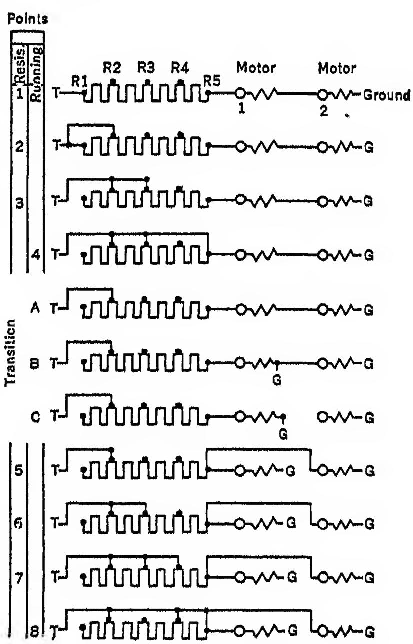

Fig. 11. Type K Control

two motors are connected in parallel but in series with a part of the rheostat. Points 5, 6, and 7 are accelerating steps with motors in parallel and resistance in series and are therefore not to be used continuously. At the last point the motors are in parallel, and all resistance is cut out; it is therefore an efficient high-speed running point. The two terminals of the armatures of each motor are led to fingers on the reversing cylinder as are also one terminal of each field and the two points of the main circuit to which the motors are connected. Thus, in reversing, the current is reversed in the armatures, but not in the fields.

In all controllers a magnetic blowout and an " arc chute " are employed to interrupt the current quickly and direct it away from the contacts, in order to prevent short-circuiting other contacts. In the older types of controllers this was obtained from one large magnet coil and a large iron pole piece covering all the contacts. In the later forms each contact has an independent blowout coil and small pole pieces. This gives a more powerful effect and more accurately directs the arc in the proper direction.

REASONS FOR MULTIPLE-UNIT CONTROL. When the total capacity of the motors on a car or locomotive exceeds 300 hp it is advisable, and when the capacity exceeds about 450 hp it is necessary, to use the indirect or multiple-unit control, for the cylinder type of controllers required to handle the large currents becomes too bulky and dangerous to place on the platforms of passenger cars. The cylinder control is also inadequate when it is desired to control simultaneously the motors on the several cars in a train, which is necessary in order to obtain the high tractive effort necessary in high-speed service on elevated and underground railways.

For these two reasons the system of multiple-unit or train control was developed. As originally proposed by Sprague this consisted of a large cylinder controller on each car and each controller was actuated by a small motor instead of by hand. These small motors were controlled synchronously from a single point by means of auxiliary control circuits. With the growth in the capacity of the motors this system became inadequate and was replaced by the systems now in use.

GENERAL ELECTRIC MULTIPLE UNIT CONTROL. Two types are in use, the type M and the type MA. The chief difference is that the type M is non-automatic

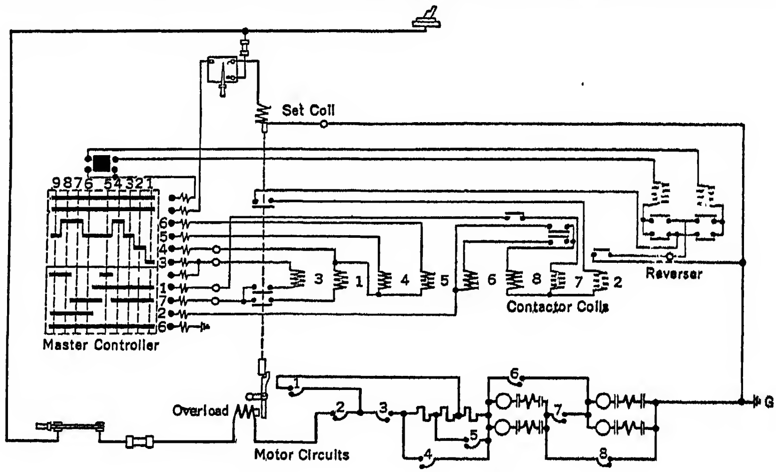

Fig. 12. General Electric Type M Control

whereas the type MA is provided with a current-limiting relay. Fig. 12 is a diagram of the type M, showing the control circuits in light lines and the motor circuits in heavy lines.

The material included in the control equipment of a motor car consists of:

2 master controllers.
1 motor controller containing 8 or 10 contactors and a reverser.
3 master control switches.
1 main switch.
1 main fuse box.
1 set of rheostats.
Cables, train couplers.

Master Controller. This is very similar to an ordinary railway drum-type controller but is much smaller, as the current carried by it is small. Each master controller is equipped with an operating handle, reversing handle, individual magnetic blowouts and (optionally) a "deadman's handle," which automatically interrupts the current and applies the brakes when the motorman's hand is removed from the button located in the top of the handle.

Motor Controller. This consists of an iron box lined with asbestos in which the several contactors and the reverser are placed and is mounted under the car.

Contactors. Each contactor consists of a powerful magnet operating an arm by means of a toggle joint against a spring pressure. This arm closes and opens the circuit in a strong magnetic field which acts as a blowout. As one contactor can carry and break currents of several thousand amperes no extra circuit breakers are required. Each contactor is provided with interlocks in the form of relays so that contactor 2 cannot be operated until after contactor 1 is closed, thus providing the proper sequence of operation under all conditions.

Reverser. This is a switch with several circuits and contacts and is comparable to the reverser cylinder in an ordinary controller. These contacts are mounted on a rocker-arm actuated by two electromagnets, one for moving the switch to the forward and the other to the reverse position. The electromagnets receive their current from the master controller and are interlocked so that only one can be operated at a time.

Switches and Fuses in Control Circuit. Motor cut-out switches are located on the reverser to permit cutting out a disabled motor. In the control circuit there is one main control switch and fuse to protect the control circuits, and near each master controller is located a "control and reset" switch, which in one position closes the circuit to the resetting coil of the overload relay in the main controller and in the other position closes the supply circuit for the master controller.

Main Switch. A knife-blade switch is placed in the power circuit and is intended to disconnect the motor circuits from the trolley when it is desired to test the motor controller.

Train Line Couplers are provided where cars are to be operated in trains. These couplers or jumpers provide a means of connecting together similar control circuits of the different cars. They contain from 8 to 12 wires and are so designed that it is impossible to couple the cars together improperly.

Current-limiting Relay. For automatic control, or acceleration at a predetermined current, a current-limit relay is provided on each car, and this prevents each successive contactor from operating until the current in the motors has decreased to a predetermined value. On roads having a fairly level profile and operating with frequent stops this refinement is desirable, as it makes it possible for the motorman to accelerate the train every time at the maximum allowable rate and yet never exceed that rate except on a down grade. When this relay is provided the control equipment is known commercially as the type MA control.

PC Control. This type was first introduced in 1914 and is a simplification of the older multiple unit systems. It uses air from the air-brake system to operate the switches in groups, thus requiring only two or three air cylinders and valves instead of many, which is the cause of its simplicity and improved reliability. On account of its cheapness, it is quite generally used for single cars as well as trains.

The "PC" control (manufactured by the General Electric Co.) uses a combination of electrically controlled pneumatic cylinders to rotate, notch by notch, a main camshaft, and the cams on this shaft open and close spring actuated switches or "contactors." These cam-operated switches cut out the starting resistance and change the motor connections from series to parallel. A separate air cylinder operates the line breaker, while other cylinders actuate the reversing drum. The line breaker has suitable magnetic blowout coils and serves as a circuit breaker by means of a series trip coil.

The advantages claimed for both forms of this type of control are:

1. All power circuits and the weight of the main control apparatus are removed from the car platform, i.e., the system is operated by remote control.
2. The main line current is always broken by large, suitably designed breakers.
3. Multiple unit operation may be secured with less apparatus and therefore adapted to smaller equipments.
4. The operation of the contactors being mechanical, it is more positive and therefore the time element is definite.
5. Automatic or selective acceleration may be provided with less complexity.
6. A greater number of motor cars may be operated in multiple in one train (16 motor cars in one train is claimed).
7. The current from the control circuits is so small that storage batteries may be used, thus making this control easily adaptable for operation on a-c or high-voltage d-c systems.

WESTINGHOUSE "UNIT SWITCH" SYSTEM. The Westinghouse "unit switch control" is designed for either multiple-unit operation of several motor cars in a train or operation of single cars or locomotives using either large currents or high voltage. Unit switch control equipments are classified according to whether they are arranged for hand or automatic acceleration, whether they employ energy from the line or from a battery, and whether they have certain other features such as field control. The standard designations are as follows: HB, ABF, HL, HLF, AL, VA, etc. Thus it will be noted that "H" signifies hand acceleration, "A" automatic, "B" battery control, "L" line control, "F" field control of motors, "VA" variable automatic, etc.

RAPID TRANSIT CONTROL. ABF control is automatic in its progression, being under control of a limit relay which permits each additional step to be taken when motor current has dropped to a predetermined value. It provides series-parallel operation of motors using bridging transition which insures smooth, uniform acceleration. The distinctive features of ABF control are the three-wire system which makes it necessary to complete three circuits at the controller before power can be applied to the motor, inherent rail gap protection, and the use of low battery voltage.

The apparatus included in ABF control includes a master controller, line switch, a group of unit switches, and the necessary protective and accelerating relays. The unit switches are electropneumatically operated and are used to make the motor and resistance connections.

ABF control is suitable for all classes of rapid transit service, such as subway, elevated, and interurban lines.

Operation. The interlocking shown in Fig. 13 provides a simple and effective means for automatic progression. The unit switches are provided with interlocks which are electrically connected with the valve magnet in such a manner that the closing of one switch energizes the magnet of the next, thus producing automatic progression of the unit switches under the control of a limit relay. This relay controls the rate at which the resistance is cut out of the circuit so as to give uniform accelerating current. The relay is of the solenoid type, being operated by one motor current. When this current exceeds a predetermined value for which the relay is adjusted, the control feed circuit is opened, thus halting the switch progression. When the current falls below the predetermined value, the control feed circuit is closed and allows the unit switches to continue their progression.

The air required for operating the unit switches is taken from the air-brake system through a reducing valve at a constant pressure of 70 lb per sq in.

HL CONTROL. HL control provides series-parallel operation of motors with resistance steps in both series and parallel like the K controller. The changes in motor and resistance connections are made by a number of independent pneumatic switches, each provided with a strong magnetic blowout and held normally open by a powerful spring. The switches are controlled by a magnet valve which admits or exhausts air from the switch cylinder. A pneumatically operated reverser controls the direction of motion of the car. This reverser is operated by two pistons similar to those used in the unit switches.

Energy to operate the magnet valves is taken from the trolley and reduced to a low voltage by taking taps across a resistor which is connected from trolley to ground. This low-voltage energy is distributed by a master controller to the various magnet valves of the unit switches and reverser. These same wires supplying energy to the magnet valves also run to each end of the car from where they may be run to other cars by means of jumpers. In this way multiple operation of a number of cars may be obtained from a single master controller. The number of master controller notches is the same as the number of steps of operation, each step being under direct control of the operator.

HL control is generally used on equipments with aggregate motor capacity of more than 200 or 250 hp where stops are relatively infrequent. It is also used on smaller equipments where train operation is required.

VA CONTROL. VA control provides series-parallel operation of motors but includes a larger number of resistance steps than is found in HL or K control. VA control is automatic in its progression, being under control of a limit relay which permits each additional step to be taken when motor current has dropped to a predetermined value. One of the most distinctive features of VA control is that the limit relay setting may be changed by changing the controller position. This gives the operator direct control of the accelerating rate of the car within certain limits.

The apparatus included in VA control includes a master controller, a group of unit switches either pneumatically or magnetically operated, a sequence switch, and a limit relay. The unit switches make the motor and resistance connections. The sequence switch is a pneumatically operated drum which has as many positions as there are steps

of operation. The drum carries a set of contacts which open and close the unit switches in the proper order. The advance of the sequence switch is controlled by a current limit relay which permits the next step to be taken when the motor current has dropped to a predetermined value. This predetermined value of current may be changed within limits by the master controller.

VA control is applied largely to street cars in city service where stops are frequent and

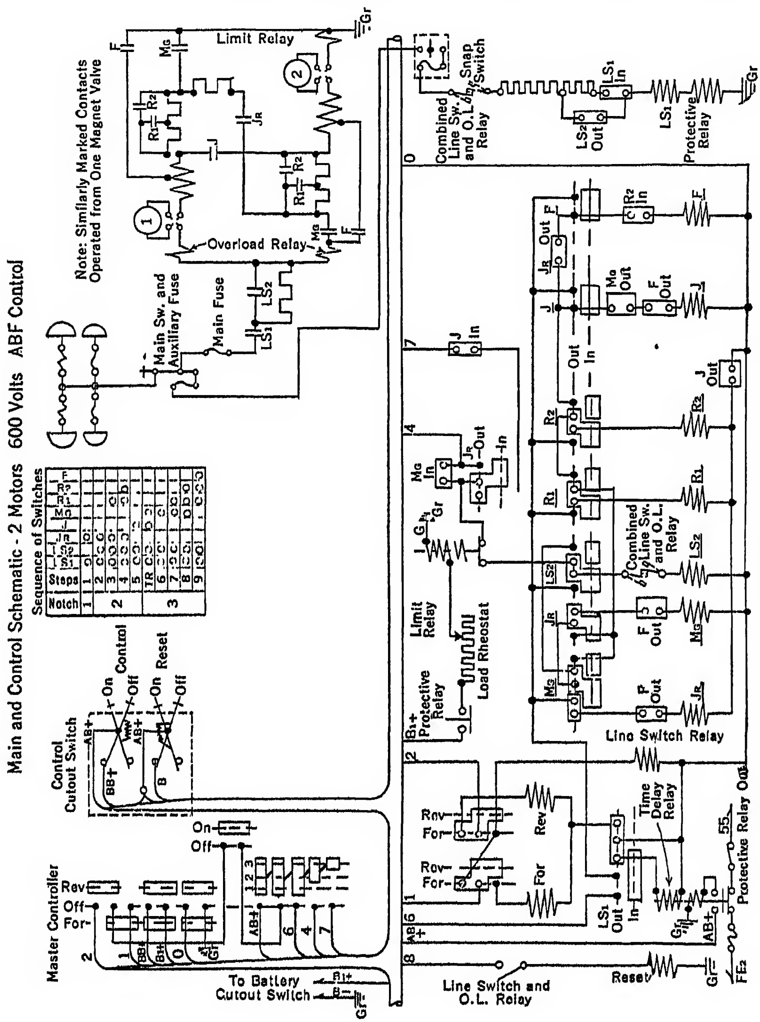

FIG. 13. Westinghouse Unit Switch Control

acceleration rates high. It also finds some use on foot-operated equipments where automatic acceleration is desirable.

CAPACITY AND WEIGHT OF CONTROL EQUIPMENTS. Table XXI gives the capacity and weight of some typical control equipments.

CABLES FOR CAR EQUIPMENT. Typical cables for car equipment have seven tinned copper strands for sizes smaller than No. 1 and nineteen for No. 1 and larger. Cotton or paper, depending upon the size of cable, is used as a separator between the bare cable and rubber compound, the compound conforming to National Electric Code standards. As

Table XXI

Number of Motors	Horsepower of Each Motor	Type of Control	Weight of Control Equipment, lb	Weight of Each Motor, lb	Total Weight of Equipment, lb
4	25	K–75	1,200	1,050	5,400
4	50	K–75	1,400	2,100	9,800
4	60	K–35	1,800	2,550	12,000
4	100	Multi-unit	2,600	2,740	13,560
2	200	Multi-unit	2,750	6,240	15,230

a final protection, the rubber is covered with a single layer of rubber-treated tape and one of cotton braid, and the cable is then subjected to a weather-proofing process.

In the Table XXII, 1-motor, 2-motor, etc., indicate that the cable carries the current

of a single motor in the former and of two motors in the latter case, etc. The numbers are American Wire gage sizes.

CONTROL FOR MINING AND INDUSTRIAL LOCOMOTIVES. On small mining and industrial locomotives where space limitations will not permit of mounting full magnetic or pneumatic control, a semi-magnetic or semi-pneumatic system is often used.

With this type of control all accelerating connections of the motors and main resistors are made with switches, magnetically or electropneumatically operated. The controller consists of a master drum which controls the sequence of operation of the switches, and a reverse drum through which the motor connections are made for the desired direction of operation.

The term " permissible " as applied to control equipment implies that, when this equipment is mounted and wired with the apparatus necessary to the operation of a storage-battery locomotive or other mining machinery, the complete locomotive or machine is approved by the U. S. Bureau of Mines for operation in gaseous mines. This control may be of the drum or semi-magnetic type. All apparatus is enclosed in metal enclosures with metal-to-metal joints between cover and container, the joints being of such a width or construction that no sparks or flame will pass from the interior of the enclosure to the outside in case of an explosion on the inside.

The term " explosion-tested " or " explosion-proof " as applied to control equipment implies that the enclosures for the same have passed the explosion tests prescribed by the U. S. Bureau of Mines for permissible control but, because of some method of operation or condition of installation, the complete locomotive or mining machine does not have the approval of the Bureau of Mines.

CONTROL OF HIGH-VOLTAGE D-C MOTORS. The motors operating on systems of from 1200 to 1500 volts are usually designed to operate two in series, thus each receives normally 600 or 750 volts. However, the insulation of each motor must be designed to withstand the whole line potential, and each motor must be able to withstand momentarily the line voltage across its commutator, for if one motor slips the voltage will be unevenly divided between them. For operation on high voltage two motors in series are normally treated as a unit and the series and parallel connection made with these double units. The multiple-unit control is preferable with these high voltages and contactors or unit switches similar to those for 600 volts are used. To operate the control it is customary to supply either a self-starting dynamotor which provides 600 volts or a motor-generator supplying 32 volts for this purpose as well as for the lights and other auxiliary apparatus.

Provision for 600-volt Operation. Where these equipments operate also over 600-volt sections of road, provision has to be made to change the connection of the dynamotor or motor-generator when the transfer is made. If the cars are to operate at reduced speed on the lower voltages, as is usually the case on entering the city districts, no change need be made in the motor connections. But if the cars must operate at 600 volts at high speed over an interurban section, then provision must be made to separate the pairs of motors so that all motors will be in parallel for full-speed operation on 600 volts. This requires a commutating switch with automatic protection in order to provide that it is always changed when the car passes from one section to another.

3000-volt Systems. For locomotive work 1500-volt motors are constructed to operate two in series on 3000 volts. The control for such a locomotive is similar to the control for a 1500-volt equipment.

CONTROL OF A-C COMMUTATOR MOTORS. To transform the line voltage (3000, 6000, or 11,000 volts) to a voltage suitable for the motors, which is usually from 200 to 300 volts per armature, early equipments used a compensator or auto-transformer. Most of the later equipments use a two-circuit transformer which, though it is slightly heavier for a given capacity, has the advantage of operating with the secondary ungrounded. Taps on the low-voltage side of the compensator or transformer provide the various voltages necessary to start and control the motors, and thus there is no need of series-parallel control or rheostats, and the energy loss in the rheostats is obviated. The transformer is usually suspended from the bottom of the car body. Early transformers for cars were oil-insulated. The modern transformer for both cars and locomotives is the dry type, air blast. The use of oil, especially in passenger service, is objectionable as a fire hazard. Fewer steps (5 to 7 in all) are required for the control of a-c motors on account of the reactance of the circuits. To avoid open-circuiting the connection to the motors in changing from tap to tap or short-circuiting the portion of the transformer between the taps a " preventive " resistance or reactance is connected in the circuit momentarily during the transition. A reverser is provided to reverse the connection of the series fields or exciting windings.

The control may be either of the cylinder or multiple-unit type. In the former type a standard controller may be adapted for the work. In a-c multiple-unit equipments a storage battery is used to supply current for the control circuit.

Provision for D-c Operation. For operation on direct current as well as alternating current provision must be made to perform the following operations: (1) cut the transformer out of circuit, (2) connect the motors for series-parallel control, (3) connect rheostats in circuit, (4) change the field connection of the motors, (5) change the connections of the compressor motors, (6) change the connections of the lighting circuits. All this is done by a " commutating switch " which is thrown over at the instant the change is made. This is so arranged that it can only be moved when the controller is at the off-position. The commutating switch is usually operated by the motorman when the car reaches a dead section of the trolley between the a-c and d-c sections.

CONTROL OF THREE-PHASE INDUCTION MOTORS. Three-phase induction motors for railway work may be controlled by three methods, viz.: (1) changeable pole windings, (2) concatenation of two motors, (3) variable resistance in secondary.

The first two methods were given a considerable trial by German manufacturers some years ago, and have been practically abandoned on account of their complications. In addition to their complications the variable resistance method must also be used with them to provide the smaller gradations of speed.

Variable-resistance Methods. The secondaries of the motors have a definite winding and the terminals are brought to collector rings by means of which a three-phase starting resistance is connected into the circuit. The speed of the motors is controlled by varying this resistance. Under these conditions the operating characteristics of the motors are similar to those of a d-c shunt motor. At all fractional speeds a considerable amount of energy is wasted in the rheostats and there is only one efficient running speed. For prolonged running at fractional speed the rheostats must have considerable heat-dissipating capacity. To reverse the direction of the motors a reverser is employed which reverses the connections of two of the three primary leads on each motor. Either the cylinder or multiple-unit control may be used. With induction motors it is desirable to provide a separate set of resistances for each motor to avoid the tendency of the motors to exchange current and " buck," which would occur if the driving wheels were not of exactly the same diameter and one set of resistances were used for all motors. With several induction motors on one car it is desirable to accurately maintain the same diameter of driving wheels on all axles in order to divide the load equally between the motors.

6. CURRENT COLLECTORS

Current collectors for electric cars or locomotives are divided into three classes in accordance with the form of the working conductor from which they collect current, as follows:

(*a*) Overhead collector, which may be of the pole type with wheel or sliding shoe contact, the pantograph type with sliding or roller contact, or the bow type.

(*b*) Third-rail shoes, which may be of the over-running or under-running type.

(*c*) Underground conduit plow.

WHEEL TROLLEY. The wheel trolley consists of a grooved brass or copper wheel held in bearings in a prong called a " harp " at the end of a steel pole which is pressed upward by a system of springs and levers carried by a spring-equipped base, with provision for vertical movement and horizontal rotation, together with adjustment for pressure against the contact wire.

The contact wire is generally from 17 to 18 ft above rails on urban and interurban roads and 22 ft on electrified steam roads with this type of collector. The pressure between wheel and contact wire varies between 20 lb and 35 lb, depending upon speed and current to be collected. The current-collecting capacity of the wheel collector, though governed by speed and by the condition of the overhead system, is generally given as from 400 to 450 amp for average urban and interurban operating conditions. As much as 1200 amp can be collected during the brief period of acceleration.

The wheel collector is generally used on street railways, and is subject to objections for heavier work on account of limited capacity, wear on rotating parts, liability of dewirements, and necessity for reversal in case of reverse movements, unless they are limited in extent.

Sliding Shoes. The slider shoe is a grooved block of bronze or steel which is used in the " harp " in place of the wheel. It gives sliding contact between the collector and the contact wire. The sliding shoe is being used to replace the wheel on many interurban and some city lines and very generally on trolley buses. With lubricated contact wires, longer shoe and wire life is obtained and radio interference is reduced.

PANTOGRAPH COLLECTOR. The pantograph collector, as generally used, consists of one or two flat sliding shoes, mounted on a collapsible frame of pantograph form. Adjustable pressure is provided by springs, compressed air, or both. A roller has been used to a limited extent instead of the shoe or shoes, but, except in one case, has been replaced by the shoe on account of undesirable weight, limited capacity, and rotating parts.

With relatively small current values, 150 to 200 amp, a plain steel shoe is used, without lubrication. For higher values, steel shoes are fitted with renewable wearing strips of copper, copper and steel, or copper alloy and are lubricated. It is practicable to collect from 1000 to 2000 amp, with one collector, with shoes so fitted and lubricated and with suitable overhead construction. Pantographs have been manufactured with operating ranges as high as 129 in. Pantograph pressures vary from 10 to 20 lb per shoe.

BOW COLLECTOR. The bow collector consists of a contact member of bow shape, generally having a renewable part of aluminum or copper alloy, mounted on one or two flexible poles carried by a spring-equipped base. For high-speed, heavy traction work, the bow is sometimes mounted on a pantograph frame. It is suitable for only small currents. The bow is little used in the United States but is used extensively in Europe.

THIRD-RAIL COLLECTORS. A third-rail collector consists of a shoe or slipper, made of cast iron or steel, which makes contact with the third rail, together with the necessary frame and attachments. The gravity type, for over-running rail, suspended by links, has been replaced largely by a type employing springs or compressed air for pressure. Collectors are of the over-running, under-running, or side contact type, to suit the type of third rail involved.

Third-rail shoes have relatively high current collection capacity—about 2000 amp at speeds of from 30 to 35 mph and from 500 to 600 amp at 60 mph. (See article on Third Rails.) As they are self-adjusting two or three may be placed on a locomotive or car just as well as one, so that there is practically no limit to the current that can be collected in this way. In fact it is customary to put two on each side of each locomotive or car in order to prevent a cessation of current when passing over breaks in the third rail due to switches or crossings.

UNDERGROUND CONDUIT PLOW. The underground plow consists of an insulated steel plate hung from a movable structure on the car. On the two sides of this plate and thoroughly insulated from it are two shoes pressed outward from the plate by springs. These shoes press against the two working conductors which are usually steel tees separated from each other by about 6 in. and supported on some form of ceramic insulator. The current is led from the shoes to the car body by flexible insulated conductors.

7. BRAKES AND BRAKING SYSTEMS

(See also Electric Cars, Art. 4, Energy Requirements, Art. 2.) In order to stop a car or train a torque must be applied to the wheels in a direction opposite to the direction of motion of the car. This may be accomplished by applying a frictional retarding force to the wheel rims, by applying a retarding force to the axle by means of a magnetically operated friction clutch, by applying a reverse torque to the axles by operating the motors as generators, or by applying a frictional force to the rails directly by a "track brake." The method of applying a retarding frictional force to the wheel rims is the most general one and lends itself most readily to the system of manipulating the brakes by compressed air. This system has done much to improve the safety of travel on railroads. The other methods have all been tried and some have been put into practical operation, but only to meet special local conditions.

FRICTIONAL RESISTANCES IN BRAKE-SHOE SYSTEM. The application of the usual brake-shoe system makes use of the frictional adhesion between the wheels and the track and between the brake shoes and the wheels. Both these quantities vary throughout a considerable range and it is therefore necessary to adjust the pressure between the various members so that it is possible to rely on a definite minimum value.

Adhesion between Wheel Rim and Rails. The coefficient of adhesion between the wheel rims and rails varies from less than 15 per cent to over 30 per cent depending upon the condition of the track and the relative motion between the track and wheel rim. (See Energy Requirements, Art. 2.) An adhesion of 15 per cent can usually be depended upon with normal track, and this can be increased to 25 per cent by the use of sand. But these values only obtain while the wheels are rolling on the track. If they begin to slide, the coefficient decreases considerably. For this reason the braking effort must always be controlled so that the wheels do not slip.

Adhesion between Brake Shoe and Wheel Rim. When the brakes are applied, the retarding force is applied below the center of gravity of the car body. The latter is therefore subjected to a couple and tends to press downward at the forward end and upward at the rear end, thus changing the distribution of weight on the axles and decreasing the adhesion on some axles or trucks. It is therefore not possible to figure on using for braking purposes the same weight per axle as exists at standstill. For this reason the brake-shoe adhesion must be less than the track adhesion. The coefficient of adhesion between the customary cast-iron brake shoe and the steel tire of the wheel varies with the speed, and decreases as the time of application increases. As the speed increases the coefficient drops off, being a maximum of from 30 to 25 per cent at speeds from 0 to 5 mph, 20 per cent at 20 mph, 14 per cent at 40 mph, and 7.5 per cent at 60 mph. Thus at high speeds a heavy pressure may be applied without stopping the wheels, while as the speed of the car diminishes the pressure on the brake shoes must be decreased in order to prevent gripping the wheels and causing them to slide on the track.

Effect of Angular Momentum. In addition to overcoming the linear momentum of the cars the brakes must overcome the angular momentum of the gears and motor armatures. The effect of the latter is to introduce a tendency of the whole motor to rotate around the car axle and introduce additional strains on the gears and on the trucks. For this reason brake shoes hung between the wheels of a truck are better than those hung on the outside of the wheels.

HAND BRAKES are always provided on cars and electric locomotives whether power brakes are employed or not, as they are necessary to hold a car left out of service on a grade, because the air brakes will not hold a car standing idle for any length of time. In hand braking equipment the "foundation" brakes (see next paragraph) are actuated through a drum or lever system which is hand operated.

Power Brakes

The "foundation" brakes are that part of the brake equipment usually furnished separately from the power-braking equipment, and consist of the brake shoes, hangers, equalizers, levers, etc., back to the brake cylinder. To this is attached the desired form or make of power brake. Of the various forms of power brakes in use, viz., air, electric, regenerative, and electropneumatic, the air brake is the most generally used.

AIR BRAKES. In electric railway practice three systems of air brakes are in use, each of which is best suited to a definite type of service and has its particular field, as follows: (1) straight air-brake system for cars always operated singly; (2) semi-automatic air-brake system for cars operated in trains of two or three but never more than three cars; (3) automatic air-brake system for cars operated in trains of any number of cars; (4) combined automatic and straight air system for cars operated singly or in trains of any number of cars.

Straight Air-brake System. The equipment for the straight air-brake system consists essentially of a motor-driven compressor, a reservoir, a brake cylinder, a motorman's valve, a train pipe, and the foundation brakes. The brakes are applied by direct pressure, that is, by admitting air from the reservoir directly to the cylinder. The advantages of the system are that it is quick-acting and the braking effort is easily controlled to any value desired. Its disadvantage is that in trains a break in the train pipe renders the brakes ineffective so that there is no means of applying the brakes on the trail-cars if the train should break apart. Sometimes instead of a compressor the motor-car carries a large reservoir which is charged at stations.

Semi-automatic Air-brake System. This system involves the use of anemergency valve and an emergency pipe on each car so arranged that if the air pressure in the emergency pipe drops, due to cars breaking apart, this valve automatically operates to admit pressure into the brake cylinders and apply the brakes. The usual operation in service is like that of the straight air brake.

Automatic Air-brake System. This system involves the use of an auxiliary reservoir and a " triple valve " on each car. Whenever the air pressure in the train pipe is reduced, either intentionally or accidentally, this triple valve admits the air pressure of the auxiliary reservoir on each car into the brake cylinders. The brakes are applied by the motorman by opening the train pipe to the atmosphere by means of the engineer's valve. The engineer's valve has at least four positions; "release," "lap," "service," and "emergency." By turning the handle to the service position the train pipe is opened to the atmosphere and the air continuously escapes. This applies the brakes with a continuously increasing pressure. When the desired pressure has been reached the handle is turned to the lap position, and the pressure of air in the train pipe and the pressure of the brakes on the wheels remain constant. By turning the handle to the emergency position a very rapid escape of air from the train pipe causes a quick, heavy application. By turning the handle to the release position pressure is restored in the train pipe, the brakes are released, and the reservoirs recharged.

Combined Automatic and Straight Air-brake System. This system combines the advantages of the flexibility and promptness of straight air operation on a single car, and the safety features of the automatic air brake.

Electro-pneumatic Brakes. This system is now in extensive use in subway and suburban service. It involves controlling the application and release of the brakes on each car by means of electromagnets receiving current from the locomotive cab. By energizing these circuits the motorman can apply or release the air brakes on all cars practically simultaneously. Each car is equipped with the usual automatic brake mechanism, so that the brakes operate pneumatically in case of failure of the electric circuits.

ELECTRIC BRAKES. Electric brakes in most cases are used to supplement the standard air brake equipment. Three types are in common use: rheostatic brakes, electromagnetic track brakes, and regenerative braking.

Rheostatic Brakes. With this type of equipment the motors are arranged to operate as generators supplying current to rheostats which absorb the energy. This type of braking is effective, of course, only when the car is in motion. It is possible to operate rheostatic brakes without the refinements in control that are required with regenerative braking.

Electromagnetic Track Brakes. For this type of braking equipment electromagnetic brake shoes energized by trolley current are spring-suspended from the car trucks, normally clear of the rails. When a brake application is desired the shoes are moved down to the rails by means of small air cylinders. There is no mechanical connection between the electric brake shoes and the wheel brake, and the air control is also separate. By exciting the magnet coils in the brake shoe the friction between the shoe and the rail acts to retard the motion of the car. When the brake is applied no weight is taken from the car wheels, and full braking is therefore available with the air brakes. Since the excitation current for the shoe is taken from the trolley there is no regenerative load on the motors. Braking is not dependent on the motion of the car. At the end of 1931 there were in operation in the United States 151 cars using this type of braking, distributed among nine operating companies.

As an outgrowth of this type of brake, experiments have been made with similar magnetic shoes, mounted in similar position but kept out of contact with the rail and designed to exert a downward pull, increasing the effective weight on the wheels by as much as 25 to 30 per cent and making possible a corresponding increase in brake-shoe pressure and in rate of retardation.

REGENERATIVE BRAKING. The term "regenerative braking" is normally used to apply to equipments where the motors act as generators and return current to the trolley line, thus effecting a retardation of the locomotive by making use of the stored

energy in the moving vehicle. This system has been most extensively used for heavy locomotive duty. It was first used by the Chicago, Milwaukee, St. Paul and Pacific Railroad on large d-c freight locomotives and subsequently on similar locomotives for various American-equipped foreign d-c electrified roads. The principal feature of these equipments is the provision of an accurately controlled exciter which separately energizes the fields of the motor, thus giving a definite control of the voltage generated. On some locomotives a separate motor-generator set, and on others a mechanically driven exciter mounted on the idle trucks, supplies this current. A further variation is the use of one or more of the motor armatures as the source of excitation for the other motors.

There are three installations in this country using regenerative braking with single-phase a-c supply. On the Norfolk and Western and the Virginian Railway polyphase induction motors are used and three-phase regeneration occurs automatically when the locomotive exceeds synchronous speed. On the Great Northern Railway, with motor-generator type locomotives, converting the single-phase supply to direct current for driving the traction motors, an unusually wide range of regeneration is obtained by controlling the fields of the d-c generators.

A number of installations have been made of light-weight street-car equipment providing regenerative braking by use of field control through an exciter. On most systems, however, it is difficult to justify the additional expense required for this type of braking.

With d-c motors and with single-phase commutator motors it is possible to secure regenerative braking over quite a wide range of speeds. With the three-phase motor regenerative braking is limited to a range fairly close to the synchronous speed of the motor. Half speed on three-phase motor equipments is usually obtained by a change in the number of field poles permitting half speed regeneration as well as motoring.

The use of regenerative braking not only relieves the air-brake equipment but also effects a saving of an appreciable amount of energy and a reduction in wear on the wheel tires, brake shoes, and tracks. Savings in power have been reported for the Chicago, Milwaukee, St. Paul and Pacific as averaging 11 per cent of the power consumed by the motors. On other installations the savings have been even greater.

8. LIGHTING OF TRAINS BY ELECTRICITY

Electricity is now used almost exclusively by the railroads of the United States for the lighting of trains. It is estimated that, at the present time (1936) of the total of about 50,000 passenger cars, including Pullman cars on Class I roads, 40,000 are lighted by electricity. The remainder, lighted by oil or gas, include a considerable number of old or obsolete cars subject to early retirement.

SYSTEMS USED. The following systems are used for the purpose of electric lighting:

a. Axle generator system.
b. Head end system.
c. Straight storage system.

AXLE GENERATOR SYSTEM. This method of lighting is by far the most popular. The recommended practice as to design, application, and methods of rating equipment of this system as formulated jointly by the Mechanical Division of the Association of American Railroads and the Association of Railway Electrical Engineers, and published in their respective Manuals of Recommended Practice, is now followed almost universally by American railroads. The principal parts of the axle generator system are:

(1) *A d-c axle generator* mounted either on the truck or under the car body and in most cases driven by a belt from a pulley on the truck axle.

The generator is usually operated at about 38 volts and delivers current to 16 cells of lead storage battery, or a larger number of cells of nickel-iron storage battery, through suitable regulating devices. The capacity of the generators, when the load is principally lighting, varies usually from 1 kw to 5 kw, depending upon the service requirements. A 1-kw machine is found to be of sufficient capacity for a baggage car. An ordinary coach requires a 2-kw machine, while the additional load on a dining car often requires a generator of 5 kw capacity. When an air-conditioning load is added, the generator capacity is generally 20 kw for motor-driven systems and up to 10 kw for steam-jet and mechanically-driven systems.

(2) *A storage battery*, usually of 16 cells, of from 150 to 1000 amp-hr capacity, with some installations of two or even three sets in parallel for a maximum total of over 2000 amp-hr.

The battery is installed in a suitable ventilated box hung under the car body. The amount of charge is regulated by an automatic device mounted on the regulator panel inside the car. When the car reaches a speed resulting in a predetermined generator voltage, an automatic switch cuts in and connects the generator to the battery. This

switch automatically disconnects the generator from the battery when the generator voltage falls below a predetermined limit.

Until recent years the preferred type of lead battery was the Planté type except where the required capacity made the use of the lighter-weight paste type necessary in order to keep within reasonable weight limits. At the present time the paste type is gaining rapidly in popularity owing to its more advanced development, improvements in the regulating equipment which contribute largely to its more successful performance, and increasing load demands with consequent emphasized advantage of its lower weight and smaller physical size characteristics as compared with the Planté type.

(3) *A regulator panel* on which are mounted a regulator controlling the output of the generator, the automatic switch, and a lamp regulator which holds a constant voltage on the lamps.

(4) *A drive* which, for generators up to 10 kw, consists usually of a belt connecting pulleys on the generator shaft and on the car axle. Rubber or balata belts are most common, with limited use, particularly in winter, of chain drive with sprocket pulleys.

Generators of larger capacity make use of gear and shaft drives, of which several forms have been developed, with or without an intermediate V-belt.

(5) *A suspension.* The former general practice of suspending the axle generator from the truck is being rapidly superseded by the body type of suspension.

By mounting the generator under the car body a much lighter form of suspension can be used. The machine is also better protected from shock due to rough track, crossing switches, etc., than when mounted on the truck, and unbalancing of the truck is avoided.

HEAD END SYSTEMS. In so-called head end systems or locomotive train lighting systems, current is supplied to the cars from a generator on the locomotive or a baggage car. Earlier systems, with the generator in a baggage car, either direct connected to a steam engine receiving steam from the locomotive or driven by a belt through the car floor from a pulley on the axle, have been largely displaced by locomotive train lighting systems, in which a d-c turbo-generator set is mounted on the locomotive or tender.

The generator, generally of 5- to 20-kw capacity, with some 2 $^1/_2$-kw installations, supplies direct current through a train line, using the loop system of wiring to make the lamp voltage uniform throughout the train. Voltages are 32, 64, or 110, the tendency being toward the higher voltages when locomotive lighting is taken care of by a separate 32 volt turbo-generator. Some use is also made of dual-voltage turbo-generators supplying current at 32 volts for the locomotive and at 64 volts for the cars. In some cases a battery is provided on one or more cars to carry the load when the locomotive is not coupled or the set is inoperative. Without batteries, these equipments are suitable only for trains which run solid between terminals, but on account of low initial and maintenance cost are being used to advantage for suburban trains, branch line trains, etc. The principal disadvantages are limited lengths of train possible without excessive voltage drop, and loss of light when the locomotive is uncoupled or the set becomes inoperative.

An a-c system has been introduced, which employs a 25-kw turbo-generator supplying 60-cycle, single-phase, alternating current at 220 volts through a train line. Each car is equipped with a transformer to reduce the voltage to the standard of 32 volts. Considerable flexibility is provided, since batteries may be used on each car and a-c supply from local power lines may be utilized when cars are parked for extended periods or standing in yards.

STRAIGHT STORAGE SYSTEM. This is the simplest method of lighting by electricity but has very largely passed out of use on account of inflexibility and high cost of operation.

Each car is equipped with one or two 16-cell storage batteries suspended under the car body and arranged for convenient charging at terminal yards.

This system requires elaborate charging facilities at terminals where it is necessary to "place" cars and either hold them long enough to give the battery proper time to charge or to have spare batteries fully charged to replace the discharged ones.

At first sight this system appears inexpensive to operate. However, when the maintenance and operation, together with fixed charges of the charging plant are considered, it is perhaps the most expensive method of lighting cars.

ILLUMINATION. Considerable study has been given to car illumination for many years. When cars were first lighted electrically no shades were used to conceal the glare of the lamp filament from the eye. Now great care is taken to protect against objectionable glare, to give as far as possible uniform illumination on the reading plane, and to secure decorative effects from the units.

LAMPS. Depending upon the style of fixtures employed, and their location in the car, lamps range from 15 to 100 watts. The tungsten-filament, gas-filled inside-frosted lamp is used almost exclusively.

The standard voltages in use are:

Straight storage and old style head end systems.......	64 volts
Modern head end (locomotive train lighting) system...	32, 64, and 110 volts
Axle generator system..........................	32 and 64 volts

There have been great improvements in the manufacture of lamps since the introduction of electricity for car lighting. The original type carbon-filament lamps operating at from 3.5 to 4 watts per candlepower have, through progressive development, been replaced by tungsten-filament, gas-filled lamps operating at approximately 1 watt per candlepower or 9 to 16 lumens per watt.

FIXTURES. As in ordinary lighting two standard types of fixtures are used: viz.: direct and semi-indirect. Fixtures are sometimes suspended from the center deck and sometimes side deck mounting is preferred. The modern trend toward pleasing decorative lighting effects has resulted in a number of interesting installations in dining cars, business cars, etc.

The Post Office Department of the U. S. Government after many exhaustive tests issued a rigid specification for the lighting of railway mail cars. This specification covers the location of light units, limits for illuminating values, emergency lighting requirements, etc., and is revised from time to time to keep it fully abreast of latest developments in the art.

GENERAL. From an operating standpoint the axle generator system is more flexible than the others. A car so equipped may be operated on any division independent of charging facilities at the division terminal points or train line connections between cars; it may also be cut out of one train at a junction point for connection to another train without special arrangements being made to supply light from an outside source.

9. THIRD-RAIL OR CONTACT-RAIL SYSTEMS

The contact rail, or third rail, is a conductor supported on insulators near the ground and presenting a continuous contact surface to a collector or shoe attached to the rolling stock. Electrical continuity between adjacent lengths is obtained by copper bonds across the joints.

TERMINOLOGY. The following terms and definitions are used in connection with third-rail systems. See also Standards of the A.I.E.E.

Contact Shoe. A third-rail contact shoe is a conductor, fastened to the rolling stock, which is designed to make electrical contact with the third rail. This is hereinafter referred to as the "shoe."

Contact Surface. The contact surface of a third rail is the surface against which the shoe presses.

Gage of Track. The minimum clearance between the inside surface of the heads of the two track rails; see Fig. 18. The standard track gage in the United States is 4 ft 8 1/2 in.

Third-rail Gage. The distance measured parallel to the plane of the running rails, between the gage line of the nearer track rail and the inside gage line of the contact surface of the third rail; see Fig. 15.

Location. Third rail locations may be described in terms of the third-rail gage and the elevation or vertical distance (see Fig. 14) between the normal contact surface and the normal top of the track rail. See also Table XXIV below.

Top-contact Rail. A top-contact third rail is one on which the contact surface is on the upper side of the rail.

Under-contact Rail. An under-contact third rail is one on which the contact surface is on the under side of the rail.

Third-rail Insulator. A third-rail insulator is that portion of the third-rail support which forms the principal electrical insulation.

Insulator Base or Bracket. A third-rail insulator base or bracket is a device used to support the third-rail insulator.

Incline. An incline is a portion of third rail sloped to gradually bring the shoe from its free position into contact with the normal surface of the third rail.

End Incline. An end incline is an incline at the end of a run of third rail and is made to receive shoes moving in line with the third rail.

Offset-end Incline. An offset-end incline is an incline *at the end* of a run of third rail and is made to receive shoes moving laterally towards the third rail.

Cross Incline. A cross incline is a combination in one piece of two end inclines from adjacent third rails which meet at a turn-out.

Side Incline. A side incline is an incline at *the side of* a third rail and is made to receive shoes moving laterally towards the third rail.

Offset-side Incline. An offset-side incline is an incline offset from the standard third rail in order to gain clearance between the third rail and the maximum equipment line of the rolling stock.

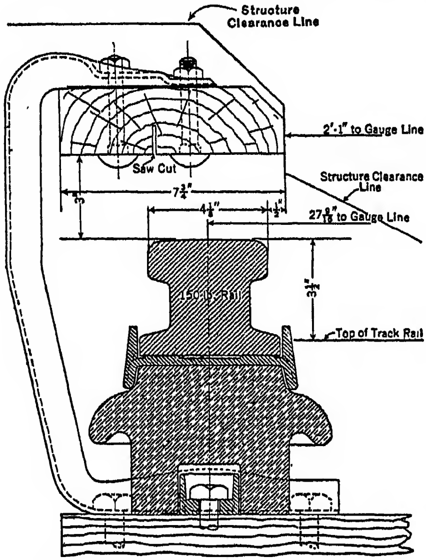

Fig. 14. Interborough Top-contact Type

Third-rail Protection. A third-rail protection is a partial covering of the third rail which affords some degree of protection from the weather or from accidental contact with foreign bodies.

Third-rail Anchorage. A third-rail anchorage is a device to prevent the third-rail creeping longitudinally.

TYPES OF CONSTRUCTION. Third-rail construction may be classified into the top-contact and under-contact types, each of which is susceptible of important variations in design, especially with reference to the type of protection.

Interborough Top-contact Type (Fig. 14). One of the most commonly used types is illustrated in Fig. 14. It is often called the "Interborough Type" on account of its use in the subways of the Interborough Rapid Transit Co., of New York. The rail rests on porcelain insulators. A board protection is attached to the rail itself by means of clamps and uprights and is thereby kept in perfect alignment.

Pennsylvania Top-contact Type (Fig. 15). Another type has the protection supported on separate brackets independent of the third rail itself. It is claimed that this reduces the amount of labor which has to be done on the live rail, when repairs are being made, but it cannot be relied upon as well as the Interborough type to keep the rail and protection in perfect alignment.

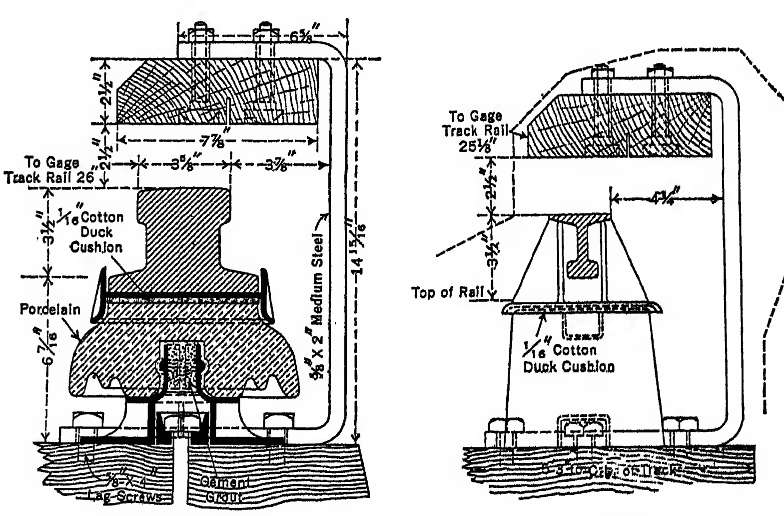

Fig. 15. Pennsylvania Top-contact Type

London Tube Type (Fig. 16). The mounting and location of the third rail and the negative contact rail of the London Tube Railways are illustrated in Fig. 16.

New York Central Under-contact Type (Fig. 17). Although the top-contact types have given first-class service, they are considered to have certain disadvantages for exposed

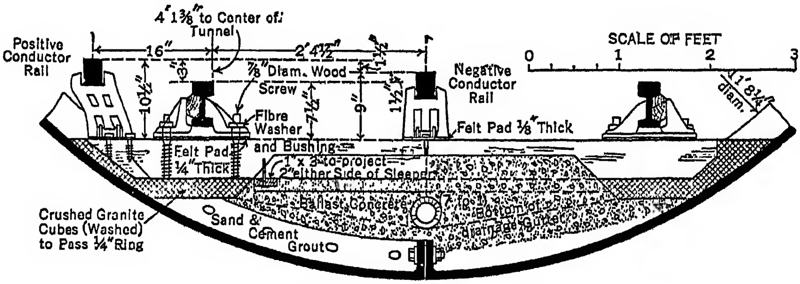

Fig. 16. London Tube Type

locations as they cannot be wholly protected from snow, ice, and sleet. The lower part is only a few inches from the ties, and holding clips generally reduce this clearance, increasing the danger of grounding from accumulation of wet snow and ashes and from flooding. The occasional suspension of traffic during sleet and snowstorms and floods, on railroads using the top-contact type of third rail, led to the idea of an under-contact third rail loosely clasped in insulators by hook bolts hung from brackets, with the top and sides of the rail completely sheathed in an insulating material for protecting the rail from accidental contact with man and beast, and from sleet, snow, and spray. With this type of rail (Fig. 17) the protection is of such character that there is no packing of snow between the protection and the contact rail, as in some other forms, and in sleet storms no ice forms on the contact surface; some icicles may form at the edge of the petticoats, but are easily broken off by the passing shoe.

Where the rail is buried in snow, the passage of the contact shoe breaks the snow away, leaving the rail surface clear, instead of ironing the snow down on the rail, as may happen with the top-contact type.

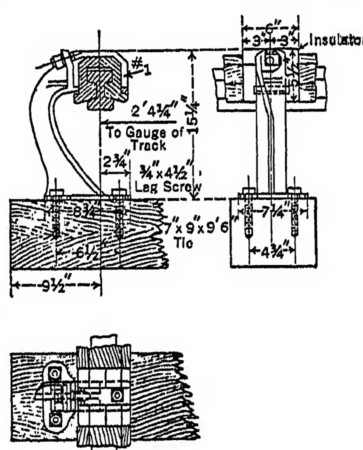

Fig. 17. New York Central Under-contact Type

Protection and Special Work. The protection between the insulator blocks, depending upon local conditions and the price of materials, as well as the potential used, is usually formed of three wooden strips, one grooved on the under side and inclosing the head of the rail, and the other two, attached to and dependent from it, reaching in toward the web of the rail. Soft rubber has sometimes been used in places where brine and manure drippings have tended to reduce the insulation resistance of wood sheathing.

Combined Top- and Under-contact Shoes. The employment of collecting shoes on rolling stock so constructed as to press upwards on the under-contact rail and downwards on the top-contact type solves the question of interchange between railroads not using the same type.

CONTACT RAILS VERSUS OVERHEAD TROLLEY. The contact rail is used as a part of the positive conductor system whenever the current to be collected by each collector exceeds the amount which can be taken safely from a trolley wire, or whenever the total current taken by a train exceeds the amount that can economically be carried by conductors of such expensive metal as copper or bronze.

Positive Contact Rails. Considered as a part of the positive conductor system, the contact rail and overhead trolley possess the relative qualifications given in Table XXIII.

Table XXIII. Relative Qualifications of Third-rail and Overhead Contact Systems
(By C. E. Eveleth)

I Protected Under-running Third Rail	II Overhead High-voltage Catenary Construction
Interference with track maintenance.	Entirely clear of roadbed.
Mechanical details can be maintained by section gangs.	Requires special crews with ladders or work trains.
Generally damaged by train derailments. Does not interfere with wrecking derricks. Quickly replaced by section gangs.	Offers obstruction to wrecking derrick. Partially overcome by insulating boom and help from linemen. Derailment liable to affect all tracks. Delays minimized by use of bridge supports and proper temporary measures.
Obstruction and hazard to brakemen and yardmen, particularly in freight yards.	Overhead bridge warnings confined to signal lights or similar devices.
Interferes with clearing snow between tracks.	No interference.
Use in heavy snow territory questionable.	Not affected.
Provides high current-collection capacity on account of large contact surface obtained with both rail and shoe.	Adequate current collection provided by suitable collectors and overhead construction.
Mechanical details can be inspected by track walker.	Some mechanical details require a lineman.
With proper precautions, may be worked on while alive.	With higher voltages, light repairs made from ladder. Heavy repairs require de-energizing catenary affected.
No interference with visual signals.	Modern light signals and methods of mounting have eliminated objections in this connection.
Absolute freedom from lightning disturbances.	Though more exposed to lightning, shielding by auxiliary circuits and proper insulation offer ample protection.
Freedom from inductive effects on nearby parallel circuits.	Some systems require adoption of measures to correct inductive effects on parallel and nearby communication circuits.
Operating voltage, to date, limited to 1500.	Maximum voltage used to date 22,000.
Contact rail must be interrupted at grade highway crossings.	Not affected.
Increases cost of track maintenance.	No effect.
Use limited by side clearances of permanent structures and equipment.	Use limited by overhead clearances of permanent structures.

ELECTRICAL DESIGN. The calculations of potential drop, network, resistance, etc., are treated in Art. 10. The composition, weight, dimensions, resistance, and reactance of rails will be found in Art. 12.

Selection of Suitable Rail. When the various types of rail are under consideration it is well to arrange a table with the following headings, in order to compare the relative economy of the different types: (1) circular mils of copper equivalent to rail; (2) additional circular mils of copper required to equal the rail of highest conductivity; (3) cost of rail for the entire railroad; (4) cost of additional copper for entire railroad; (5) total cost of rail and additional copper for entire railroad.

MECHANICAL DESIGN. The general design of the rail itself having been settled, the next step is to secure a set of track plans on which to lay out the special work. When an entirely new railway is being projected, the track designer and the third-rail designer can work together; but when an existing line is being converted, the general track plans cannot be used as they are seldom sufficiently accurate for the electrical engineer's purpose. In this case, the contact-rail engineer has to take measurements of the track work in order to make drawings of the cross-overs and other complications.

Location and Weight of Third Rails (Table XXIV). There is no standard gage for contact rails, corresponding to the standard track gage. This unfortunate condition arises from lack of uniformity in the clearance lines of the right-of-way and in the maximum equipment lines of various railroads. The following clearances are the standards of the Association of American Railroads, and the American Transit Association:

The clearance lines for third-rail and permanent-way structures and rolling equipment to be as shown in Fig. 18, thus reserving the space within lines *AT*, *BT*, *CT*, *DT*, *ET*, *FT*

and *AT*, *JT*, *KT*, *LT*, *MT* for third-rail structures; rolling equipment not to encroach upon the third-rail space under conditions of maximum wear and deflection beyond the line *AE*, *BE*, *CE*, *DE*, *EE*, *FE*, *GE*, and permanent-way structures not to encroach upon the third-rail space beyond the line *AS*, *JS*, *KS*, *LS*, *MS*; this leaves a clearance space or neutral zone of 1 in. both horizontally and vertically upon which neither the third-rail structures nor equipment shall encroach. On curves of less radius than 800 ft, the third rail must be moved back and the equipment may be allowed to swing outward as indicated by the lines and notes on the diagram.

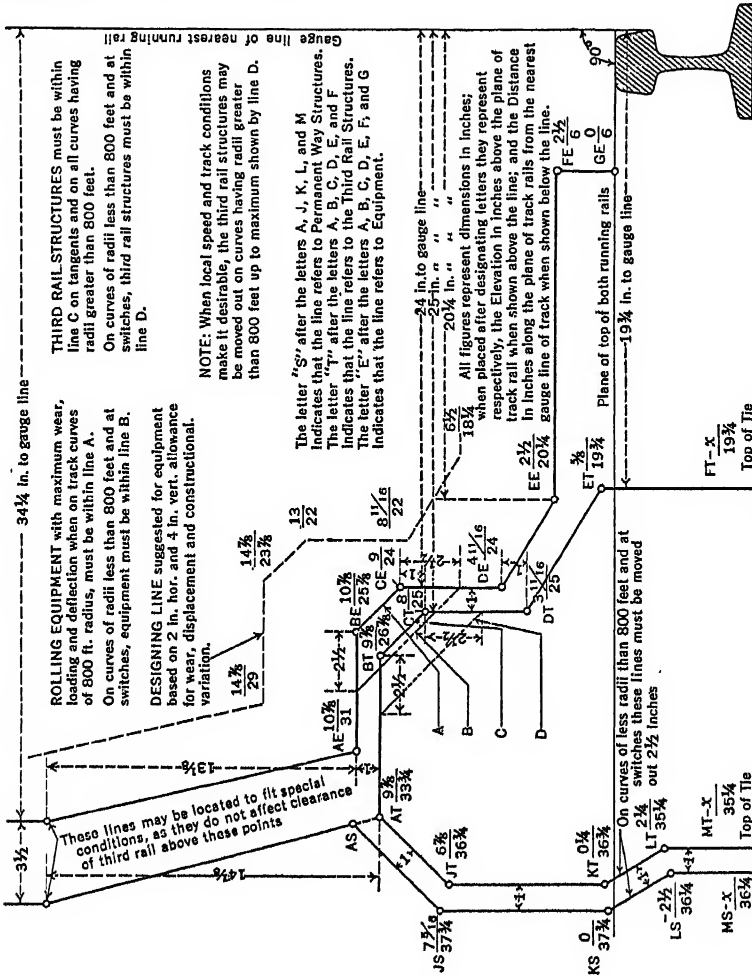

FIG. 18. Clearance Lines for Third Rail, Permanent Structures and Rolling Equipment

In the design and construction of new rolling stock to be used in interchange service allowance must be made for such horizontal and vertical variations as may in any reasonable probability occur in combination at one time as well as allowance for deflections on curves. Encroachments on normal clearance due to deflection of springs and wear vary with the type of construction used, and the practice of the respective roads as regard permissible wear and deflection before repairs and adjustments are made. For the general guidance of the roads, in designing equipment, but not as a standard, therefore, a dotted line is shown on the diagram located 2 in. distant horizontally and 4 in. distant vertically from the limiting clearance line for equipment.

* Bottom contact surface. All others have top-contact surface.

Turnouts. A typical turnout is indicated diagrammatically in Fig. 19, which shows the lengths which should be measured; F is the distance from the point of the switch to the point of the frog, and is called the "frog distance"; D is the length between the adjacent frogs, and Z the distance apart of the track centers. In such a diagrammatic view the lines represent the gage lines of the track rails. When, however, a contact rail is represented by a line, it is the center line that is given. Having measured the four distances specified above, the radius of the turnout curve may be calculated from the following formulas:

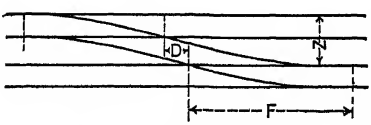

FIG. 19. Typical Turnout

$R = 0.127\ F^2$, when the turnout is from a straight track.

$R = 0.271\ F^2$, when the turnout is from a track of equal radius to the turnout.

Graphical Method of Locating Contact Rail. The track plans having been drawn from the field sketches, to a scale of, say, 1/4 in. to the foot, the contact rail may be drawn in, as outlined below. An aid in this work is a template of the car or locomotive to the same scale as the track drawings, as shown in Fig. 20, in which the points W represent the wheels, S the contact shoes, and K the king-pins. This had better be made of celluloid with a large pinhole at each point S. In order to lay out the contact rail the car template is drawn along the tracks with the points W on the rails and a pencil stuck in one of the pinholes. The line traced by the pencil represents the center line of the shoe path, and therefore that of the contact rail. Such a line should be made on each side of the car. In cases where there are sharp curves, it will not do to run the wheel points W along the tracks, as an error will arise due to the truck rotation not being represented. In such a case the king-pin points must be run along a track center line.

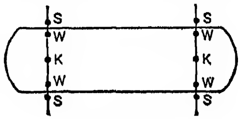

Fig. 20

Fig. 21

Location of Inclines. The exact location of the contact-rail inclines on each side of a track-rail intersection depends upon a number of conditions, an important one of which is the extent to which the equalizer bar and journal box project outward. If there is a train-bus line connecting all the cars, the end inclines may be situated many feet back from the switch point or frog, but if there is no such bus line, the contact rail will probably have to be terminated in a cross incline extending as near as possible to the switch point or frog.

Sectionalizing the Contact Rail. Where a train-bus line is not used, it is customary to break the third rail in front of substations and use an isolated section of third rail between the two main sections, as shown diagrammatically in Fig. 21. The length of this isolated section and of the gaps which bound it should be such that both gaps are never spanned by cars at the same time. If the isolated section is connected to one of the main sections by a switch, the cost of a separate feeder to the isolated section is saved.

Let L = car length, feet.
T = distance between shoe centers (usually the same as distance between truck centers).
S = shoe length.

Then
$$\text{Total space must be} > L + T + S$$
$$\text{Rail section must be} < 2L - T - S$$
$$\text{Length of each gap must be} < T - S$$

Cross and End Inclines. Inclines serve the purpose of assisting the contact shoes to rise (or fall) from their free position to the position of contact with the rail. They should, therefore, have sufficient slope to prevent any undue shock either to the rail or to the shoes. Low-speed lines and sidings may therefore have shorter inclines than high-speed lines. The usual length of straight slope (i.e., without end nose and flat surface at top) is from 60 to 70 in. for high-speed work and 30 or 40 in. for sidings. The slope ranges from 1 in 45 for high-speed work to 1 in 30 for urban railways. Inclines are almost invariably made of cast iron. A typical design is shown in Fig. 22.

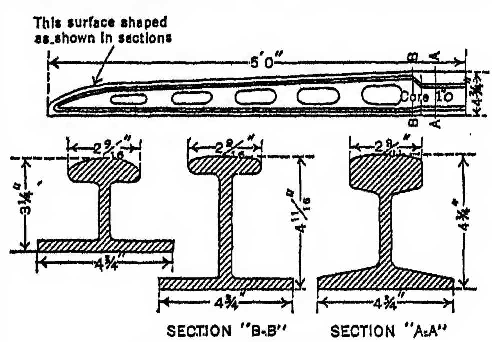

Fig. 22. Typical Inclines

Third-rail Insulators. Third-rail insulators should have the following qualifications. Strength to withstand weight and vibration; surface impervious to moisture; resistance wet shall not be less than 1 megohm; shall have a drip edge; shall allow free motion of rail laterally, longitudinally, and vertically to allow for expansion, contraction, and tie motion; and must be capable of easy and quick removal without disturbing the rail.

Spacing of Insulators. A spacing of 10 ft between insulators is recommended for 30-ft rails, 11 ft for 33-ft rails, and 9.75 ft for 39-ft rails. Location on joint ties should be avoided. Proper and systematic relation of insulators and joints is facilitated by having third rail and track rail of the same length.

INSTALLATION OF CONTACT RAIL. In electrifying an existing railway, the first step is to replace standard ties at proper intervals by long ones. A man then proceeds along the line with a template and marks on them the location of the screw holes of the insulator bracket. He is followed by an auger gang which drills the holes. Meanwhile the brackets (in the case of an under-contact rail) or the stool and insulators (in the case of a top-contact rail) are distributed along the line, and a gang following the auger gang screws the brackets or stools to the ties.

In the case of under-contact rails the brackets must be accurately checked for principal dimensions before being distributed.

The rails and fish-plates, etc., are next distributed along the line on that side of the track where they are to be installed, and a gang follows which installs the rail, and, in the case of an under-contact rail, attaches the insulators and hook bolts; in the case of a top-contact rail, another gang follows, attaching the clips or whatever is used to fasten the rail to the insulators. Another gang follows to install the fish plates, expansion joints, and anchorages, if any. If there are no anchorages or expansion joints, expansion and contraction are provided against by making an allowance at all joints, depending on the temperature at which the rails are installed. This is done by inserting an " expansion shim " while the rails are being bolted together. The thickness of shim for different temperatures on a 30-ft rail is given in Fig. 23.

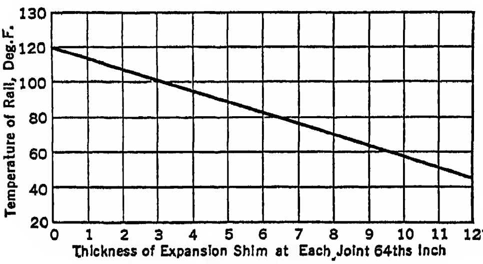

Fig. 23

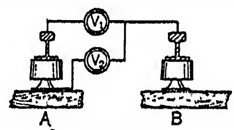

Fig. 24

OPERATION AND MAINTENANCE OF CONTACT RAIL. The wear of the third rails is negligible, and even without painting the deterioration due to rust is very slow. The life of a rail of any of the usual sections should, even under the worst combination of circumstances, seldom be less than 25 years, and present experience seems to indicate a life of upwards of 40 years. The principal items of maintenance are the insulators, protection, and bonds. Unless the supports are carefully designed, insulators are shattered by " tie motion," i.e., by the depression and rebound of the ties as the trains pass over them.

Removal of Sleet. The best protection against sleet is undoubtedly the under-contact third rail, and the next best is a top-contact third rail with a wide protecting board. Where these are impracticable the deposit of ice on the rail cannot be prevented and means for its removal have to be adopted. The two principal means are scrapers and hot water. Electrical heating of the rail has also been suggested but found to require too much energy. When the hot-water method is used, some salt such as calcium chloride, or some other substance, which lowers the freezing point of water, must be added to the water.

TESTING OF CONTACT RAILS. The Conductivity Test is best performed by passing a considerable current through a length, measuring the drop with a millivoltmeter, and calculating the resistance by Ohm's Law.

The Insulation Test is best performed by means of a pair of voltmeters, as shown in Fig. 24. The rail A to be tested is connected to a live rail B through a voltmeter, and the voltage V_1 between the two noted. At the same instant the voltage V_2 between the

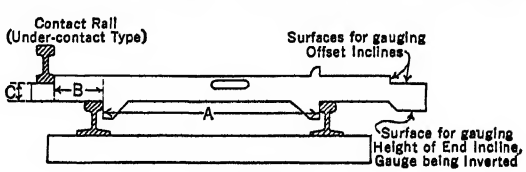

Fig. 25

rail B and ground is also read. Let L be the length in miles of the rail A. Then the insulation resistance of the rail A in megohms per mile is

$$\frac{rL}{10^6}\left(\frac{V_2}{V_1} - 1\right)$$

where r is the resistance in ohms of the voltmeter on which V_1 is read.

Testing of Gage. The gage line of a third rail is measured by means of a template which fits over the track rails as shown in Fig. 25.

10. OVERHEAD CONTACT SYSTEMS

General

CONTACT WIRE. The contact wire is usually made of hard-drawn copper. Where a harder material is required to withstand greater wear and give a larger life, a bronze alloy is used. The conductivity of alloy contact wire is usually between 55 and 80 per cent of that of copper, depending on the particular materials used in the alloy and on the degree of wear resistance desired.

SUSPENSION. The contact wire is usually suspended at heights varying from 15 to 25 ft above the top of the running rails. In any one particular installation, however, it is unusual to find a variation in the height of the contact wire of more than 6 ft. The contact wire presents a continuous contact surface (except for section insulating gaps in some types of construction) to the trolley wheel, bow, or pantograph mounted on the rolling stock.

There are two general classes of contact wire suspensions, direct and catenary.

Direct Suspension. In the simple direct suspension class the contact wire is suspended by insulators from span wires stretched across the tracks between poles or building walls, or from bracket arms attached to the poles. A combination of the two types is sometimes made by using a short-span wire connecting two bracket arms on the same pole. In this single bracket type of construction the poles are usually placed from 90 to 120 ft apart on tangent track, and the contact wire sags considerably between supports, allowing a vertical motion between supports with a very decided "hard spot" at bracket arm supports. This construction is unsuited for high-speed service, owing to the considerable collector motion with resultant arcing and decreased life of the collector and contact wire.

Catenary Suspension. The catenary suspension was designed to overcome the difficulties encountered with the previous type of construction. In general it consists, in its simplest form, of a messenger wire sagging between supporting structures with the contact wire supported from the messenger wire by hangers spaced at equal intervals. The hanger spacing varies from 15 to 30 ft. This method of support results in the contact wire being in a plane approximately parallel to the plane of the running rails by using hangers of varying length at the different points in the span. The bracket arm, span wire, or cross-bridge type of support may be used with the catenary system with supporting structures placed usually 150 to 300 ft apart on tangent track.

Applications of Various Types of Construction

The direct suspension type of contact wire construction is generally used on urban street railways, where it is not objected to on the grounds of unsightliness or danger due to the exposed construction. It is also used on some of the older interurban installations. Center pole construction with bracket arms is usually chosen for street railways for double-track work where it is not objectionable so to locate the poles. The alternate method for street railways is the use of cross-span wires with the poles located near the curb or by attaching the span wires to buildings. This latter method is used quite extensively in Europe.

The catenary-type suspension is generally used for all other overhead contact systems except where the current required by the rolling stock is too great to be economically carried by copper wires or to be satisfactorily collected without undue arcing. This is illustrated by the overhead third-rail construction for special conditions.

Electrical Design of Conductors

In designing the overhead contact system careful attention must be given to both the electrical and the mechanical features. In this division the electrical features will be treated and the mechanical features in a following division.

FEATURES TO BE CONSIDERED. The electrical design of railway distribution systems involves the consideration of potential drop, economy in use of copper, and the heating of the conductors. The heating of conductors is seldom an important feature in

railway distribution system design, as it is generally necessary to use a low current density in order to keep the potential within the limits required. A discussion of the heating of conductors will be found in Section XIV, Art. 51. The feeder system being sufficient to meet the conditions imposed by the allowable potential drop, it will be economical to install more copper, if the saving in the cost of energy which will result is greater than the increase in interest and other charges on the additional investment, plus any additional maintenance charges that may be encountered because of the new facility.

ALLOWABLE POTENTIAL DROP. The maximum allowable potential drop is limited by various features; such as

1. The necessity of running the trains or cars at certain speeds and meeting schedule requirements.
2. The necessity of keeping the illumination in street railway or multiple unit cars at an intensity which varies with the requirements of various localities.
3. The danger of electrolysis in the grounded portion of the return circuit. The maximum drop in grounded circuits, under maximum load conditions, is limited by law in certain localities. In Great Britain the limit is 7 volts drop between any two points in the negative system. In Germany it is generally 1 volt per kilometer (1.61 volts per mile). A usual limit for some cities in the United States is 1 volt per 1000 ft.
4. The necessity of maintaining voltage at the rolling stock to such a value that satisfactory operation of the control circuits will be obtained.

CALCULATION OF POTENTIAL DROP. The method of calculation of potential drop depends upon the following conditions: (1) whether the current is direct or alternating; (2) whether the load is concentrated at one point, sparsely distributed or evenly distributed; (3) the distribution of metal in the feeder circuits, and (4) whether the section is being fed by one or by two or more substations. Calculations for a-c lines differ from those for d-c lines only in taking into account the inductance, as described below. On city railways it is usual to assume the load to be evenly distributed, it being stated as a given number of amperes per foot. (See Art. 2.) If the load is actually concentrated at n equidistant points, the drop will exceed that calculated on the assumption of uniform distribution by about $\frac{100}{n}$ per cent. On interurban and trunk lines, the cars are usually concentrated at one or two points between substations, making the assumption of uniform distribution impracticable. In such cases the loads should be located so as to give the worst conditions, and calculations made as for any network.

Where electrolytic damage is to be guarded against, the drop of potential in the track rails themselves has to be calculated, as well as the total drop in the rails and feeders.

Resistance of Trolley and Track. Values of the resistance of trolley wires to direct current will be found in Section 14, Art 47, and values of the resistance of rails to direct current will be found in Art. 12. It should be noted that the resistances of the trolley and positive feeders are in parallel and that the track rails and negative feeders are in parallel. Also note that in high-voltage systems a considerable portion of the current returns through the earth and not through the rails, and consequently the drop in the rails is due only to that part of the current which returns through them. For preliminary calculations, however, the full current may be assumed as returning through the rails.

FORMULAS FOR D-C TROLLEY CIRCUITS. The following formulas apply to certain typical circuits which frequently occur in practice.

Let I = total current in amperes taken by all cars on section considered.
L = total length of section in 1000 ft.
V_p = total drop in volts, in positive conductors between substation bus and far end of line.
V_n = total drop in volts in negative conductors between substation bus and far end of line.
$V = V_p + V_n$ = total drop in volts in both positive and negative conductors.
r_p = resistance in ohms of all the positive conductors in multiple per 1000 ft of line.
r_n = resistance in ohms of all the negative conductors in multiple per 1000 ft of line.
$r = r_p + r_n$ = total resistance in ohms per 1000 ft of line.
l = distance in 1000 ft, from far end of line to any point P.
v = drop to the point P, subscripts used as for V.

Uniformly Distributed Load, Uniform Conductor, Fed from One Substation. Then

$$v = \frac{rIl^2}{2L}$$

$$V = \frac{rIL}{2}$$

These formulas are applicable to either the positive or negative conductors considered separately or to both in series.

Uniformly Distributed Load, Conductor Tapered to Give Minimum Weight of Metal, Fed from One Substation. For minimum weight the tapering must be such that at any point P

$$r = \frac{3V}{2I\sqrt{L}\sqrt{l}}$$

i.e., the cross-section, if all the conductors are of the same metal, must increase directly as the square root of l. The drop to the point P is

$$v = \frac{V\sqrt{l^3}}{L^3}$$

These formulas also apply to either the positive or negative conductors separately or to both in series.

Uniformly Distributed Load, Conductor Divided into Sections (Fig. 26); Each Section of Constant Resistance, Fed from One Substation. The drop from P_n to the far end of line is

$$\frac{I}{2L}\sum_{n=1}^{n=n} r_n[l^2{}_n - l^2{}_{(n-1)}]$$

This formula is applicable to either the positive or negative conductors. The subscript n is here the general form of the subscript corresponding to each section, represented by 1, 2, 3, and 4 in Fig. 26.

Concentrated Load, Section Fed from One End. Fig. 27 shows a 4-track road with 4 trolley wires and 3 feeders with the tracks cross-bonded at intervals. The solution given below is a general one, and may be applied to any case from 1 track and 1 trolley wire up. Let all distances be expressed in 1000 ft and let

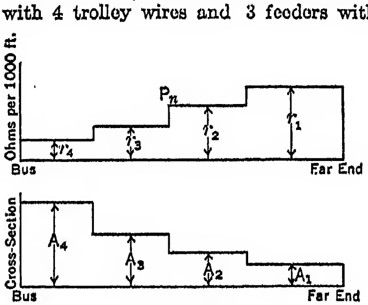

Fig. 26

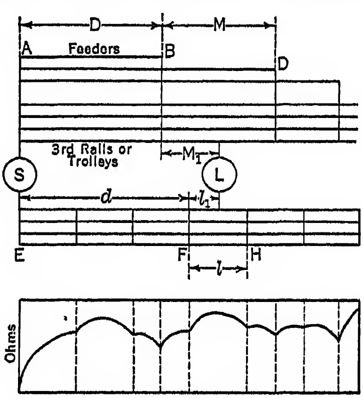

Fig. 27

N_f = number of feeders in section considered, e.g., for the section AB, $N_f = 3$, and for the section BD, $N_f = 2$.

N_c = number of contact conductors, trolley wires or third rails in section considered, e.g., four are shown in Fig. 27.

N_t = number of tracks in section considered.

R_f = resistance of each feeder per 1000 ft.

R_c = resistance of each contact conductor per 1000 ft.

R_t = resistance of each track per 1000 ft (1 rail or 2 rails in multiple depending upon whether 1 or 2 rails are used for return conductor).

$n = N_c + \frac{R_c}{R_f} N_f$ for the section considered.

Then for the section in which the load may be, the resistance of the positive conductors from the load to the end of that section in the direction of the substation, e.g., the resistance from L to B, is

$$R_c M_1\left[1 - \frac{(n-1)M_1}{nM}\right]$$

The resistance of the positive conductors in any section such as BA is

$$\frac{R_c D}{n}$$

(Note that the value of n for this section is not the same as for the section BD.)

The resistance of the negative conductors from the load to the first cross bond in the direction of the substation, e.g., the resistance from L to F, is

$$R_t l_1 \left[1 - \frac{(N_t - 1) l_1}{N_t l} \right]$$

The resistance of the remaining portion of the negative conductors, e.g., from F to E, is

$$\frac{R_t d}{N_t}$$

(Note that if negative feeders are used, each negative feeder having a resistance of $R_f{}'$ per 1000 ft, then for N_t in the last two formulas substitute $n' = N_t + \frac{R_t}{R_f{}'} N_f{}'$, where $N_f{}'$ is the number of negative feeders for that section.)

The total resistance from the load to the substation is the sum of the resistances as above calculated.

Concentrated Load, Section Fed from Both Ends, Substation Voltage at the Two Ends the Same. The most convenient method of treating such problems is to plot an "equivalent-resistance-distance" curve such as shown in Figs. 27 to 30. By "equivalent resistance" is here meant that resistance by which the total current taken by the load must be multiplied to give the total drop in voltage between the load and either substation. For example, if the substation voltage is 600 at each end, the voltage across the load is 550 and the current taken by the load is 200 amp, then the equivalent resistance is $R = \frac{600 - 550}{200} = 0.25$. This method avoids the determination of the distribution of the current in the various parts of the network, and the resistance when once determined can be applied to any load.

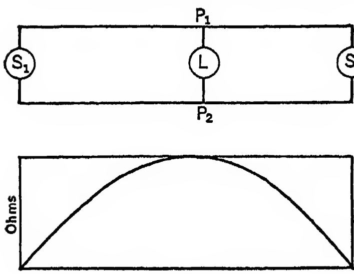

FIG. 28

1. In Fig. 28 is shown a single track and single trolley. S_1 and S_2 are substations; L is a load placed arbitrarily between corresponding points P_1 and P_2 on the positive and negative conductors respectively.

Let a = resistance of the conductors between the points $S_1 P_1 P_2 S_1$;
b = resistance of the conductors between the points $S_2 P_1 P_2 S_2$.

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. Then the equivalent resistance is

$$R = \frac{ab}{a + b}$$

2. In Fig. 29 is shown a 4-track road with 4 trolleys, both track and trolley cross-bonded. Fig. 29a is a simplified diagram of Fig. 29, corresponding points being designated by identical letters.

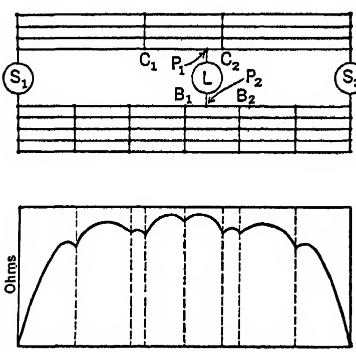

FIG. 29

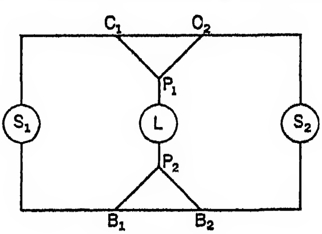

FIG. 29a

S_1 and S_2 are substations; L is a load placed arbitrarily between points P_1, on the positive system and P_2 on the negative system; C_1 and C_2 are ties between positive conductors and B_1 and B_2 ties between negative conductors.

Let

a = resistance of loop $S_1\,C_1\,P_1\,LP_2\,B_1\,S_1$.
b = resistance of loop $C_1\,P_1\,C_2\,C_1$.
c = resistance of contact conductor $C_1\,P_1$.
d = resistance of contact conductor $C_2\,P_1$.
e = resistance of loop $B_1\,P_2\,B_2\,B_1$.
f = resistance of track $B_1\,P_2$.
g = resistance of track $B_2\,P_2$.
h = resistance $\dfrac{d^2}{b} + \dfrac{g^2}{e}$.
i = resistance $\dfrac{c^2}{b} + \dfrac{f^2}{e}$.
j = resistance $S_2\,C_2\,P_1\,LP_2\,B_2\,S_2$.

These resistances are the resistances of the transmitting conductors and do not include the internal resistances of the substations and load. The equivalent resistance is

$$R = \frac{aj - ah - ji - 2\left(\dfrac{fg}{e} \times \dfrac{cd}{b}\right) + \dfrac{f^2\,d^2 + c^2\,g^2}{eb}}{a + j - h - i - 2\left(\dfrac{fg}{e} + \dfrac{cd}{b}\right)}$$

Concentrated Load, Section Fed by Feeders from Both Ends. Fig. 30 shows a simple case with feeders for the positive conductors only. No general formula is available for such a circuit. Any such network can, however, be calculated by Kirchhoff's Laws (q.v.), using the numerical values of the resistances for the various resistances. The equivalent resistance from the substations to the load is then the drop in voltage for a load of one ampere.

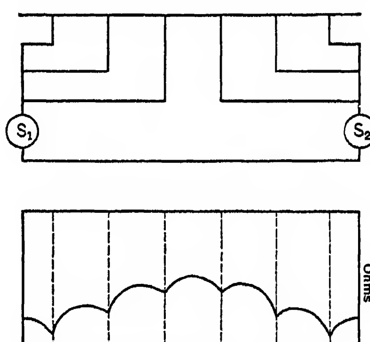

FIG. 30

METHODS OF REDUCING TOTAL DROP. Three methods are employed for reducing the total drop between the substation and the load. The one in most general use is the installation of additional copper as feeders connected to the contact wire, third rail, or track at frequent intervals. These feeders are usually bare and carried on insulators on the pole line. The resistance of the positive or contact wire side of the circuit is usually high compared to the negative or rail side of the circuit, and the feeders are therefore added usually on the positive side of the circuit only. Feeders on the negative side of the circuit are usually installed only as an electrolysis protective measure, but are sometimes required in order to permit track repairs on a single-track line to prevent the danger of a high voltage existing across the gap when track rails are removed at the time that a car or train may be using power. Figs. 27 and 30 indicate two methods of making feeder connections.

The second method, which is not in general use, is to connect a feeder to the contact wire or third rail at one point only, using a booster in the feeder circuit at the substation. The principle of this method is to make the feeder carry more current than it would on the basis of resistance ratios. The first cost and operating costs are usually prohibitive from an economical standpoint, when measured by the improvement obtained. This method is, however, successful and economical on the negative side of the circuit as a means of electrolysis protection, in which case, however, boosters are usually omitted.

The third method consists of the use of an additional substation either fixed or portable at or near the point of low voltage.

A-c Railway Circuits

When alternating current is used the current returning in the rail does not distribute itself uniformly throughout the rail because of the skin effect. On account of the irregu-

larity of the perimeter of a rail a simple mathematical formula cannot be given for the effective resistance or for the internal reactance. At the present time there are two general methods of attack in estimating the constants of an a-c railway system. One method is to use constants which have been measured on a road which has been electrified. This method is most useful when extending a system already in operation or in making calculations on a new system having the same-size rails and same overhead circuits as an electrification already in existence. The other method is to use certain approximations which have been found satisfactory.

In an a-c railway system the return current divides between the rails, the earth, and any other return conductors in parallel with the rails. This division is to a large extent influenced by the mutual effects between the outgoing and returning currents especially when the load and supply points are far apart. The current in the rail is out of phase with the current in the contact wire by a few degrees, but this may be neglected without serious error. For a railroad having the contact wire approximately 20 ft above the rails it may be assumed that the current divides between the rails and ground approximately as follows:

Single track—40 per cent in rails—60 per cent in ground
Double track—60 per cent in rails—40 per cent in ground
Four track—70 per cent in rails—30 per cent in ground

The a-c resistance of a single rail may be calculated by means of the following approximate formula:

$$R_{a-c} = \frac{0.91\sqrt{f}}{P}$$

where f = frequency in cycles per second.
P = perimeter of rail in inches.

The equivalent resistance of earth and rail in parallel may be taken as

$$R_{eq.} = \frac{a}{b} R_{a-c}$$

where a = the percentage of catenary current in the rail.
b = the number of rails in parallel.

The ground current may be assumed to return in the image of the overhead conductors at a depth of from 500 to 3000 ft, depending on the locality and the nature of the strata.

The reactance components are calculated by considering the division that has been assumed and applying the law that the voltage drops in parallel paths are equal. The current in each path sets up a flux which is assumed to extend to a finite distance. When all the linkages have been considered this factor cancels out. The assumed divisions of currents appear as exponents of the different separations.

In calculating the constants of three-wire systems two methods may be followed, depending on whether the equivalent circuit is to be set up with the three circuits intact, or in the calculations to have circuits replaced by single impedances. The fundamentals are the same in both cases. The vector sum of the currents in the feeder, catenary, and track is equal to zero, but the division of currents between the feeder, catenary, and rail depends on the circuit constants.

If an equivalent system is to be set up with the three circuits intact, the current in the catenary is assumed to be I and the current in the rail aI. The equivalent impedance is calculated by determining the voltage drop in each line and dividing by the current in the line. It will be found that the finite distance cancels out and that the assumed division of current appears as an exponent of the separations of catenary, feeder, and rail.

If an equivalent circuit is to be set up in which circuits are replaced by equivalent impedances, the impedance of each circuit and the mutual impedance between circuits are calculated separately. In a three-wire system there are three circuits—the catenary-rail circuit, the feeder-rail circuit, and the feeder-catenary circuit. The *self*-impedance of each of these circuits is calculated as if it existed alone. The *mutual* impedance between the catenary-rail and feeder-rail circuit is calculated by assuming a unit current in one circuit and calculating the voltage in the other when it is open-circuited. In the same way the mutual impedances between the catenary-rail and the feeder-catenary circuits and between the feeder-rail and catenary-rail circuits are calculated. The system may be represented by any two of the three circuits and the mutuals between the circuits selected.

The current division in a two-wire or three-wire system may be calculated most easily by using a calculating board. The a-c board involves the least amount of labor but it is possible to obtain sufficiently accurate results by using a d-c board.

The more laborious method is to work back to the source of supply, by starting from

the point where the load is being considered, and then expand the circuit as the current divisions and voltage drops are determined. In general a separate calculation must be made for each load point and for each source of power. A unit current load at zero angle is assumed at each substation, and the current division throughout the network is determined. The load between substations is assumed to be equivalent to a load at the substation on either side of the load. The equivalent load at a substation is assumed to be inversely proportional to the distance of the substation from the load. The principle of superposition is then applied to determine the current division for the entire system.

High-voltage transmission lines for a-c railway systems are usually single phase. In two-wire systems and in some three-wire systems the transmission line must act as a distribution line in addition to its normal function as a transmission line. The constants of the line may be calculated by the methods used for calculating the constants of three-phase lines. The problems of wave form, relaying, insulation coordination, stability, and other problems of high-voltage engineering require special methods of attack, but the same fundamental principles may be used as in considering three-phase systems.

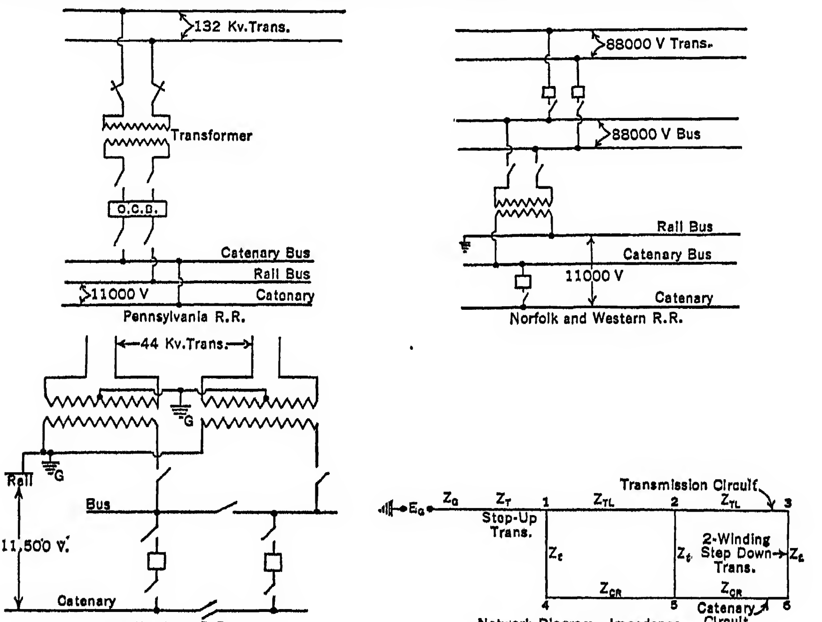

FIG. 31. Two-wire A-c Railway Distribution System

Inductive coordination must be considered in all railway systems whether d-c or a-c. In a-c systems acoustic shock is probably the most serious problem. On the part of the railroads the application of the a-c high-speed breaker has done much to reduce this trouble in addition to protecting overhead lines, current collectors, and apparatus. In laying out a power system for a railroad all interferences are considered and the system is so designed as to reduce such interferences to the minimum consistent with economical design.

The three distinct types of a-c railway distribution systems are illustrated in Figs. 31, 32, and 33.

THE TWO-WIRE SYSTEM (Fig. 31). In this system the power, after being transformed to a suitable transmission voltage, is carried by single-phase lines to step-down transformer stations at suitable locations, stepped down to the catenary voltage, and connected to the catenary and rail. Examples of this type of system are:

Railroad	Transmission Voltage	Catenary Voltage
Pennsylvania R.R.	132 and 44 kv	12 kv
Norfolk and Western R.R.	88 and 44 kv	11 kv
Great Northern R.R.	44 kv	11.5 kv

THE THREE-WIRE SYSTEM (Fig. 32). For systems of limited extent (25 to 30 miles either way from the power supply source), the transmission voltage may be fairly low and the catenary is used as one side of the transmission circuit. The other wire is called the feeder. Three-winding transformers are generally used at the power source. Power is transformed to a suitable transmission voltage, usually 24 or 36 kv, and fed over the transmission circuit consisting of the catenary and feeder to auto-transformer stations where it is transformed to catenary-rail voltage. The three-winding transformer at the power source also supplies power directly to the catenary-rail circuit. By varying

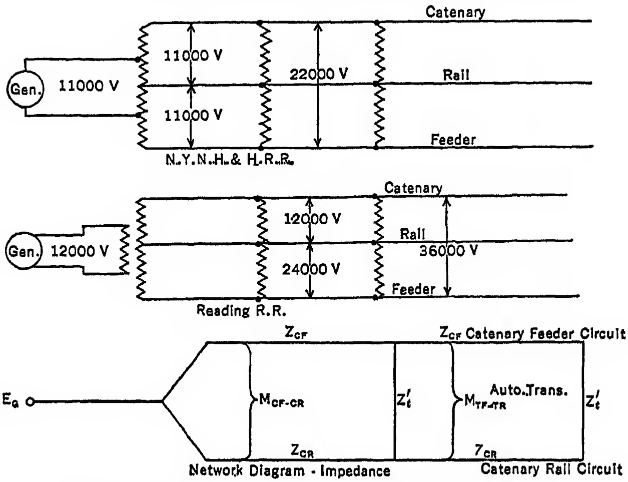

FIG. 32. Three-wire A-c Railway Distribution System

the reactance of the three-winding transformer the power flow may be proportioned between catenary-rail and catenary-feeder circuits to reduce interference in communication circuits. The following are examples of this system:

Railroad	Catenary-feeder Voltage	Catenary-rail Voltage
New York, New Haven & Hartford R.R.	22 kv	11 kv
Reading Railroad (initial installation)	36 kv	12 kv

THE THREE-WIRE SYSTEM WITH TRANSMISSION CIRCUIT (Fig. 33). Economies may sometimes be effected by the use of a combination of the two previously

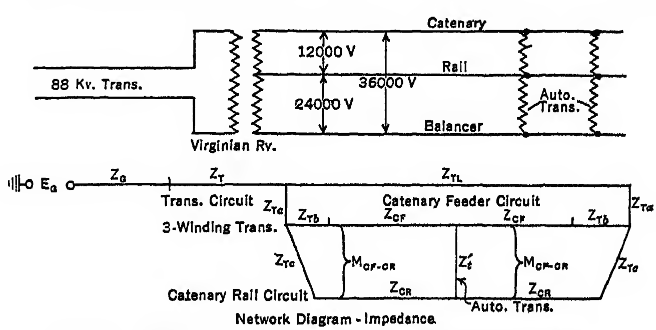

FIG. 33. Three-wire A-c Distribution System with Transmission

described systems. The transmission circuit may be run on a shorter route cross-country meeting the railroad right-of-way only at infrequent intervals with the three-wire system between these points. The three-wire system may be used for the initial electrification and the transmission system added in later years when increased power demand requires it. Examples of this system are:

Railroad	Transmission Voltage	Catenary-feeder Voltage	Catenary-rail Voltage
Virginian Ry.	88 kv	36 kv	12 kv
Reading R.R.	66 kv	36 kv	12 kv

IMPEDANCE DIAGRAMS. In the figure for each system there is shown a single line impedance diagram for use in calculating short-circuit currents, regulation, induction, load division, relaying problems, etc. The constants of the various branches having been determined, these networks can then be solved by the usual "network methods." Impedances for all apparatus and aerial circuits can be calculated the same as for power systems. Impedances of circuits having ground and rail return, such as a catenary-rail circuit, can be calculated the same as for ground return power circuits in which ground wires are accounted for. However, a larger proportion of the current generally returns in the rails than in the ground wires. Average values for 100-lb rails are given in Table XXV. Since a rail is made of steel its internal reactance is high so that a fictitiously low equivalent radius must be used to account for this. The radius for a 100-lb rail has been found experimentally to be 0.35 in. Based on this equivalent radius for 1 rail, geometric mean radii for 1, 2, 3, and 4 tracks are given in Table XXV.

Table XXV

No. of Tracks (Pairs of Rails)	Rail Current in Percentage of Catenary Current	Geometric Mean Radius, ft
1	40	0.37
2	60	2.16
3	65	4.54
4	70	7.17

Owing to the large skin effect the ratio of a-c to d-c resistance of rails is high, the 25-cycle resistance per pair of rails being 0.092 ohm per mile.

On the basis of the proportions of rail current given in Table XXV total impedances of typical catenary circuits are given in Table XXVI. Variations in earth conductivity or catenary height encountered in practice would not ordinarily cause variations of more than 10 per cent in the values given in this table.

Table XXVI *

Catenary-rail Circuit	Catenaries	Tracks	Catenary Circuit	Return Circuit	Total Impedance
3/0 55% 1/0 copper 100-lb rails	1	1	0.316 + j 0.306	0.037 + j 0.084	0.353 + j 0.390 = 0.526

* From Regulation and inductive effects in single phase railway circuits, by A. W. Copley, in *Elec. J.*, August, 1920.

Mechanical Design of Overhead Systems

The American Electric Railway Engineering Association has adopted specifications for overhead line material and construction which cover most of the mechanical details pertaining to ordinary contact wire suspension systems.

DIRECT SUSPENSION CONSTRUCTION. The contact wire is secured to an " ear " by soldering, clamps, or other means; the ear is bolted to a " suspension " which may or may not be provided with an insulating portion. These suspensions may be fastened directly to the bracket arm, or carried by span wires which in turn are fastened to the poles or bracket arms. If the ear is not insulated, strain insulators are inserted in the span wire between the ear and the point of attachment to the poles or bracket arms. A slightly different construction called " pull-off " is used on curves. In a system designed for use with trolley wheels, " trolley-frogs " must be used at turnouts to guide the trolley wheels. Complete information and dimensions of the various parts referred to are contained in the A. E. R. E. A. specifications previously cited. A few of the more important items of construction are covered briefly in the following paragraphs.

LENGTH OF SPAN. In general this type of construction should not be used for spans greater than 150 ft, 90 to 110 ft being most generally used.

HEIGHT OF CONTACT WIRE. The height of contact wire above the top of the rail varies between 15 and 22 ft with a recommended height of 18 ft in streets and general locations, except where special conditions govern; the usual height over steam railroad crossings should be 22 ft. These values are for conditions of maximum sag.

RAKE OF POLES. Wood poles for bracket-arm construction should in general have a backward rake from the track of 6 in. in 24 ft. For cross-span construction wood poles should have a rake of 12 in. in 24 ft. Steel poles should have a rake half that of wood. Center poles (between tracks) should be set without rake.

ANCHORAGE. A permanent anchorage for the contact wire should be provided at intervals of $^1/_4$ to $^3/_4$ mile and at both ends of every grade and curve.

CURVES. On curves of less than 500-ft radius a pole spacing of 50 ft should be used; for 500 to 800-ft radius, 75-ft spacing; and over 800-ft radius the same spacing should be used as for tangent track but not over 100 ft.

At curves the contact wire is made to follow the curvature of the track by pull-offs (wires pulling the contact wire toward the outside of the curve). Pull-offs should be radial to the contact wire where possible and not too expensive.

The number of pull-offs should be such that the contact wire is kept within about 2 $^1/_2$ in. from the theoretical curve and is given by the formula

$$L = \sqrt{\frac{2aR}{3} - \left(\frac{a}{6}\right)^2}$$

where L = distance between pull-offs in feet.
R = radius of curve in feet.
a = offset of contact wire in inches from the theoretical curve, midway between pull-offs, the ears being assumed to be on the theoretical curve.

Or
$$L = 0.815\sqrt{aR}$$

with an error less than $^1/_4$ per cent for all radii greater than 40 ft. If a is to be 2 $^1/_2$ in. then

$$L = 1.29\sqrt{R}, \text{ approximately.}$$

CATENARY SUSPENSION CONSTRUCTION. In general, catenary construction may be divided into simple and compound. In the former the contact wire or wires are supported by hangers directly from the messenger wire. In the latter another wire, called the auxiliary messenger, is used to support the contact wires by clips or very short hangers, being itself supported by hangers from the main or primary messenger wire.

The compound catenary is more flexible than the simple catenary unless some form of flexible or loop hanger is used which might necessitate the use of shunts in each span in order to prevent arcing at the hangers. Flexibility in the overhead construction is very important especially where high-speed operation is encountered, as a " hard spot " in the overhead results in arcing with decreased life of contact wire and collector device. An aid to flexibility is the use of two contact wires in approximately the same horizontal plane, each wire being fastened to alternate hangers or clips. The choice between simple and compound construction also depends on the total conductivity required.

The same general requirements for pull-offs, anchorages, etc., are encountered with catenary construction with the direct suspension type.

At curves the catenary construction may be handled by either the " tangent chord " or the " inclined " construction. This latter type does not require pull-offs but does require more detailed attention to hanger design.

It is almost the universal custom to provide "steadies" in tangent track at each supporting structure to prevent side sway caused by wind or resulting from rolling stock motion. "Steadies" are very similar in construction to pull-offs. See Table XVII.

Cleveland Union Terminal; Compound catenary cross-bridge construction, 56 miles. Two trolleys; on main, side by side; in yards, one above the other.

Ill. Central. Compound catenary cross-bridge and center pole construction, 154.5 miles. Cross-span construction in yards.

D. L. & W. R. R. Compound catenary cross-bridge construction on main line, 160 miles. Simple catenary on side tracks and yards. Bracket construction over single-track branch.

New York, New Haven & Hartford R. R.: 576.8 miles. Three point compound catenary, regular compound catenary, special double compound catenary, and simple catenary in yards. Cross bridge on main line, cross span in yards, and pole and bracket on the Danbury branch.

Norfolk & Western: 208.63 miles of cross-span compound catenary construction. Poles and brackets on single-track sections.

Penna. R. R.: 1400 miles. Cross span compound catenary construction. H poles and tubular poles are used which also carry feeders.

Virginian R. R.: 228.54 miles. Cross span compound catenary construction. Some sections have two auxiliary messengers in vertical plane with contact wire. Single track, pole and bracket construction.

11. UNDERGROUND TROLLEY SYSTEMS

This system is little used on account of its cost, the installations at Budapest, New York, Washington, and London being the only notable ones. The essential feature is the underground conductor which is reached from the car by a "plow" extending through a continuous slot parallel to the tracks.

NEW YORK SYSTEM. The New York type, in successful use for many years, is described briefly below.

General Description. The street is excavated and cleared of obstructions for a width of about 5 ft 6 in. and a depth of about 3 ft and yokes (Fig. 34) set in the excavation about 5 ft apart. The track and slot rails are supported on these yokes and the whole

system made solid with concrete which fills the excavation from the foundation to near the top of the rails leaving only a tunnel under the slot free from masonry. The conductors, of a special rolled-steel flanged tee section, are suspended in this tunnel, by special strain insulators, no part of the electrical system being grounded. The use of two insulated conductors avoids trouble in case of accidental grounding.

Yoke. The yoke shown in Fig. 34 is made in three parts: an I-beam which rests on the floor of the excavation; and two castings riveted to this, each supporting one track rail and one slot rail. The track rail is carried on a timber stringer which extends from yoke to yoke along the whole line. The stringers are held to the yokes by bolts which serve also to fasten the rails to the stringers. The rails are further secured by long bolts running to the center of the yoke. The slot rails are bolted direct to the yoke and are connected to the track rails by long bolts every 30 in.

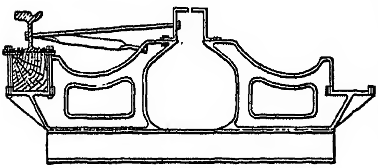

Fig. 34

Insulator Boxes. Cast-iron boxes are laid across from the slot rails to the track rails every 15 ft and bolted to them. These contain the insulators which support the contact conductors. In each box is a pair of shelves; resting on these shelves is a cast-iron bridge which holds the insulator. A cast-iron cover is flush with the street surface.

Concrete Work. The tunnel which is to protect the conductors and do the draining is formed with collapsible forms. Concrete is then poured into the excavation, completely filling every part but the tunnel and its offsets at the insulator boxes to within the height of a paving block of the rail tops. The depth of the completed tunnel is 18 in. from the base of the slot rails.

THE LONDON SYSTEM has alternate long and short yokes, the long ones fulfilling the same function as the New York ones, the short ones serving merely to give additional support to the slot rails. No stringers are used, the rails resting on hardwood blocks at the yokes only.

THE BUDAPEST CONSTRUCTION has the slot in the track rail, thus saving considerable iron, but necessitating an excessively wide slot to accommodate the wheel flanges.

12. TRACK AND THIRD RAILS

(See also Bonds, Railway Track; Traction Systems for Electric Railways; Third-rail Systems; Trolley Systems.)

The American Electric Railway Engineering Association has standardized the rail sections summarized in Table XXVIII, which are described fully in its Engineering Manual.

Table XXVIII. Rail Sections

Designation of Rail	Height, in.	Weight, lb per yd	Designation of Rail	Height, in.	Weight, lb per yd
Standard section.....	5	80	Girder grooved......	7	103, 122
" "	5 5/8	90	" "	9	134
" "	6	100	" guard........	7	140
Plain girder..........	7	82, 92, 102	" "	9	152

The standard (" tee ") and plain girder sections are listed for use on private right-of-way and in macadam or other shallow paving, and the girder grooved and guard sections for paved streets.

Standard lengths are as follows: plain girder and girder grooved rail, 60 and 62 ft; girder guard rail, 30 and 32 ft; standard section (" tee ") rail, 33 or 39 ft as ordered, 62 ft when so specified.

RESISTANCE AND CHEMICAL COMPOSITION. The chemical composition of steel rails with respect to the impurities or elements other than iron (chiefly carbon, manganese, phosphorus, sulfur, and silicon) varies over a considerable range, depending upon the process of manufacture. According to J. A. Capp, the specific resistance of an ordinary* steel rail may be taken as a rough indication of the total impurities present. Fig. 35 shows the results of tests on a number of samples of different makes, ranging in total impurities from 0.1 per cent to 1.9 per cent, the specific resistance referred to copper

* This does not apply to special forms of rails submitted in the process of rolling to extra heavy pressures.

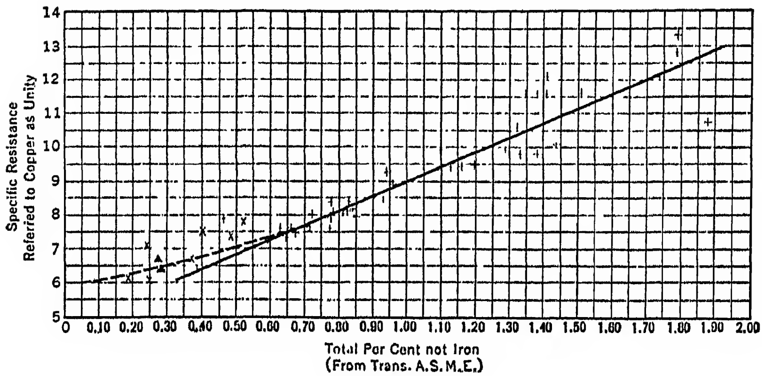

FIG. 35

Table XXIX. Chemical Composition, Track Rails

A "May be low carbon, but should have sufficient stiffness to retain shape during shipment and installation."
B Desired not less than 0.15; must not be less than 0.12.

as unity ranging from 6.1 to 13.3. The greater hardness caused by the presence of impurities is an advantage in the case of track rails which offsets the disadvantage of low conductivity, but it is usually economical to employ for the third or contact rail a rail of fairly high conductivity.

The compositions given in Table XXIX are recommended by the American Electric Railway Engineering Association. The specific resistance of track rails, referred to copper as unity, ranges between 10 and 12.5.

As shown, by specification requirements, in Table XXX, current practice favors the use of copper in third rails and low content of carbon and sulfur, to reduce both corrosion and electrical losses.

ALLOWANCE FOR WEAR IN RESISTANCE CALCULATIONS. Resistance calculations should be made for rails worn down to the weight at which they will be scrapped. It is usual to scrap rails when they have lost from 10 to 20 per cent of the original weight, depending upon the importance of the line. The resistances in Table XXXI should therefore be increased from 10 to 20 per cent.

* To find the resistance of rails of any specific resistance x referred to copper as unity multiply these resistances by x and divide by 8.

A-c Resistance and Reactance. See articles on Overhead Trolley Systems; Railway Signaling.

13. RAILWAY TRACK BONDS

(See also Third Rail Systems; Track and Third Rails; Wires and Cables.) Rail bonds are electrical conductors for bridging the joints of rails. They consist of stranded or laminated copper conductors welded or pressed into copper or steel terminals. Sometimes the conductors are made up of copper and steel wires stranded together.

TYPES OF BONDS. Bonds may be classified, according to the method of fastening them to the rail, as welded bonds, soldered bonds, brazed bonds, and bonds applied by mechanical pressure.

Welded Bonds (Figs. 36 and 37) are designed for oxy-acetylene flame welding, steel-electrode arc welding, copper-electrode arc welding, and carbon-electrode arc welding.

They usually consist of all-copper or bimetallic copper and steel stranded conductors with mechanically attached steel or copper terminals or with steel terminals butt-welded to the conductors. The flame-welded bonds are usually installed with a flux-containing copper-alloy welding metal. The arc weld bonds are installed with steel electrode or flux-containing copper-alloy electrode, or with carbon electrode in conjunction with a carbon mold with flux-containing copper as the welding metal.

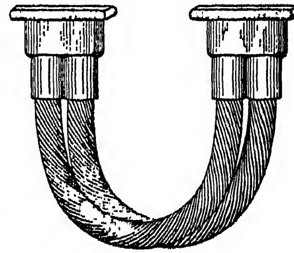

FIG. 36

The designs of welded bonds are many in number and are changing so rapidly that no details of construction are given.

Soldered Bonds (Fig. 38) usually consist of a series of thin strips of annealed copper with tinned terminals. They are soldered direct to the head of the rail. One or more bonds per joint may be used. They are suitable for use only on third rails.

Brazed Bonds resemble soldered bonds except that the terminals are enveloped in brass. They are brazed or welded to the rail by heat generated electrically in a carbon which constitutes the clamp holding the bond against the rail.

Expanded and Compressed Terminal Bonds. Bonds fastened to the rail by mechanical pressure may be divided into two general classes, expanded terminal and compressed terminal bonds. Both kinds are called "stud terminal" bonds.

Pin-expanded Terminal Bonds (Fig. 39) have their heads drilled with an axial hole,

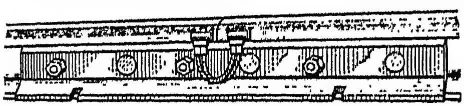

FIG. 37

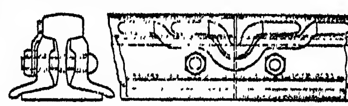

FIG. 38

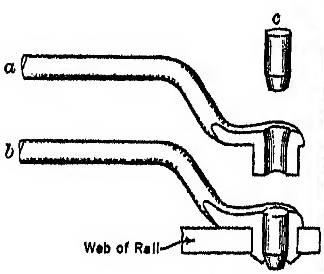

FIG. 39

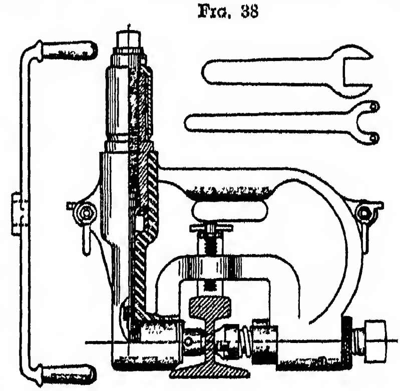

FIG. 40

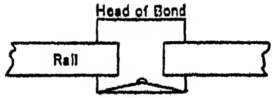

FIG. 41

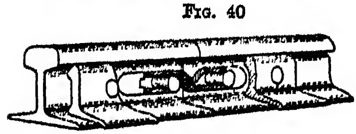

FIG. 42

through which a tapered steel pin *d* is driven, forcing the copper outward and against the steel. This type of bond is fastened to the web of the rail.

Compressed Terminal Bonds have solid copper terminals and are installed with pressure applied at both ends of the stud. The bond is applied to the web of the rail by means of a heavy screw or hydraulic press (Fig. 40) which engages the bond head and causes it to compress longitudinally and expand laterally as the pressure is applied, bringing the copper into firm contact with the steel and spreading the projecting end of the terminal into a button-shaped rivet-head, as shown in Fig. 41.

Exposed Versus Concealed Bonds. Bonds may be either exposed or concealed (Fig. 42) under the fish-plates. The former condition is preferable, if there is no likelihood of theft, as it permits inspection to be easily made.

Welded type bonds are always of the exposed type and are applied either to the head or the top of the flange of the rail. Stud terminal bonds (pin or compressed) may be of the concealed or exposed type. They are always applied in holes drilled in the web of the rail. The choice of type is largely a matter of economics. While concealed bonds are necessarily applied to the web of the rail, exposed bonds may be applied to the foot or head. Head bonds have the advantage of being short. Web or base bonds, unless concealed, have to be long in order to span the splice bars.

USES OF VARIOUS TYPES OF BONDS. Bonds are used for track rails, third rails, and girders of elevated and subway lines. Soldered bonds find their best application in third-rail work, where good electrical contact is of greater importance than mechanical strength. Expanded or compressed terminal bonds, especially of the concealed type, are excellent for heavy traction work, where space underneath the splice bars is adequate. Welded bonds are nearly always used on the head of the rail, within the limits of the splice bars; they are easy to inspect, but are more subject to damage from vibration where traffic conditions are severe.

SUBSTITUTES FOR BONDING. Several efficient substitutes for bonding are now in use, such as electrical welding, cast welding, and Thermit welding. Welded joints are used almost exclusively in paved streets.

Electric Welding is almost exclusively of the arc welding type. Various methods of "sewing" the splice bar along its top and bottom edges to the rail head and rail base by different methods of arc welding are in general use. Resistance welding of the splice plate, because of its relatively high cost, has given way almost entirely to arc welding.

Cast Welding is accomplished by setting a mold around the rail joint and pouring molten iron around it. The Thermit process is a modification of this, the iron being liberated at a white heat from a mixture of iron oxide and aluminum, which is ignited in a crucible.

Flame-welding by oxyacetylene torch is also in successful use.

The **Coullié Bond,** used in France, is a short mechanical splice bar of special shape such that, when the joint is depressed by a wheel, four points make rubbing contact with the head and flange of the rail, thereby maintaining clean electrical contacts.

SELECTION OF TYPE AND SIZE OF BOND. Considerations determining the choice between concealed and exposed bonds are liability to theft, electrolytic corrosion, facility of inspection, and injury to bonds in service.

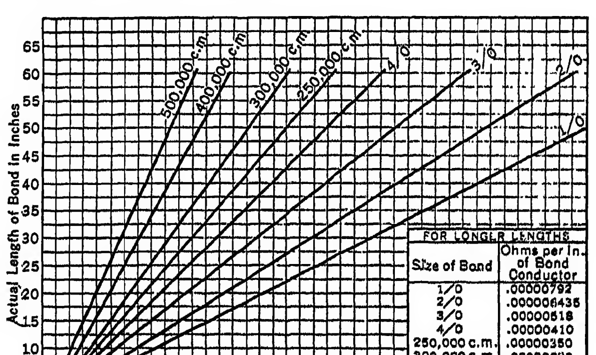

Fig. 43

The choice between mechanically attached and welded bonds depends largely upon the importance of rapid installation, the mechanical stresses to be withstood in service, the type of labor available, and the facilities for the use of drills, presses, etc.

Single vs. Double Bonding. Joints are sometimes bonded with one and sometimes with two bonds. Double bonding has the advantages of less chance of complete failure

and greater carrying capacity for a given cross-section of copper. It has the disadvantages of being more expensive and giving uncertain results in testing, however.

Selection of Cross-sectional Area of Bond. The cross-sectional area of a rail bond should, as a rule, be not greater than is necessary to keep its temperature at a safe working value, unless greater area is required for mechanical strength. The resistance of the bonded joint is of secondary importance unless very high, because the resistance of the joints is usually a mere fraction of the total track-rail resistance (see below).

Carrying Capacity of Bonds. The excellent heat conductivity of copper and the large heat-storage capacity of steel rails tend to make the carrying capacity of bonds in cold weather considerably greater than that of free wire of the same size, especially if the bonds are short. In hot weather, however, the rails and consequently the bonds are likely to become hot from exposure to the sun's rays, thereby reducing the effective carrying capacity of the bonds.

It is not safe to set up a formula for carrying capacity. A very conservative rule is to use 1 amp per 500 cir mil cross-sectional area. If 250 cir mils per amp is used there will be no injurious heating of the bond but the length of bond conductor is a very important factor. Very short bonds will carry considerably more current than long bonds.

Resistance of Bonds. The ohmic resistance of stud terminal rail bonds, at 68 deg fahr, including rail contact resistance, is given in Fig. 43.

Although the resistance values of welded bonds are in general higher, the stud terminal bond resistance values can be used with fair accuracy for welded bonds of all types. There is very little difference between the resistance of one form of welded bond and another when properly applied.

Resistance of Bonded Joint. The conductivity of the splice bars may be neglected. The resistance of a bonded joint can be computed as follows:

Let b = resistance of joint, ohms.
a, a_1, a_2 = resistance of bond A, A_1, A_2 (extended length) ohms, from Fig. 43.
d = resistance of length D of rail, ohms.

Then, for a single bonded joint, $b = a$. For a joint bonded with two equal bonds, lapped, Fig. 44*a*, $b = {}^1/_2\,(a + d)$, and for a joint bonded with two unequal bonds, Fig. 44*b*, $b = \dfrac{a_2(a_1 + 2d)}{a_2 + a_1 + 2d}$

Resistance of Bonded Rail. The resistance of bonded rail can be computed from the following formula:

$$x = nb + r\,\frac{(5280 - ns)}{5280}$$

where x = resistance of bonded rail per mile, ohms.
b = resistance of joint, ohms, from preceding paragraph.
s = length between outside bond terminals, feet (Fig. 44).
n = number of joints per mile.
r = resistance of rail per mile, ohms. (See Rails, Art. 12.)

Length of Bond. The length of concealed bonds is necessarily determined by the spacing of the bolt holes. The bonds for attachment to the head of the rail are usually 7 or 7 $^1/_2$ in. long for single bonding and about 8 $^1/_2$ in. long for double bonding where U-shaped bonds are used. Bonds to span the splice bar must be of sufficient length to have the terminals beyond the ends of the splice bar and far enough away to permit the bond conductor to clear the splice bar properly.

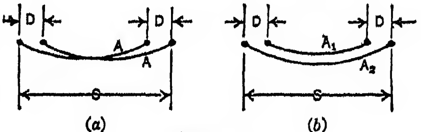

FIG. 44

SPECIFICATIONS. (See also article on Specifications and Contracts in Fund. of Eng.) Specifications for rail bonds should state the exact service conditions under which the bond is to be used, the style of attachment desired, the part of the rail they are to be applied to, the style of conductor (ribbon, solid wire, or cable), the cross-sectional area, the contact area of the stud, the formed length between centers of terminals, and the fish-plate and bolt layout, if the bonds are to be concealed.

INSTALLATION. An important consideration in the installation of bonds is the cleanliness of the bonds and bond holes, or other adhesion surface. Unless this is secured the bonds will be electrically defective whatever their mechanical strength may be.

Welded Bonds. For the correct installation of any type of welded bond it is essential that the proper welding apparatus and welding metal for applying the bonds be selected. Flame-welding requires the use of flux-containing copper alloy of the proper composition

Exposed Versus Concealed Bonds. Bonds may be either exposed or concealed (Fig. 42) under the fish-plates. The former condition is preferable, if there is no likelihood of theft, as it permits inspection to be easily made.

Welded type bonds are always of the exposed type and are applied either to the head or the top of the flange of the rail. Stud terminal bonds (pin or compressed) may be of the concealed or exposed type. They are always applied in holes drilled in the web of the rail. The choice of type is largely a matter of economics. While concealed bonds are necessarily applied to the web of the rail, exposed bonds may be applied to the foot or head. Head bonds have the advantage of being short. Web or base bonds, unless concealed, have to be long in order to span the splice bars.

USES OF VARIOUS TYPES OF BONDS. Bonds are used for track rails, third rails, and girders of elevated and subway lines. Soldered bonds find their best application in third-rail work, where good electrical contact is of greater importance than mechanical strength. Expanded or compressed terminal bonds, especially of the concealed type, are excellent for heavy traction work, where space underneath the splice bars is adequate. Welded bonds are nearly always used on the head of the rail, within the limits of the splice bars; they are easy to inspect, but are more subject to damage from vibration where traffic conditions are severe.

SUBSTITUTES FOR BONDING. Several efficient substitutes for bonding are now in use, such as electrical welding, cast welding, and Thermit welding. Welded joints are used almost exclusively in paved streets.

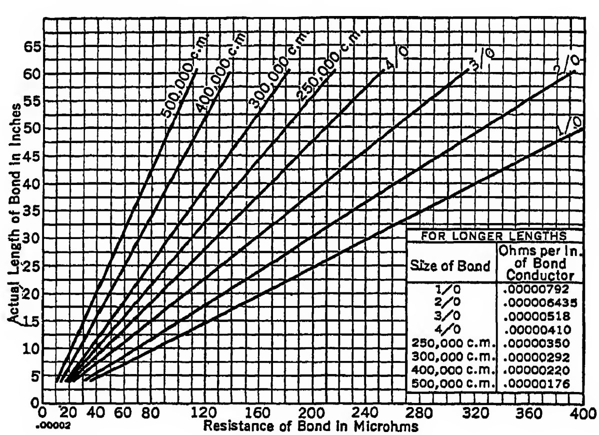
Electric Welding is almost exclusively of the arc welding type. Various methods of "sewing" the splice bar along its top and bottom edges to the rail head and rail base by different methods of arc welding are in general use. Resistance welding of the splice plate, because of its relatively high cost, has given way almost entirely to arc welding.

Cast Welding is accomplished by setting a mold around the rail joint and pouring molten iron around it. The Thermit process is a modification of this, the iron being liberated at a white heat from a mixture of iron oxide and aluminum, which is ignited in a crucible.

Flame-welding by oxyacetylene torch is also in successful use.

The Coullié Bond, used in France, is a short mechanical splice bar of special shape such that, when the joint is depressed by a wheel, four points make rubbing contact with the head and flange of the rail, thereby maintaining clean electrical contacts.

SELECTION OF TYPE AND SIZE OF BOND. Considerations determining the choice between concealed and exposed bonds are liability to theft, electrolytic corrosion, facility of inspection, and injury to bonds in service.



FOR LONGER LENGTHS	
Size of Bond	Ohms per In. of Bond Conductor
1/0	.00000792
2/0	.000006435
3/0	.00000518
4/0	.00000410
250,000 c.m.	.00000350
300,000 c.m.	.00000292
400,000 c.m.	.00000220
500,000 c.m.	.00000176

Fig. 43

The choice between mechanically attached and welded bonds depends largely upon the importance of rapid installation, the mechanical stresses to be withstood in service, the type of labor available, and the facilities for the use of drills, presses, etc.

Single vs. Double Bonding. Joints are sometimes bonded with one and sometimes with two bonds. Double bonding has the advantages of less chance of complete failure

and greater carrying capacity for a given cross-section of copper. It has the disadvantages of being more expensive and giving uncertain results in testing, however.

Selection of Cross-sectional Area of Bond. The cross-sectional area of a rail bond should, as a rule, be not greater than is necessary to keep its temperature at a safe working value, unless greater area is required for mechanical strength. The resistance of the bonded joint is of secondary importance unless very high, because the resistance of the joints is usually a mere fraction of the total track-rail resistance (see below).

Carrying Capacity of Bonds. The excellent heat conductivity of copper and the large heat-storage capacity of steel rails tend to make the carrying capacity of bonds in cold weather considerably greater than that of free wire of the same size, especially if the bonds are short. In hot weather, however, the rails and consequently the bonds are likely to become hot from exposure to the sun's rays, thereby reducing the effective carrying capacity of the bonds.

It is not safe to set up a formula for carrying capacity. A very conservative rule is to use 1 amp per 500 cir mil cross-sectional area. If 250 cir mils per amp is used there will be no injurious heating of the bond but the length of bond conductor is a very important factor. Very short bonds will carry considerably more current than long bonds.

Resistance of Bonds. The ohmic resistance of stud terminal rail bonds, at 68 deg fahr, including rail contact resistance, is given in Fig. 43.

Although the resistance values of welded bonds are in general higher, the stud terminal bond resistance values can be used with fair accuracy for welded bonds of all types. There is very little difference between the resistance of one form of welded bond and another when properly applied.

Resistance of Bonded Joint. The conductivity of the splice bars may be neglected. The resistance of a bonded joint can be computed as follows:

Let b = resistance of joint, ohms.
a, a_1, a_2 = resistance of bond A, A_1, A_2 (extended length) ohms, from Fig. 43.
d = resistance of length D of rail, ohms.

Then, for a single bonded joint, $b = a$. For a joint bonded with two equal bonds, lapped, Fig. 44a, $b = {}^1/_2\,(a + d)$, and for a joint bonded with two unequal bonds, Fig. 44b, $b = \dfrac{a_2(a_1 + 2d)}{a_2 + a_1 + 2d}$

Resistance of Bonded Rail. The resistance of bonded rail can be computed from the following formula:

$$x = nb + r\,\frac{(5280 - ns)}{5280}$$

where x = resistance of bonded rail per mile, ohms.
b = resistance of joint, ohms, from preceding paragraph.
s = length between outside bond terminals, feet (Fig. 44).
n = number of joints per mile.
r = resistance of rail per mile, ohms. (See Rails, Art. 12.)

Length of Bond. The length of concealed bonds is necessarily determined by the spacing of the bolt holes. The bonds for attachment to the head of the rail are usually 7 or 7 ${}^1/_2$ in. long for single bonding and about 8 ${}^1/_2$ in. long for double bonding where U-shaped bonds are used. Bonds to span the splice bar must be of sufficient length to have the terminals beyond the ends of the splice bar and far enough away to permit the bond conductor to clear the splice bar properly.

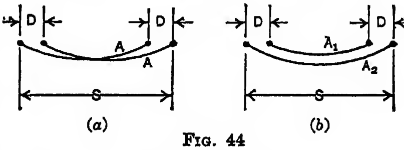


FIG. 44

SPECIFICATIONS. (See also article on Specifications and Contracts in Fund. of Eng.) Specifications for rail bonds should state the exact service conditions under which the bond is to be used, the style of attachment desired, the part of the rail they are to be applied to, the style of conductor (ribbon, solid wire, or cable), the cross-sectional area, the contact area of the stud, the formed length between centers of terminals, and the fish-plate and bolt layout, if the bonds are to be concealed.

INSTALLATION. An important consideration in the installation of bonds is the cleanliness of the bonds and bond holes, or other adhesion surface. Unless this is secured the bonds will be electrically defective whatever their mechanical strength may be.

Welded Bonds. For the correct installation of any type of welded bond it is essential that the proper welding apparatus and welding metal for applying the bonds be selected. Flame-welding requires the use of flux-containing copper alloy of the proper composition

which the leading manufacturers have developed. Steel electrode welding requires the use of low-carbon steel. Coated electrodes are very desirable. Copper-electrode welding requires the use of a flux-containing copper-alloy electrode and high amperage in order to " puddle " the metal as much as possible. Carbon-electrode welding requires the use of a carbon mold to surround the bond terminal. Flux-containing copper alloy (same as copper-alloy electrode) is melted in the carbon arc until the mold cavity is filled. Proper polarity of electrode is essential. Steel electrodes may be used either positive or negative. Copper electrodes should always be positive. Carbon electrode must be negative.

Brazed Bonds. The rail surface is first ground clean. The bond terminal, being covered with a brass plate, is then placed against the clean surface. A carbon block is pressed against the surface of the bond terminal opposite the rail. The carbon block is then heated to incandescence by means of an electric arc, which does not come in contact with the bond. Borax flux is introduced between the bond terminal and the rail. When the terminal reaches the proper temperature a braze is effected between the bond terminal and the rail.

Soldered Bonds. The rail surface is brightened by means of a silicon carbide (Carborundum) or emery wheel, then tinned, using an acid flux. The bond is then clamped in place and the rail and bond heated by means of a blow-torch, to a temperature at which the solder will melt and cause the bond to adhere firmly to the rail.

Pin-expanded Bonds. The rail is drilled through the web, with or without lubricant. Drilling without lubricant has the advantage of giving a perfectly clean hole. Holes are drilled to the same diameter as the bond studs, and rust or scale on the web of the rail is removed around the hole. The bond stud is then inserted into the hole, and a long taper punch lubricated with grease is driven entirely through the terminal. Then a short drift pin is driven home, as shown in Fig. 39. About 100 bonds may be installed with one taper punch.

This type of bond requires a smaller equipment in tools and materials than most other types and does not necessitate the use of any apparatus which obstructs the track and thereby endangers traffic.

Compressed-terminal Bonds. The drilling having been performed as for a pin-expanded bond, and the bond studs inserted into their respective holes, a screw or hydraulic compressor, as shown in Fig. 40, is applied at both ends of the bond head, the conical point of the press fitting into the conical depression of the bond. Pressure is applied, either until a collar on the ram touches the rail, or until the head of the bond acquires the proper shape. Where no collar is used the point of the press (if of the screw type) sometimes cuts into the bond head; this may be avoided by placing a small amount of flake graphite mixed with oil in the depression of the bond head.

For durable contact the bond terminal stud should be installed with a direct pressure of at least 25 tons per square inch of contact area. Actual contact resistances of stud terminals at 15 tons per square inch contact pressure are given in Table XXXII.

Table XXXII. Contact Resistance of Stud Terminals

Diameter of Terminal Stud, in.	Area of Contact, sq in.	Contact Resistance, ohm	Diameter of Terminal Stud, in.	Area of Contact, sq in.	Contact Resistance, ohm
1	1.77	0.00000040	5/8	1.10	0.00000064
7/8	1.55	0.00000045	1/2	0.88	0.00000080
3/4	1.33	0.00000053	2 twin terminal studs	2.00	0.00000035

The copper of a bond head is hardened by the pressure it is subjected to, and, like the steel, is distorted within its elastic limit, causing the surfaces to adhere even if the pressure is reduced to one-third its original value, say 10,000 lb per sq in. Between these two pressures, the electrical resistance does not vary. Expansion due to heat, therefore, has no effect upon the resistance of bonds.

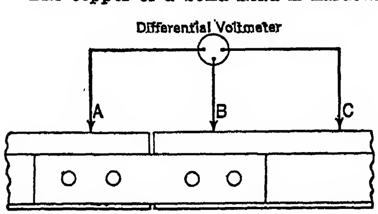

Fig. 45

TESTS AFTER INSTALLATION. The usual method of testing is to measure the drop of potential across the bonded joint and find simultaneously the length of continuous rail in which the same drop occurs, i.e., the " equivalent " length of the bonded joint. Several ingenious instruments have been devised for making this comparison with ease and accuracy.

Voltmeter Method. The simplest form of bond tester consists of a center zero millivoltmeter with three connections to the rail. (See Fig. 45.) With current flowing through the rail in the direction from A to C, the current flows through the millivoltmeter movable coil in the direction A to B to indicate the difference of potential between A and B. The drop between B and C is indicated by the current flowing through the same coil in the direction B to C, thus opposing the drop between A and B, and indicating the difference. By varying the distance BC the drop across the joint and the drop from the solid rail can be equalized. The distance between B and C is then measured and represents the length of rail equivalent to the resistance across the joint.

Many commercial bonding sets have rail contact devices with a fixed spacing of the contacts, which span the rail joints, of 3 ft. In order to obviate correction of the readings of the rail joints as tested, the resistance of 3 ft of joint may be calculated and used for comparison.

14. DISPATCHING OF TRAINS BY TELEPHONE

(See also Pender and McIlwain.) Up to 1907 train dispatching was done almost entirely by the telegraph. In that year the telephone began to replace the telegraph for this purpose. At the beginning of 1935 approximately 151,000 miles of railroad in the United States was being dispatched by telephone, as against approximately 94,000 miles dispatched by telegraph.

Telephone train dispatching has many advantages over the former method. The dispatcher's duties consist in the main of gathering information and issuing orders for train movements. This work is performed much more rapidly and no less accurately by the use of the telephone. Special training in the use of the apparatus is not necessary, as when telegraphy is employed. All the agencies are brought into closer personal relations, with the result that there are closer cooperation and better discipline. The dispatcher can call and speak at the same time, which is impossible by telegraph.

It now is possible to operate dispatching lines as long and with as many stations as railway conditions permit. The length of line and number of stations are not limited by the nature of the electrical equipment. Lines of 300 miles length are in operation, and as many as 115 selector stations, and numerous pole boxes without selectors, on one line are in successful use.

Dispatching circuits are multi-station lines, like the telegraph-dispatching lines they displace. Broadly speaking, they are selective party lines, but are equipped with systems of apparatus which allow the placing of many more stations on a line than is possible with any other party-line system so far developed.

Several train-dispatching systems are on the market, the principal ones being known as the Gill System and the Western Electric System. These are in general similar in that the dispatcher has means of calling any station selectively. In some systems he can call several stations at once by setting keys for them in advance and operating a common calling key.

Each way-station is equipped with a device called a selector. These selectors are operated only by the dispatcher. They work on the step-by-step principle, and the whole object of the device is to close a contact at the station called and thus to ring a bell. No provision is made for cutting the way-station telephone set on and off the line, as secrecy is not aimed at. Any way station may communicate with the dispatcher at will by lifting the telephone receiver. Loud-speaking receivers are generally provided for the dispatcher's use, with head sets for optional use, the dispatcher in either case listening on the line at all times.

Train orders are written as given and received and are read back to the dispatcher by each station, the dispatcher underscoring each word once for each correct repetition from a way station.

15. CAR BARNS, INSPECTION SHEDS, AND REPAIR SHOPS

In every electric railway system it is necessary to provide inspection sheds where the cars may be taken regularly for a systematic inspection. In some cases these buildings are used for the storage of cars and in special cases are equipped as repair shops. On street railroad systems they are generally combined with the necessary facilities for conducting transportation (crew rest rooms, sand facilities, ticket receivers' and superintendent's offices, etc.). Construction of indoor storage space for cars has practically ceased, since the increased deterioration of the cars left in the open is likely to be less than the fixed charges on a car barn. In the case of urban roads, the high value of land may justify a car barn of more than one story because of the smaller area occupied.

LOCATION. The location of a car barn and inspection shed may be determined by several considerations. They may be located in the city on account of the convenience of the employees, the possibility of placing the general offices in the same building, and on account of the fact that the city service is an important part of the whole system. They may be located in the suburbs where real estate is cheap and ample space available. They may be located at a point selected to make the dead mileage of the cars between the ends of their runs and the barns, and between the barns and inspection sheds (if not located together), a minimum. Finally, they may be located adjacent to the power station or other company facilities so that the activities of the two departments may be combined and thus be more efficient.

Repair shops are now generally located where land is inexpensive, so that all tracks may be laid on the ground, and all buildings containing tracks may be approached by ladder tracks, avoiding the expense of transfer tables, car elevators, and the heavier construction required by second-story tracks. For a large shop, location permitting connection with a steam railroad is economical. In remote locations, lacking convenient access to suitable residence districts for employees, the difficulty of securing labor must be considered.

CONSTRUCTION. Preparatory to designing a car house inspection shed, or repair shop, it is necessary to become acquainted with municipal and underwriters' regulations. Facilities required in a centralized building include space for car storage, inspection, administration offices, line department, road department, car employees' lobby, car sign storage, sand drying and storage, salt storage, oil storage, wash-room and toilets.

The standard construction consists of a steel frame on a concrete foundation, and brick walls, but many of the smaller railroads have mill frame buildings of slow-burning construction. The floors are of concrete with cement finish, and sloped for drainage. In most localities it is desirable to provide roller-shutter doors, which can be handled with less labor and greater safety than large hinged doors. Provision must be made for lifting at least one end of any unit of rolling stock handled; depending on the size of the shop this may be fixed hoists or a traveling crane, hand or power operated.

INSPECTION PITS. Inspection pits between the rails are usually 4 ft 6 in. deep below the top of rails. It is important to have these pits thoroughly drained and well illuminated, with recessed and guarded lights. Ample outlets for electric and pneumatic tools should be provided.

In locomotive shops and large car shops a drop pit, equipped with a jack arranged to lower a truck, a pair of wheels, or any heavy underbody apparatus into the pit and transfer it to an adjacent track, will repay its cost.

TRACKS. Tracks in a carhouse used for storage only need be spaced just far enough apart to leave walking space between rows of cars, or between cars and columns or walls; in inspection sheds and shops the track spacing should be several feet greater. Placing top of rail 12 to 15 in. above floor level facilitates work on trucks and underbody parts; the floor must be ramped up to rail level at transverse aisles. The tracks at the entrance to the car house should be designed to permit the rapid movement of cars with the least interruption to traffic.

ILLUMINATION. Illumination should be both general and local. The general illumination should consist of incandescent lights, suspended from overhead between the tracks and spaced about a car length apart. These may be run five in series on a 600-volt trolley circuit, although an ungrounded system is better. The intensity of illumination on the floor should be from 1 to 1.5 ft-c or lumens per square foot. Frequent sockets for drop lights must also be provided, for many portions of the car equipment are in dark corners.

POWER. On low-voltage trolley systems the trolley wire may be run into buildings, but on third rail and high-voltage trolley systems, the contact conductor should end at the doors and movements within the building be made by the use of portable contacts applied to the third-rail shoe or trolley and connected by flexible insulated cable either to a fixed outlet or a roller contact on a live rail overhead between tracks.

The traction power supply is in most cases unsuitable for machine tools, etc., because of voltage fluctuations.

FIRE RISKS. Attention should be given to minimizing fire losses by: (1) use of automatic sprinklers; (2) provision of two sources of water supply such as mains and tank; (3) division of building by fireproof walls; (4) avoiding proximity to inflammable buildings; (5) having ample provision of water pails, sand pails, chemical extinguishers and hoses; (6) locating near a fire station; (7) building tracks on a grade so that cars may be easily pushed out by hand; (8) having auxiliary fire alarms; (9) consulting underwriters when planning; and (10) care in storage of inflammables.

ELECTRICAL EQUIPMENT OF INTERNAL-COMBUSTION AUTOMOBILES

By Herbert Chase

17. ELECTRIC IGNITION

FUNCTION. It is the function of the ignition system of an internal-combustion engine to initiate the burning of the charge of fuel within the engine cylinder at the proper instant in the cycle; i.e., when the explosive mixture of gas and air is at or near the point of maximum compression. The typical system, see Fig. 1, comprises (1) a source of electrical energy (battery or magneto generator); (2) a timer for correlating the production of the spark with the rotation of the engine (this may be either a " timer " or " commutator " which closes the primary circuit of a vibrator system at the proper instant, or a " breaker " which interrupts the primary circuit of an induction coil); (3) an induction coil (which may be incorporated as part of the magneto) for transforming the energy to a high voltage; (4) a distributor for leading the high voltage discharge to the successive cylinders in the proper sequence; and (5) a spark plug in each cylinder to provide a fixed insulated gap at which the igniting spark is produced.

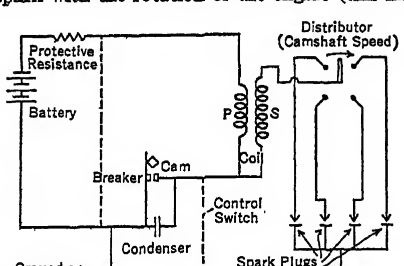

Fig. 1. Circuits of Typical Single-spark, Jump-spark Ignition System. Solid lines show battery system. If the battery and resistance are omitted, the dotted connections added, and the " coil " taken to represent the windings of a magneto, the circuits become those of a high-tension magneto ignition system.

IGNITION OF GASES. When combustible mixtures of air and gas or vapor, or even of air and finely powdered solid combustible fuel, are ignited, a wave of flame spreads through the mixture. Inflammation of the mixture is not instantaneous. In general, the rate of flame propagation is relatively slow, but under some conditions the velocity increases with great rapidity and the charge is said to **detonate.** Detonation is accompanied by exceedingly sudden and violent rises in pressure and so rapid a release of energy that overheating of parts exposed to the high temperature is likely to occur. If these parts reach incandescence or become hot enough to ignite the charge before the normal time, preignition starts and may result in serious injury to engine parts. It is desirable to avoid detonation not alone because of the high temperatures that accompany it but also because the rapid pressure rise may result in mechanical injury. The rate of flame propagation, prior to detonation, varies with different gases, with different proportions of air and fuel

in otherwise similar mixtures, with the density and the temperature of the charge, and probably with other factors that are less definitely understood.

When detonation occurs, the power developed decreases, but, if the compression pressure and consequent density of the gases compressed can be increased without detonation, power output can be materially increased. Knowledge of this fact and of the destructive effects of detonation have led to the extensive use of fuels less subject to detonation and to the use of certain so-called "dopes," small quantities of which have a marked tendency to prevent detonation. One of the most effective dopes is tetraethyl lead. Even a few cubic centimeters of this liquid per gallon of fuel will suppress detonation and permit marked increase in the allowable compression pressure and in power output. Changes in the molecular grouping of hydrocarbon fuels, especially of petroleum derivatives, such as can be effected by variations in the refining process or by hydrogenation, are capable of producing fuels that are not subject to detonation even at the highest compressions ordinarily encountered. The availability of these two types of fuels has led in recent years to the use of much higher compression pressures and to obtaining much higher power outputs from engines of a given displacement. This in turn has necessitated important change in ignition equipment some of which have been made necessary by the increase in voltage required at the spark plug to break down the gap between spark-plug electrodes resulting from the greater density of gases surrounding the gap.

Detonation is much more likely to occur if ignition takes place at a point in the cylinder remote from a highly heated area, such as that around the exhaust valve, so that the flame wave is propagated toward the hot area, than if the reverse condition is established. For this reason, it is now common practice to place the spark plug over the exhaust valve instead of over the inlet valve where it was formerly customary to place it. Regardless of the location of the ignition source, however, there is an appreciable time lag between the instant of combustion and that at which the entire charge is inflamed. It is necessary, therefore, in order that the charge may all be ignited at or very near the top of the stroke, to ignite the charge well in advance of top center, and usually to increase this advance by some means as the engine speed increases. To prevent back kicks or sudden reversal of the direction of rotation during the cranking period, it is usually necessary to provide means for retarding the spark during this period. Both hand-operated and automatic means of effecting the required advance and retard of spark timing are now in extensive use, and in many instances a combination of hand and automatic controls is employed. As timing of the spark has a marked effect both upon power output and upon specific fuel consumption, as well as upon the general responsiveness of the engine to demands for change in speed and power output, increasing attention has been paid in recent years to a variety of means for securing an automatic control by the use either of centrifugally operated mechanism or of devices actuated by the pressure difference between the inlet manifold and outside air. In some instances both centrifugal and vacuum controls are applied.

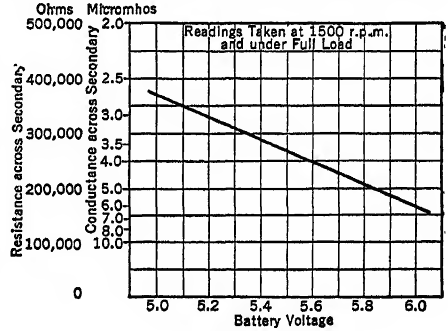

FIG. 2

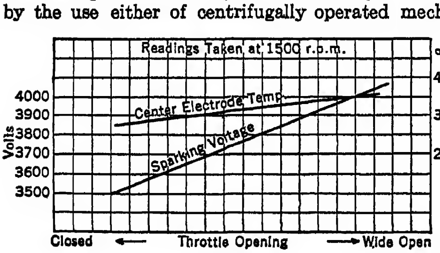

FIG. 3

According to Hector Rabezzana and Donald W. Randolph (*The Automobile Engineer*, England, June, 1930), the voltage required to cause a spark to jump the gap in a spark plug, when the gap measures less than 0.035 in., is nearly proportional to the width of the gap and to the density of the gases in the gap. Under apparently identical conditions in the engine, however, consecutive sparks may have as much as 50 per cent variation in the breakdown or sparking voltage at the plug. In addition to the size of the gap and the density of the gases in the

gap the sparking voltage is affected mainly by the shape, temperature, material, and deterioration of the electrode material. It is also affected materially by electrically conducting deposits on the insulator, especially when, as is often the case, these deposits are not composed entirely of carbon but contain iron oxide or other metallic materials some of which are known to come from certain dopes. The lower the resistance of the shunt which this deposit forms, the lower is the voltage which the spark coil is capable of delivering to the gap. The allowable secondary leakages, resulting from fouling of the spark-plug insulator, for different primary voltages, for an engine running at full load and 1500 rpm, are as shown in Fig. 2.

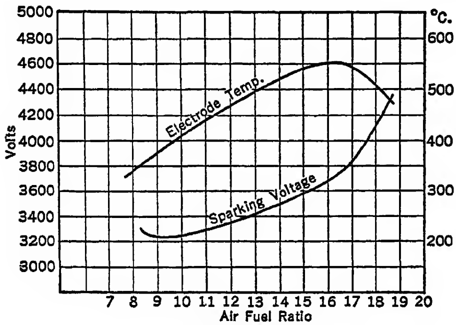

FIG. 4

Other conclusions of Rabezzana and Randolph may be noted as follows: For a given engine speed, the actual compression pressure and resulting density of the charge at the time of ignition increase as the throttle is opened. The secondary or sparking voltage rises accordingly, even though the temperature of the center electrode also rises. See Fig. 3. The sparking voltage and [the temperature of the electrode also vary with changes in the air to fuel ratio, as shown in Fig. 4. Atmospheric humidity, as well as barometric pressure and turbulence of the gases in the cylinder at the time of ignition, have an effect upon combustion temperature, and also upon sparking voltage and electrode temperature. The effect of humidity on these factors under full-load engine conditions is shown in Fig. 5.

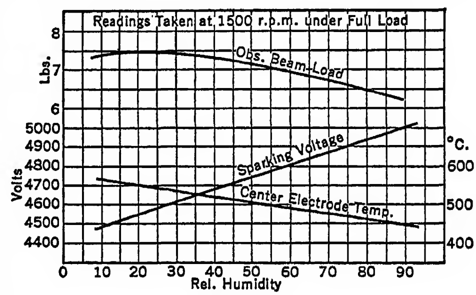

FIG. 5

Sparking voltage increases as the gap between electrodes increases, but not in a straight-line ratio, as shown in Fig. 6, which applies to an engine of rather low compression. A small increase in conductance (resulting from fouling of the insulator) or in the size of the spark-plug gap may result in missing. This is shown by reference to Fig. 7, which shows the maximum allowable fouling conductance on the insulator for a given gap size.

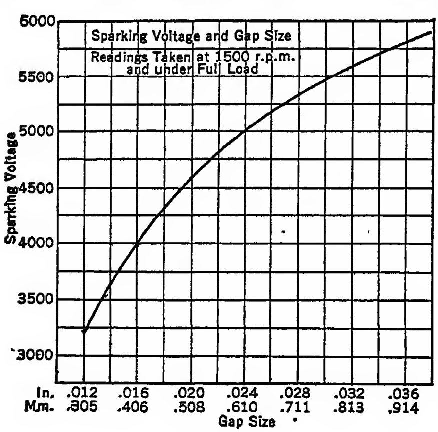

FIG. 6

Sharp edges on electrodes may slightly lower the sparking voltage, but such edges soon wear away after a few hours of engine operation. In other respects the shape of the electrodes has little effect. As hot electrodes emit a greater number of electrons than those that are relatively cool, the sparking voltage falls off quite rapidly as the temperature of the electrodes rises. See Fig. 8. This is an important effect frequently overlooked, and is one reason why a higher voltage is required in starting a cold engine than is needed to cause sparking when the engine and electrode become heated. Since a spark jumps a gap because the gases in

the gap become conductors as a result of the presence of ions and free electrons in the gap, and most of the electrons are furnished by the electrode wire itself, the belief that the material of the electrode has no effect upon sparking voltage is not admissible. The characteristics of the ordinary commercial electrode alloy are such that the emission of electrons decreases as the plug is used and requires a proportional increase in the sparking voltage necessary to break down the gap. The increased voltage required sometimes amounts to as much as 3500 volts under the same gap conditions. Continued use of the conventional electrode tends to exhaust the electron-emitting material in the surface of the wire and results in wide variations from spark to spark in the voltage required to break down the gap. There is also a physical disintegration of the wire resulting from the action of combustion gases at high temperature. Individual particles are loosened by intercrystalline corrosion and become detached with resultant widening of the gap. A new type of electrode material, called Isovolt, retains the same sparking voltage throughout its life and also requires a lower voltage for sparking than the usual commercial electrode wire. So long as the spark gap is not increased, corrosion of this new alloy does not increase the sparking voltage. Tests with it indicate easier starting in cold weather, and the greater resistance of the electrodes to corrosion enables the engine to run longer without regapping the plugs. In addition, the sparking voltage from spark to spark remains substantially constant.

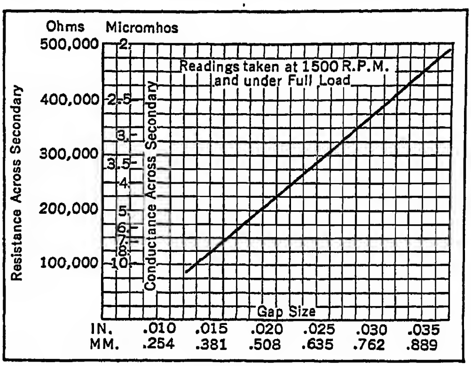

Fig. 7

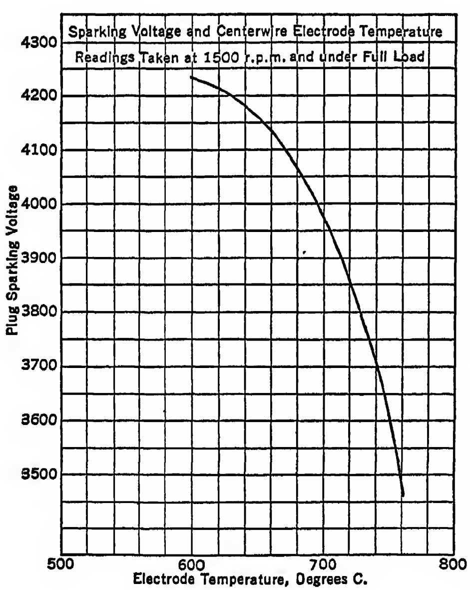

Fig. 8

As a result of the work of Rabezzana and Randolph the following recommendations are made to minimize spark-plug missing: (1) spark-plug gaps of 0.015 to 0.018 in. for high-compression engines and of 0.018 to 0.022 in. for low-compression engines; (2) electrode shape least affected by corrosion; no sharp edges or points at gap; (3) good electrode wire; (4) correct carburetion; (5) proper position of plug in combustion chamber; (6) correct breaker point gaps; (7) clean and square breaker points; (8) correct plugs for conditions under which engine is used; (9) avoidance of metal shielding on secondary leads and minimum length of said leads.

TYPES OF IGNITION SYSTEMS. Virtually all ignition systems in general use today are high-tension jump-spark types in which the initial or primary current is generated at a comparatively low voltage which is stepped up to a voltage sufficiently high to break down the gap at the spark plug and produce an ignition arc or spark at the gap.

Make-and-break Low-tension Systems were extensively used at one time but are now seldom found in practical use except on old engines. This type of system employs a

high inductance connected to a pair of contacts within the combustion chamber of the engine. These contacts are arranged so that mechanical separation occurs at a predetermined point in the cycle, resulting in an arc which ignites the charge. This type of system is not well suited for high-compression engines nor for those operating at high speed, and it also suffers the disadvantage of mechanical complexity.

Jump-spark or High-tension Systems are the most general source of electric ignition. The high voltage for jumping the spark gap is induced in the secondary winding of an induction coil, which in some cases forms a part of a magneto winding, when the primary circuit is broken. Systems of this type are sometimes classified as follows:

Vibrator Systems, in which the primary circuit is broken by vibrating contacts, as on Model T Ford cars, are now nearing obsolescence.

Single-spark Systems, in which a single spark is produced by one interruption of the primary circuit for each power stroke of the engine, are now practically universal on American passenger car engines and are extensively used on many other types of engines. In general, the source of electrical energy is a storage battery, usually floating on the line with a charging generator, but it may be a set of dry cells or a magneto. As a rule, the primary circuit remains closed during a considerable proportion of the engine cycle in order that the flux in the induction coil may build up to a maximum value. The field thus created collapses rapidly, of course, when the primary circuit is broken by separating the cam-actuated contacts, the lines of force cutting the secondary winding and building up a voltage high enough to jump the gap of the spark plug. Because of the long time that the primary circuit of this type of system remains closed as compared to so-called open-circuit types, the current flow is greater and the energy in the spark is correspondingly increased.

Electric sheets of high-silicon steel or annealed core wire are used for the core of the induction coil in order to break up eddy currents, to avoid residual magnetism, and to insure the most rapid collapse of the magnetic field when the primary circuit is broken. In general, the primary winding has from 150 to 225 turns and is wound on the core, the size of wire running from No. 19 to No. 22 A.W.G. From two to four layers are used, and enameled wire is generally employed except on the better grades of coil, in which cotton-covered wire is used. The latter is more resistant to overheating in the event that the user leaves the ignition switch closed when the engine is not operating. Under the latter conditions enamel insulation is likely to lose its insulating value. Many coils, however, are protected to some extent by a resistance unit with a high temperature coefficient so arranged that, if the current becomes excessive, the increasing resistance of the heated resistance unit is sufficient to prevent an excessive flow of current. Another benefit derived from the use of a resistance unit in series with the primary is that it permits of a higher current flow when the engine is being started and the unit is still cool. During operation at low speed, when the primary circuit is closed for comparatively longer intervals, the resistance unit heats and reduces the current flow, whereas at higher speed the reverse effect is secured. This tends to equalize the current and resulting sparks at all speeds.

Secondary windings of No. 38 plain enamel wire are commonly used. About 1 volt per turn is generated, hence if there are 250 turns per layer the difference in voltage per layer approximates 500. Insulating paper is therefore applied between layers, which in the better grades of coil are wound outside the primary. If, as often happens, the insulation between layers of the coil becomes punctured, missing of the engine is likely to occur, especially under heavy loads or at high speeds. In cheaper grades of coils the secondary is sometimes wound next to the core, with the primary outside. Although this is a less favorable arrangement from the standpoint of the magnetic circuit, it makes it possible to eliminate a resistance unit, since the primary is made to act in place of such a unit in addition to performing its normal function. This arrangement also makes possible the use of a less expensive case (stamped metal in place of molded phenolic material) and of a cheaper secondary winding.

COIL AND CONDENSER. In the ordinary ignition system using a coil connected as shown in Fig. 1, when the switch is closed, the current flows through the resistance unit, through the primary winding, through the closed contact points, and back to the battery. Opening of the contact points by the cam provided for this purpose, and driven, of course, in timed relation to the engine, causes a surge of current in the primary and a sudden increase in voltage which, except for a condenser in parallel with the breaker gap, would tend to continue the flow of current in arcing at the gap and result in burning the breaker points. The condenser temporarily absorbs the surge, reduces the arcing, and reverses the direction of current flow in the primary, thus aiding the rapidity of the collapse of the magnet field in and around the core and correspondingly increasing the voltage induced in the secondary winding. The condenser should be of sufficient capacity to prevent excessive arcing at the contact points, but according to some authorities, if it

has sufficient capacity to prevent any visible flash upon breaking of the contact a blue coating will form on the contacts, producing a high resistance and making starting more difficult.

Some observers have contended that so-called hot sparks (presumably those in which a relatively large amount of energy is dissipated) are of little advantage, so long as a spark occurs at all at the spark-plug gap. This belief appears to have been discredited, however, partly because coils of low inductance which build up rapidly and give adequate voltage to jump the plug gap have not proved conducive to easy starting and good operation, especially when the engine is cold. Coils of higher inductance, in combination with cam and breaker designs such as to increase the *dwell* or period during which the contacts remain closed and permit the magnetization of the coil to build up to high values, are said to improve running conditions and be more economical of fuel, especially in engines that are inclined to run too cold in service. In any case, some makers of ignition systems have found it advantageous to use coils of high inductance along with breaker and cam designs such as to increase the period during which the circuit is closed, especially in high-speed engines. The advantages gained are attributed to the larger current induced in the secondary and the resultant increase in spark heat.

MAGNETOS. Highly successful ignition from battery sources has resulted in practically eliminating magneto ignition on American passenger cars and trucks and on many other types of automotive equipment in which a battery is required anyway for lighting and/or starting purposes. This is in no sense an indication that magneto ignition is less successful than formerly, but rather that the higher cost of a magneto equipment is not justified when less expensive and satisfactory ignition means are available. For airplane engines, many forms of industrial engines, tractor engines, and some of the smaller marine engines, magnetos are extensively used with excellent results.

Magnetos are electric generators in which the field is produced by permanent steel magnets rather than by excitation through a field winding. In some cases there is a single primary winding on the rotating armature which produces a low-tension current that is afterward stepped up to sparking voltage in a separate induction coil. More frequently, however, the armature has a high-tension as well as a primary winding and then the magneto is termed a high-tension type. The latter is the most widely used type and is fitted with fixed U-shaped magnets between the ends of which the armature turns. An alternative arrangement, however, involves the use of a primary and secondary winding that are fixed while the magnet or magnets are rotated.

Magnetos are also classified as single-spark and two-spark types, the former being the more common, and having one end of the secondary grounded through the primary while the other end is connected to a distributor. So-called two-spark magnetos have both ends of the secondary insulated and connected through a double distributor to two spark plugs in the same cylinder. With this arrangement the charge is ignited at two points simultaneously. If the points are correctly located, the distance that the flame must travel as combustion proceeds may be materially decreased and the time for combustion correspondingly decreased, often with some increase in power output. The shorter average distance which the flame must travel may also result in avoiding detonation under conditions where otherwise it might occur. Magnetos usually are driven in timed relation to the engine and are fitted with a breaker mechanism by which the primary circuit is opened at the desired instant. High-tension types also incorporate a distributing device for connecting spark plugs successively to the terminal or terminals of the secondary winding.

A further classification of magnetos follows:

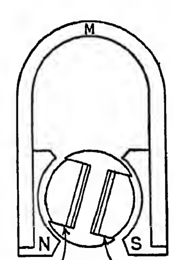

FIG. 9

High-tension Shuttle-type. As shown in Fig. 9, this type has an H-shaped shuttle or armature on which both primary and secondary windings are placed. The armature rotates in ball bearings with a minimum gap between the soft iron laminated pole pieces that are attached to the ends of the U-shaped magnets. The primary usually has about 150 turns of No. 22 wire and is next to the laminated shuttle. Secondary turns may approximate 10,000, the layers being insulated with oiled paper and/or oiled silk. One end of the secondary is usually grounded to the primary and the other is connected to a collector ring which in turn is connected to the central point of the distributor. The latter has a rotating brush which is driven by gearing from the armature shaft within a distributor head having one metal segment for each plug to which the high-tension current is to be led. The rotating brush contacts with or comes close to the metal segments so that the current may be led successively to various spark-plug wires, either by jumping the gap between the rotating arm and the segments or by actual contact of a carbon

brush on the arm with them. The rubbing surface between contact segments against which the brush bears is usually made from vulcanized rubber to minimize the effect of arcing, but the remainder of the distributor is usually molded from phenolic materials which have excellent insulating qualities and are not softened by heat. The electric circuit is closely analogous to that of the battery system, as shown by the dotted lines in Fig. 1. To operate the breaker mechanism two cam surfaces are provided on the breaker cover, which is coaxial with the armature, and a plate carrying the breaker contacts. One of the latter is on an L-shaped lever one end of which strikes the cams as the breaker plate rotates with the armature. This mechanically opens the breaker points. The breaker cover and the cams attached to it can be turned by a lever which is attached to an advance and retard linkage. With this type of magneto there are two sparks per revolution of the armature, hence for a four-cylinder four-cycle engine the magneto is driven at crankshaft speed and for a six-cylinder engine at one and one-half times crankshaft speed.

Inductor-types. Inductor-type magnetos differ from the shuttle-type in that the windings are stationary and the magnets themselves or their pole pieces rotate. A diagram of one inductor-type magneto that has seen extensive use, especially on aircraft engines, is shown in Fig. 10. In this make, the rotating magnets form a bell-shaped structure with either two or four poles. The rotor is made from a special chrome magnet steel, and the poles have laminated extremities which are held in place by an end plate on which a breaker cam is mounted. The rotating magnet, in the design diagrammed in Fig. 10, has four poles, but in other designs of the same make, two poles are used. The pole extremities of the magnets rotate in close proximity to the two pole shoes that are fastened to the core of the coil. The latter has an inner primary winding and an outer secondary winding with a condenser between the two. The paths of the magnetic flux are indicated by the arrows in Fig. 10, the flux being reversed each time that a pole piece passes through the gap between pole shoes. One breaker point is carried on a rocker lever the other end of which has a shoe riding on cam. The cage which carries the pivot for this rocker lever carries the second contact and is pivoted so as to turn about the armature axis in advancing and retarding the spark. Both points are made from an alloy containing 75 per cent platinum and 25 per cent iridium. In this, as in some other magnetos, especially those used in aircraft work, a tap is sometimes provided whereby an external source of high-tension current can be applied during the starting period, connections being as indicated in the diagram.

Other Inductor-type Magnetos of several designs are used to some extent, a schematic drawing of the polar type being shown in Fig. 11. Its coils are wound on a laminated core having extended pole pieces between which rotate a pair of soft iron blocks mounted on opposite sides of a non-magnetic shaft. The outer ends of these blocks form disks which rotate close to the poles of a permanent U-shaped magnet. Four or more pole pieces can be used, the number of sparks produced per revolution being equal to the number of poles. In the **sleeve-inductor-type** magneto there is a fixed shuttle-type armature. Between this and fixed permanent magnet poles rotates a sleeve of non-magnetic material having segments of soft iron. As the sleeve rotates there is a reversal of flux through the armature core. With two segments four sparks per revolution can be produced.

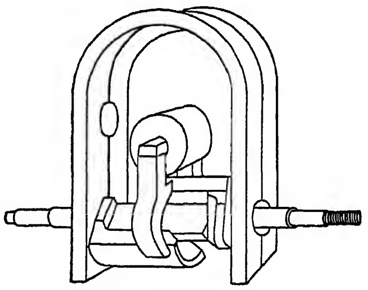

Fig. 11

Miscellaneous Magnetos: Low-tension Magnetos have only a primary winding the current from which must be stepped up in an external coil in order that it may jump a spark-plug gap. Such magnetos sometimes have a self-contained breaker for interrupting the primary circuit unless the coil employed is a vibrating type such as was used in the Model T Ford car. In this case a timer is required to close the circuit through the coil.

Other Types of Magnetos, of which there are many, include the **oscillating type** in which the armature is rotated through part of a revolution against springs and is then released so that it is snapped back across the position of flux reversal, thereby generating enough energy to produce a spark. Another type sometimes used has a single winding comprising many turns of fine wire. Translatory motion of a pair of soft-iron cores into and out of contact with the poles of a permanent magnet reverses the flux with sufficient rapidity to produce a high-tension current that will jump a spark-plug gap.

Impulse Couplings are often fitted between the magneto shaft and the engine shaft

which drives the magneto. Their purpose is to snap the rotating part of the magneto through a fraction of a revolution at a relatively high speed at the instant when a spark is required during the cranking or starting period of the engine, instead of allowing these parts to turn at the slow uniform speed which a positive coupling would impose. This sudden acceleration produces a relatively high voltage and a correspondingly hot spark, which is a decided advantage, especially when the engine and its charge are cold. The coupling includes a spring and latch device so arranged that the spring is wound up during a part of the revolution and is then suddenly released, imparting to the rotating part of the magneto a momentary angular velocity equivalent to that at about 800 rpm uniform speed. When the engine starts and the magneto attains a speed of 150 to 200 rpm a centrifugal device renders the latch inoperative and the coupling then functions at a normal uniform angular velocity.

Combination Ignition Systems, involving two or more systems that are more or less independent but to some extent interconnected, were widely employed, chiefly on automobile engines, at one time. The terms " dual," " duplex," " double," and " two-spark " have been used in different senses by different makers who have sought to increase dependability, provide more convenient starting, or boost the power output of the engine by this means. Today such combinations are not common, largely because of their added expense and because the degree of dependability of a single system is sufficient to meet most requirements. At least one American automobile manufacturer, however, fits so-called " twin " ignition, involving the use of two spark plugs per cylinder, on some models, and motor-coach manufacturers apply two more or less independent ignition systems to some bus engines. Combinations of magneto and battery ignition, once very popular, are seldom employed today.

CYCLE OF OPERATION. There are four periods in the cycle of operation of all jump-spark systems, each marked by an abrupt change in conditions: During the *first period*, the impressed voltage from the battery or magneto builds up the primary current and consequent storage of magnetic energy. With a battery system the build-up is exponential and gradually approaches the closed-circuit value. In the magneto, the emf wave is peaked, the short-circuit current wave at moderate and high speeds being flat-topped but of sufficient value to produce a spark if the break occurs over a 90-deg electrical half wave. At slower speeds the current wave is more peaked and the spark can be produced only over a narrower range of timing. The normal current at break ranges from 3 to 5 amp. The inductance of the magneto is usually greater, hence the heat energy in the spark is greater. Discharge of the battery on the closed circuit or the operation of the magneto as a short-circuited a-c generator is suddenly interrupted by the opening of the breaker contacts, introducing the second period.

The *second period* is of extremely short duration (of the order of 0.00005 sec) and extends from the opening of the breaker contacts to the initiation of the spark at the spark-plug gap. At the start of this period the primary current continues to flow unabated, charges the condenser, and introduces a back emf into the primary circuit. This decreases the primary current and the resultant flux in the core, and induces in the secondary a voltage which is higher than that of the primary in approximately the ratio of the number of turns, or from about 50 or 60 to 1. The secondary is thus charged as a condenser, one " plate " of which is the secondary winding, distributor, and spark-plug leads, and the other the engine and other grounded metal parts of the assembly. When the charge is sufficient to jump the gap at the spark plug, the discharge occurs, often when only a small fraction of the magnetic energy available has been transformed.

In the *third period*, immediately following attainment of the breakdown voltage of the gap in the second period, the gap becomes conducting and the secondary " condenser " discharges through it. After completion of this condenser discharge there follows the *fourth period* during which the magnetic energy still left in the coil continues to deliver an inductive spark for several thousandths of a second until the entire energy is dissipated. The spark delivered by a magneto is usually of longer duration than that delivered by a battery system, both because of the greater amount of stored magnetic energy and because the voltage generated in the secondary by continued rotation (if the spark is sufficiently advanced) may force an additional flow of current across the gap.

According to M. Mallory, a spark of low amperage and high voltage may jump the gap at the plug and still not ignite the mixture because the heat generated is insufficient. Under these conditions it is practically impossible to secure good engine performance. Again, a weak spark, even though it may ignite the charge, may result in burning so slowly as to cause back-spitting in the carbureter, indicating that the mixture is still burning when the intake valve opens to admit a fresh charge. This is true especially when the engine is cold. A lack of sufficient heat in the spark may result from too wide a gap at the spark plug, a gap in some other portion of the secondary circuit, an inadequate or imperfect

ignition coil, too short a dwell, leakage (or so-called " corona " effect) resulting from deterioration of the insulating qualities of secondary wiring, and several other factors. As engine speed increases, the length of time that the primary circuit remains closed decreases with a corresponding decrease in the time available for building up the flux in the core. The result is a weaker spark with more or less tendency toward missing at very high speed.

COIL PERFORMANCE. Fig. 12 shows the current output of three coils over wide ranges of speed. Curve *A* indicates good performance at engine speed up to about 1800 rpm, but above this speed the output is low and becomes zero at a little over 2200 rpm. At low speed and in starting, coil *A* is much better than coil *B*, but at high speeds, as shown by curve *B*, this coil continues to give a spark up to speeds approximating 4500 rpm. Its maximum output, however, never exceed 1.3 milliamperes. Coil *C*, as shown by curve *C*, has a higher output than either *A* or *B* through most of its range and a maximum more than twice as great as coil *B*. A coil such as *C*, if made with one secondary winding, would be costly, bulky, and difficult to insulate as there would be about 1000 volts pressure difference between layers. Outer layers would be far from the core and the length of winding so great as to increase the resistance to a point where it would affect performance. To avoid such drawbacks, some coils have been made with two secondary windings (on an elongated core) connected in series. In this case insulation problems are less difficult, the diameter is reduced, despite the use of larger wire of lower resistance, and a total of 30,000 turns, or 15,000 per coil, is feasible. Such coils give good starting

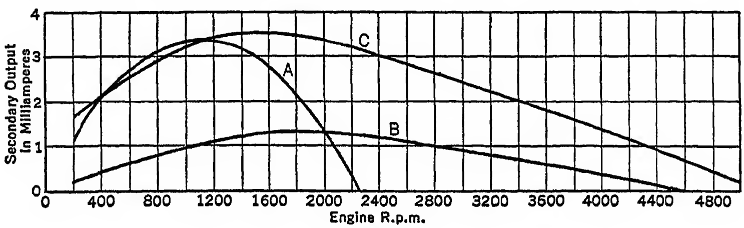

FIG. 12

sparks on only 2 volts and with a properly designed circuit breaker and distributor meet the requirements even of an eight-cylinder engine at speeds up to 5000 rpm.

During the starting period of engines that are cranked by a motor driven by energy from a storage battery, the heavy drain on the battery may drop its voltage as low as 2 volts, especially when the engine is cold. As ignition current is taken from the same battery during this period, only 2 volts may be available at the primary. This, together with the need for a hot spark under these conditions, imposes a difficult problem upon the designer of ignition coils. This has led to the development of so-called automatic coils, designed to give a hot spark at low voltage and automatically accommodating themselves to the higher voltage which obtains when the engine picks up speed and the generator raises the voltage to about 8 volts.

SPARK TIMING. To obtain maximum power output and greatest fuel economy from an engine depending upon electric ignition it is necessary to vary the timing of the spark with changes in speed and in throttle opening. This is partly because the time interval for completion of the engine cycle decreases in direct proportion to increase in speed and partly because the rate of combustion is influenced by changes in compression pressure which varies in turn (in the four-stroke throttling type of engine) with changes in throttle opening. For many years, hand setting of the spark timing device was depended upon to provide the optimum setting, and this method is still used extensively. Its chief disadvantage lies in dependence upon the human element, as its success, if best results are to be secured, depends upon the skill and willingness of the operator in varying the setting with changes in conditions. One alternative sometimes resorted to is to select the best fixed setting for average running conditions and permit the advance to remain at this fixed setting regardless of changing speed and load conditions, with the exception that a retard is provided to prevent a back kick in starting.

Automatic Spark Timing Controls. Two general types of automatic spark advance and retard mechanisms are now in quite general use either separately or in combination and with or without an added manual control. The first type is operated by a centrifugal governor designed to advance the spark with increase in speed but not necessarily in direct proportion thereto, although some designs have this objective. It should also be either capable of adjustment or especially designed for the particular engine, as engines

vary greatly in the degree of advance required, some needing only 10 deg or less and others requiring as much as 50 deg. Good centrifugal governors are generally considered a decided improvement over dependence upon hand advance mechanisms and are now extensively used. They have the disadvantage, however, that they are controlled only by variations in speed and not by changes in load.

Use of a vacuum-control, in addition to centrifugal control, has been made to overcome the disadvantage of a centrifugal device alone. The difference in pressure which actuates the device is that which exists between the interior of the inlet manifold of the engine and the atmosphere. Manifold depression decreases as the throttle is opened to meet increases in load, and increases again when the throttle is closed with decrease in load. Since spark advance should be greater when the throttle is closed, because the compression pressure is then lowered and flame propagation is then less rapid, the vacuum control is so arranged that the advance is increased as the load falls off, and vice versa. This type of control is superimposed upon that effected with a centrifugal governor, so that the combined effect is one of speed and load, as is desired.

SPARK PLUGS. (See also under Ignition of Gases.) The function of the spark plug is to provide a gap having a fixed breakdown voltage between two electrodes one of which is almost always grounded to the shell of the plug, which has a male thread and is screwed into a threaded hole in the wall of the combustion chamber, and the other (the central electrode) is insulated and connected to the secondary of the ignition coil. Among the requirements sometimes imposed by purchasers of spark plugs are the following: The voltage necessary to produce a spark shall not exceed 6000. Insulation resistance shall not be less than 100,000 ohms. The plug shall be substantially gas tight. In practice these conditions sometimes must be fulfilled under pressures as high as 1000 lb per sq in., and in the presence of gases that vary rapidly in temperature from atmospheric to 3000 deg fahr or above and frequently tend to deposit carbon on the surface of the insulator.

The electrode passes through the center of a vitreous ceramic insulator and is cemented in place in good electrical contact with a brass cap for receiving the secondary lead. Shells are of steel and are either crimped or spun over a shoulder on the insulator in such a way as to hold the latter permanently in gas-tight contact with a seat, or are provided with a threaded bushing which performs the same function but enables the insulator to be removed for cleaning and inspection. Gas-tight joints are essential, for if appreciable leakage occurs the flow of hot gases between the shell and the insulator is likely to cause overheating with consequent preignition of the charge. Most modern spark plugs have straight central electrodes. The grounded electrode is usually an L-shaped piece of wire one end of which is pressed into a hole in the shell and often welded to the shell to insure the good thermal contact which is necessary to prevent overheating. Electrodes are made from relatively non-corrosive wire usually containing a considerable percentage of nickel. Authorities differ as to the best setting for the gap. The optimum setting depends partly upon the compression of the engine and partly upon the voltage which the ignition system is capable of generating under the operating conditions that obtain. One authority recommends a gap of 0.015 to 0.018 in. for high-compression engines and of 0.018 to 0.022 in. for low-compression engines. Others recommend an average setting of 0.025 to 0.030 in., but advocate following the specific recommendations of the engine manufacturer or maker of the ignition equipment. It is probable that gaps in excess of 0.035 in. should not be used, as they are likely to result in leakage in the external secondary circuit. Gaps that are set too close are likely to result in excessive burning of electrodes and in rough engine performance. In setting the gap it is recommended that only the grounded electrode be bent, as bending of the center electrode is likely to result in breakage of the insulator at the time or later when it is heated in use.

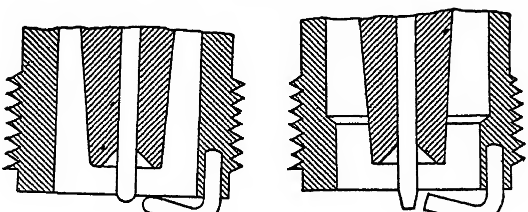

Fig. 13

Insulators in most modern spark plugs have what is termed a "semi-petticoat" tip such as is shown in Fig. 13. With this shape there is a heat gradient which prevents the lip or relatively thin edge from overheating but at the same time keeps it hot enough to burn off oil or carbon that may be deposited on it. Much care is usually exercised in locating the spark plug where the shell and the insulator in contact with it will be properly cooled, as otherwise overheating with consequent preignition is likely to result unless

conditions are such that the engine normally runs rather cool. On the other hand, excessive cooling of the plug is likely to result in fouling of the insulator with consequent formation of a high-resistance shunt across the gap. For these reasons, many plugs are specially designed to meet the particular cooling conditions that exist in engines of various types. Thus there are hot-running plugs for cool-running engines and cool-running plugs for hot-running engines, and it is important that the right plug for the particular conditions encountered be selected. Plugs designed to run hot in cold engines have an insulator that is relatively long from its firing end to the shoulder where it seats against the shell. Plugs designed to run cool in hot engines have an insulator which is relatively short between the points mentioned, so that the heat is conducted away from the hottest end more rapidly.

Spark-plug shells are also varied in length so as to fit into heads of differing thicknesses and in some cases to bring the spark gap well away from the inner wall of the combustion chamber so that the gases, which are rendered turbulent as a result of velocity imparted during the intake and compression stroke, may sweep across the gap during the ignition period. In some cases this velocity exceeds the rate of flame propagation, and the turbulence is depended upon to spread the flame quickly to parts well removed from the point of ignition. In some engines this turbulence is presumed to prevent or to minimize detonation by helping to bring about combustion before a wave of detonation velocity can be set up. Many engine manufacturers have made extensive tests to determine the best type, location, and size of spark plug to be used, and when new plugs are installed it is usually desirable to make sure that they duplicate the type selected as a result of such tests. Plugs used in **aircraft engines** that are air-cooled often run at much higher temperatures than are prevalent in conventional water-cooled engines, and in some instances special cooling provisions are required for the plugs of such engines, especially as high compressions and high specific power output are required in the average case. The combined cooler and radio shield used on some Wright aircraft engines is shown in Fig. 14. The finned shell is entirely of aluminum and is in intimate thermal contact with the cylinder. Its use resulted in a temperature drop of about 100 deg fahr in plugs fitted to the rear of the engine in question. With the cooler, erosion at the gap was less in 50 hours of service than in 10 hours on a plug not fitted with a cooler. The cooler also provides an effective shield against radio interference such as is required in planes fitted with radio equipment.

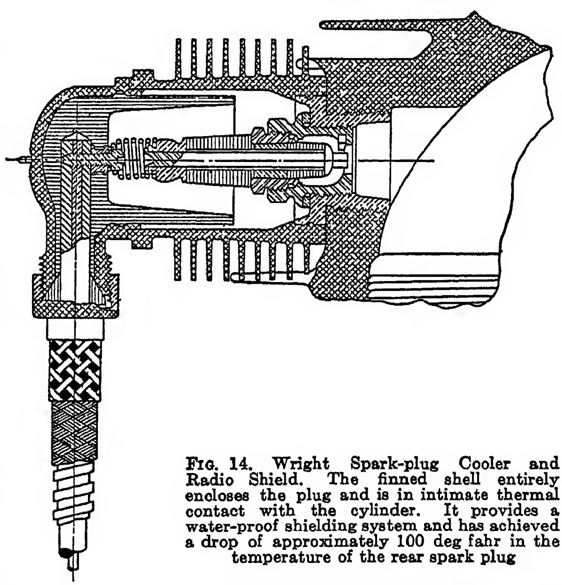

FIG. 14. Wright Spark-plug Cooler and Radio Shield. The finned shell entirely encloses the plug and is in intimate thermal contact with the cylinder. It provides a water-proof shielding system and has achieved a drop of approximately 100 deg fahr in the temperature of the rear spark plug

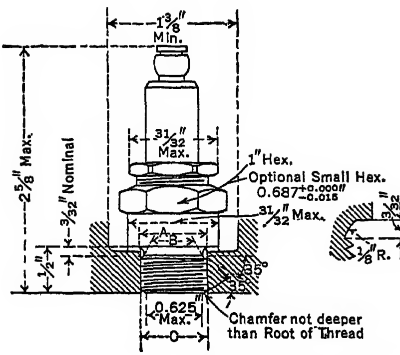
Spark-plug Standards. Three sizes of spark plugs are in more or less general use in this country, namely, the 1/2-in., the 7/8-in., and the 18-mm, the last-mentioned being generally used also in Europe. The 1/2-in. size has a standard 1/2-in. Briggs pipe thread. There are 14 threads per inch, and, as the thread is tapered, no gasket is required to make a tight joint. This size of plug is now rapidly going out of use. Shells having 7/8-in. and 18-mm threads have been standardized by the Society of Automotive Engineers, as shown by accompanying tables, and now are almost universally used on American automotive engines, the 18-mm size being especially recommended for aviation and other high-compression engines. Both the 7/8-in. size, which has 18 threads per inch, and the 18-mm size, which has 1 1/2 mm pitch (about 16 3/4 threads per inch), have straight threads and depend upon seating against a gasket to insure a gas-tight joint. Terminal posts for attachment of secondary leads to the upper ends of the plugs have also been standardized by the S.A.E. in accordance with dimensions given in Fig. 15.



Thread—18 mm diameter; pitch 1 1/2 mm.
Form of thread—International standard (same as American Standard except 1/2 as much truncation at root of thread).
Clearance—Minimum distance from terminal to nearest metallic object, 3/4 in.

SPARK-PLUG DIMENSIONS*

Dimensions	Maximum		Minimum	
	Mm	In.	Mm	In.
A	18.50	0.728	18.00	0.709
B	.....	0.633 †	.....	0.625
C	17.97	0.708	17.85	0.703

* These dimensions are the same as those of the regular S.A.E. metric spark-plug specifications.

† The thread and body dimensions, excepting the depth of chamfer at the skirt of the plug, are substantially in accordance with those recommended by the Inter-Allied Aircraft Standards Conference at London in April, 1918.

Fig. 15. Aeronautic Spark-plugs. S.A.E. Standard

Mountings for magnetos, as well as for timer-distributor units, the latter as used with battery ignition systems, have been standardized by the S.A.E.

18. STARTING AND LIGHTING SYSTEMS

The items comprising the electric starting and lighting equipment of a gasoline automobile are (1) the generator, (2) storage battery, (3) starting motor, (4) lamps, (5) wiring, (6) switches, cut-outs, and fuses, (7) ammeter. In the so-called single-unit systems the generator and starting motor are combined in a single unit, but this type of system is now almost obsolete. The battery is used not only to supply energy for starting and lighting but also for ignition and often for operating supplementary apparatus such as windshield wipers, cigar lighters, and radio receiving sets.

Generator

Practically all generators now employed on passenger cars are shunt wound. They are driven by the engine, sometimes through gears or silent chains, but more often by belts which as a rule are V-types. The primary function of the generator is to keep the storage battery, which floats on the line, charged, but in some installations, especially on buses, the generator is sometimes designed to carry the lighting and ignition load even though the battery becomes disconnected. Since with a shunt-wound generator the voltage normally varies in substantially direct proportion to the speed, and the speed constantly varies with changes in engine and vehicle speed, means for maintaining a nearly constant voltage have to be applied.

BATTERY CUT-OUT. To prevent the battery from discharging through the generator when the battery voltage exceeds that of the generator, it is usually necessary to provide an automatic switch, variously termed a cut-out, a circuit breaker, and a reverse-current relay, designed to open the circuit when the speed of the generator falls below that at which the battery is charged. A relay of this type is shown in Fig. 16; the wiring diagram, Fig. 17, shows the two windings of the relay and how it is connected in a normal automobile electric system. Essentially the relay consists of an iron core with a shunt and a series winding. The shunt winding is connected permanently across the main generator terminals, one of which is usually grounded. It serves to magnetize the core and attract a hinged armature as soon as the voltage is high enough and the magnetizing force great enough to overcome the tension of a spring which tends to hold the armature away from the core. When the armature is attracted, it closes a pair of contact points,

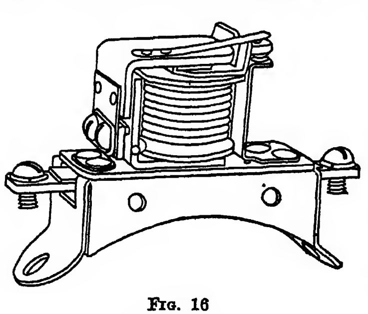


Fig. 16

thereby closing the battery circuit and also the series winding circuit of the cut-out. The additional flux added by this winding presses the contacts more firmly together. Both the spring and the stops that limit the travel of the armature of the relay are usually so set that the contacts close at 7 to 7.5 volts, equivalent to a charging rate of about 3 amp, with an ordinary automobile type relay for a 6-8-volt system. Contacts open again at a discharge current not greater than 2.5 amp, when the series coil bucks the shunt coil and decreases the pull on the armature enough for the spring to pull it away from the core. In general

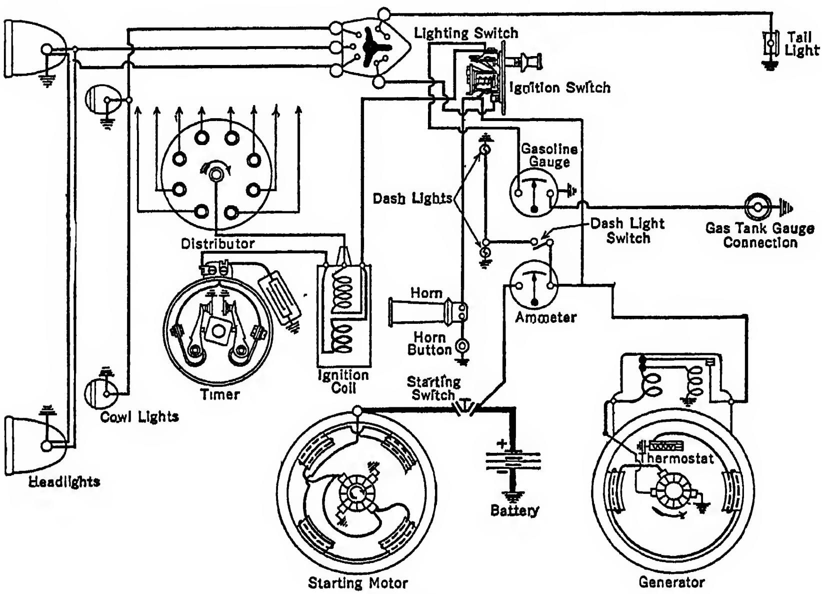

Fig. 17

this actuation of the relay takes place at an engine speed of about 600 rpm, equivalent to a car speed, in high gear, of around 10 mph.

COMMON TYPES OF VOLTAGE CONTROL. Only two types of voltage control are now in extensive use, and of these by far the most widely employed is the third-brush system. The other form is a vibrator regulator, which is most frequently employed on third-brush generators. A regulator operating upon a thermostatic principle has also seen some use in recent years, but it too is applied to third-brush generators. Like the vibrator regulator, its true function is to control the charging rate at the battery and to prevent overcharging of the battery with consequent gassing and loss of electrolyte.

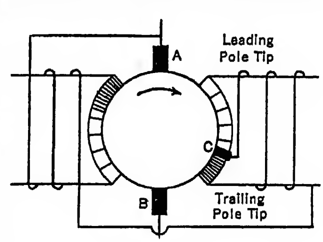

Fig 18

Third-brush Regulation. In this system, use is made of the distorting effect of armature reaction. When current flows through the armature, the resultant flux is skewed around in the direction of rotation (see Fig. 18), with the result that the number of lines of force entering the armature from the leading pole-tip is reduced and a corresponding increase in the number of lines of force takes place at the trailing pole-tip. Consequently, referring to Fig. 18, it is evident that the electromotive force generated between the brush A and the third brush C, located as shown, will decrease as the current through the armature increases. If the shunt field is connected between the brushes A and C, the current through the shunt field will therefore decrease as the current in the main circuit increases, which in turn will reduce the electromotive force between A and C still further. Consequently, if the battery is connected across the main brushes A and B, any tendency for the current to the battery to increase when the speed of the generator increases is counteracted by the

decrease in the field current. Such a generator when connected to a storage battery tends to act as a constant-current machine, irrespective of the speed. As a matter of fact, because of the effect of the short-circuit current in the coil passing under the brush *C*, which current is practically proportional to the speed and which produces a demagnetizing action, the current to the battery actually reaches a maximum value at a definite speed and then falls off.

The maximum current supplied to the generator is readily controlled merely by shifting the position of the intermediate brush. For a full treatment of the theory of third brush regulation, see Langsdorf's Principles of Direct-current Machinery.

Among the advantages of the third-brush control system are its simplicity and the fact that it requires, in most instances, no supplementary apparatus outside the generator. It also permits of ready variation of the current output by the simple expedient of shifting the brush. Shifting the brush in the direction of armature rotation increases the output, and shifting it in the reverse direction decreases the output. The output rises slightly as the battery becomes charged, and it is this characteristic that gives rise to overcharging of the battery when the output of the generator continues to progress much more rapidly than the battery is being discharged. It is partly to avoid this disadvantage that supplementary voltage regulators or battery charge regulators are sometimes used. Another reason for the use of voltage regulators is that, without them or some other protective device, an open circuit or high resistance in the charging circuit of a third-brush generator results in a rapid rise in voltage which is likely to burn out all the lights or cause a sufficiently heavy overload on the generator to damage its windings. A protective fuse in the field circuit of the generator is frequently provided.

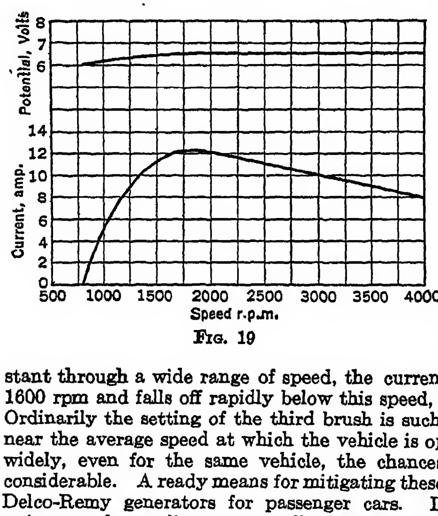

Fig. 19

In Fig. 19 are given the characteristic potential and current-speed curves of a third-brush 6-8-volt generator with a battery load. Although the voltage remains substantially constant through a wide range of speed, the current output reaches a maximum at about 1600 rpm and falls off rapidly below this speed, while above it the decrease is less rapid. Ordinarily the setting of the third brush is such that the peak of the curve comes at or near the average speed at which the vehicle is operated, but since this speed often varies widely, even for the same vehicle, the chances of overcharging or undercharging are considerable. A ready means for mitigating these disadvantages is that employed in many Delco-Remy generators for passenger cars. It consists of a simple thermostat and resistance shown diagrammatically in Fig. 20 and connected in the field circuit of the generator as shown in Fig. 17. This thermostat is placed inside the field frame of the

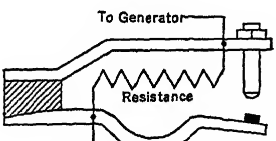

Fig. 20

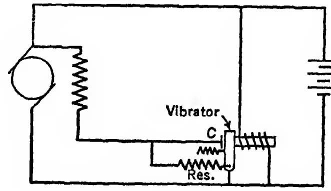

Fig. 21

generator, where the bimetallic element (the lower one in Fig. 20) is subjected to variations in the temperature of the generator itself. When the temperature rises to or about 165 deg fahr the contacts open and cut the resistance into the generator field circuit. The effect of this change is to decrease the output of the generator and thereby to lower its temperature. The resistance element, which is made easily replaceable, also acts as a fuse to protect the generator in case an open circuit occurs between the generator and the battery.

In starting, considerable current is drawn from the battery, so that, after starting, a

high charging rate is desirable. As the generator is then cold, the thermostat contacts are open and the field resistance is cut out, so that the high charging rate is secured. By or about the time that the energy taken from the battery in starting is replaced, the generator will have become warm and the contacts of the thermostat will open, cutting in the resistance and lowering the charging rate to a point where overcharging of the battery is unlikely to occur. If the car is used extensively for long trips with few stops, especially in warm weather, it sometimes becomes necessary to burn the headlights during the day or to resort to some other expedient to avoid overcharging of the battery. One of these is the voltage or battery-charge regulator designed to decrease the charging rate as the battery becomes charged. Such regulators are of special importance in buses, where the lighting load is likely to be heavy and a large generator with a high charging rate is required.

Vibrating Voltage Regulators. A simple form of voltage regulator is shown in diagram in Fig. 21. An external resistance is included in the field circuit, which resistance is short circuited when the vibrator is in contact with the contact *C*. When the vibrator is pulled away from the contact *C* by the electromagnet the resistance is inserted in the field circuit and the field current is thereby reduced. As long as the vibrator is operating, the field current varies between maximum and minimum values, and its average value depends upon the rate of vibration. The rate of vibration in turn depends upon the voltage across the winding of the electromagnet, and a very small increase in this voltage causes a relatively large increase in the rate of vibration, and therefore makes a substantial decrease in the average value of the field current. Consequently, as the speed of the engine varies, thereby tending to produce a varying voltage at the generator terminals, this tendency is counteracted by the reduction in the field current, so that the terminal voltage of the generator remains substantially constant for all values of the speed.

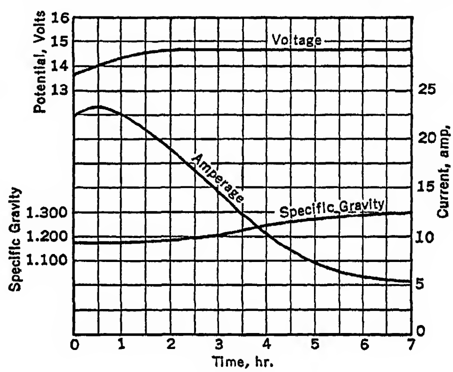

FIG. 22

Since the regulator holds the voltage substantially constant and that of the battery gradually increases as charging progresses, the voltage differential, and therefore the rate of charging, become steadily less as charging proceeds. In Fig. 22 is given a characteristic curve showing how the charging current of a voltage-controlled generator falls off as the battery becomes charged, until the current delivered assumes a low and almost constant value which is only slightly in excess of that normally consumed by the ignition system of the engine which drives the generator.

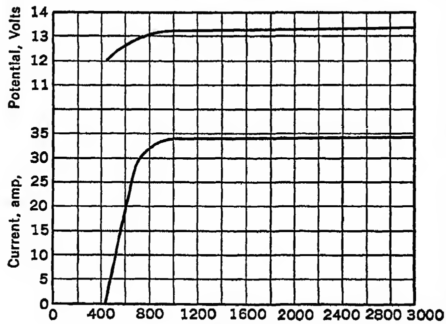

FIG. 23

Fig. 23 shows typical performance curves of a voltage-controlled generator operating with a battery load. It will be seen that both the voltage and current remain substantially constant over a three to one speed range from about 900 to 3000 rpm.

In a paper entitled "Generation of current for automotive apparatus" (*J. Soc. Automotive Engineers*, June, 1928, p. 658), from which Figs. 19, 22, and 23 are reproduced, B. M. Leece states the advantages of the voltage-regulated generator, which may be summarized as follows:

1. Connected batteries cannot be overcharged.
2. The rate of charge is proportionate to the need for charge, and gives a desirable trickling charge at the end.
3. There is less boiling away of battery electrolyte, hence less frequent filling is required.
4. Battery life is greatly increased.

5. Loose or corroded battery terminals do not cause excessive voltage with consequent burn-out of lamps.

6. Lamps can be operated directly from the generator when engine is running without a battery connected.

7. Generator output is proportional to load: no waste in overcharging battery.

8. In general, the generator can carry its load without assistance from the battery.

9. According to one large-scale operator of motor coaches, the cost of operating batteries from a voltage-regulated generator is as low as 0.0015 cent per coach-mile.

Constant voltage is beneficial in improving the performance and increasing the life of lamps as compared to systems in which the voltage constantly varies.

Thermostatic Battery-charge Regulator. Another form of regulator operated by a thermostat and shown diagrammatically in Fig. 24 has been produced by Owen-Dyneto and used on Packard cars. It has two arms of thermostatic bimetal, *k* and *l*, set firmly into an insulated block *n*, which can turn about the pivot *o*. The lower arm *l* is held by the spring *p* against the screw *q*, at the same time tending to rotate the arm *k* downward and close the contacts *r*, around which the resistance *s* is shunted. Thus *r* and *s* are in parallel and together are in series with the field of the generator, and the fuse *t*. Arm *l* is bare and consequently is affected thermostatically only by the atmosphere. Its purpose is to compensate for seasonal temperature changes in such a way as to give a higher charging rate in cold than in hot weather. Arm *k*, however, is wound with a heating coil of resistance wire which is connected directly across the generator and battery terminals. Its temperature varies, therefore, with the battery potential, being higher when the battery is fully charged and lower when it is discharged. When the battery is fully charged arm *k* becomes hot enough to open the contacts *r* and thus to throw the resistance *s* into series with the field, thereby reducing the generator output to such a value that the battery cannot be overcharged. Screw *q* is so adjusted that the contacts open when the battery is properly charged and just before the gassing point is reached. The generator is provided, of course, with the usual reverse current relay (not shown) for opening the circuit when the generator speed falls below the charging speed.

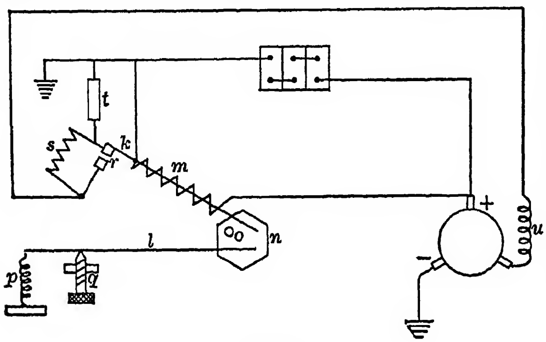

Fig. 24

GENERATOR MOUNTING STANDARDS. Generators for automotive lighting systems are usually mounted by a flange which bolts to the crankcase of the engine, but in some cases a base mounting is employed. Some of the larger generators such as are used in motor coach service employ a combination of flange and base mounting. Generators for some of the smaller cars are mounted on hinge pins in such a way that the generator can be swung about the pin to tighten the belt that drives the generator pulley. Three standard forms of mountings have been adopted by the Society of Automotive Engineers, each of which involves a standard shaft end such that generators are made readily interchangeable. There are also S.A.E. standards for generator brushes and cable terminals.

19. BATTERY

Storage batteries of the lead-acid type are universally employed. In general, jars are of hard rubber and usually are assembled in a one-piece molded case of acid-resisting material. All up-to-date American passenger cars are fitted with three-cell (nominally 6-volt) batteries, but motor coaches often use the six-cell type, and still higher voltages are required in some forms of automotive applications. Ampere-hour capacities for passenger cars vary from about 60 up to 140, but considerably larger batteries are used in some buses and for certain other automotive applications, notably in motor boats. Batteries for the smaller cars weigh from 55 lb upward, and the largest American cars have batteries weighing about 80 lb.

A number of standards covering dimensions and ratings for storage batteries have been adopted by the Society of Automotive Engineers. A summary of the more important follows:

Ratings. Batteries for combined starting and lighting service shall have three ratings, except as noted. The first rating shall indicate the lighting ability and shall be the capacity in ampere-hours of the battery when it is discharged continuously to an average final terminal voltage equivalent to 1.75 per cell, the temperature of the battery at the beginning of such discharge being 80 deg fahr, and an average temperature of 80 deg fahr being maintained during discharge, with a maximum variation of ±5 deg fahr from 80 deg fahr at the 20-hr rate for passenger-car and motor-truck service and at the 8-hr rate for motor-coach service. New batteries shall meet these ratings on or before the third discharge when discharged at a rate in amperes obtained by dividing the rated capacity in ampere-hours, as shown in the following tables, by the number of hours at which the rating is specified. The second rating shall be the minimum amperes when the battery is discharged continuously at the 20-min rate to an average final terminal voltage equivalent to 1.5 per cell, the temperature of the battery at the beginning of such discharge being 80 deg fahr. New batteries shall meet this rating on or before the third discharge, when discharged at the rate in amperes specified in the following tables. The third rating shall apply only to batteries used in passenger-car and motor-truck starting and lighting service. This rating shall indicate the cranking ability at low temperature, and shall be the minimum time in minutes when the battery is discharged continuously at 300 amp to an average final terminal voltage equivalent to 1 volt per cell, the temperature of the battery at the beginning of such discharge being 0 deg fahr. The batteries shall be prepared for this test by being placed in an atmosphere of 0 deg fahr ±1 deg fahr for not less than 24 consecutive hours and are to be tested in an atmospheric temperature of 0 deg fahr. New batteries shall meet this rating on the first discharge of a battery which has been fully charged following an initial discharge for 5 hr at a rate in amperes equal to one-seventh of the 20-min rate in amperes specified in the following tables, the temperature of the battery at the beginning of such preliminary discharge being 80 deg fahr.

Table I. Low-plate Type

S.A.E. Battery No.	No. of Cells	Minimum Capacity at 20-hr Rate, amp-hr	Minimum Current for 20 Min, amp	Minimum Time at 300 Amp and 0 Deg Fahr, min	Maximum Overall Dimensions, in.		
					Length * L	Width W	Height H
1	3	85	100	1.70	9 1/8	7 1/4	9 1/4

27	6 †	118	160	21 5/16	11 7/16	10 7/8

* Side to side assembly of cells.
† Double row end-to-end assembly of cells.

Batteries 11 and 12 are for lighting service only; batteries 13, 14, and 15 are for combined starting and lighting service.

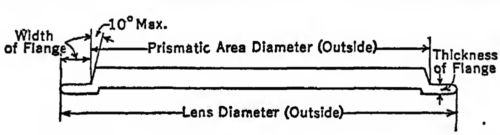
20. LAMP EQUIPMENT

Lighting equipment on most automotive vehicles includes a pair of headlamps, usually a separate pair of side (cowl or fender) lamps, a tail lamp (two often used) and various supplementary lights for illuminating instruments and body interiors, for stop signals, and for other purposes. Many states have stringent regulations governing the construction and adjustment of headlamps and in some cases of tail lamps, and often specifying the candlepower of the incandescent light source. The S.A.E. has standards covering all dimensions and tests of lamp equipment.

HEADLAMPS. The following is a summary of S.A.E. recommended practice pertaining to the construction of headlamps:

Means for holding the incandescent lamp base firmly should be provided. Both the focusing socket guide and the socket itself should be of non-ferrous metal. Not more than one focusing adjustment should be necessary, and the focusing screw should be readily accessible from outside the lamp. The focusing mechanism should permit of a 5/32-in. adjustment both forward and back of the focal point of the reflector. It should also maintain the relative position of lamp and reflector when the door and lens are removed. Paraboloidal reflectors should produce a beam, a normal section of which, at 100 ft from the lamp, should be entirely within a 105-in. circle. The mounting should be in the vertical center plane of the lamp, and fenders should not be tied together through the headlamps.

Table V. S. A. E. Standard Headlamp Lenses and Prismatic-area Diameters



Outside Diameter		Diameter of Prismatic Area, in.		Outside Diameter		Diameter of Prismatic Area, in.	
Wide Flange (Approx. 1/2 in.)	Narrow Flange (Approx. 1/4 in.)	Maximum	Minimum	Wide Flange (Approx. 1/2 in.)	Narrow Flange (Approx. 1/4 in.)	Maximum	Minimum
8.00	7.50	6.980	6.955	10.75	10.25	9.730	9.705
8.25	7.75	7.230	7.205	11.00	10.50	9.980	9.955
8.50	8.00	7.480	7.455	11.25	10.75	10.230	10.205
8.75	8.25	7.730	7.705	11.50	11.00	10.408	10.455
9.00	8.50	7.980	7.955	11.75	11.25	10.730	10.705
9.25	8.75	8.230	8.205	12.00	11.50	10.980	10.955
9.50	9.00	8.480	8.455	12.25	11.75	11.230	11.205
9.75	9.25	8.730	8.705	12.50	12.00	11.480	11.455
10.00	9.50	8.980	8.955	12.75	12.25	11.730	11.705
10.25	9.75	9.230	9.205	13.00	12.50	11.980	11.955
10.50	10.00	9.480	9.455				

HEADLAMP MOUNTINGS. Headlamp centers (according to S.A.E. standards) should be not less than 32 in. nor more than 42 in. from the ground, 36 in. being the preferred height.

HEADLAMP LENS DIMENSIONS. Standard dimensions for headlamp lenses adopted by the S.A.E. are given in Table V. The thickness of lens flange for the first 12 diameters listed in the table is $^5/_{32}$ in. at the edge of the prismatic area and not less than $^1/_8$ in. at the edge of the lens. For other sizes the corresponding dimensions are $^3/_{16}$ in. and $^1/_8$ in., minimum, respectively. The rear surface of the lens flange is plane. A lens notch, $^{17}/_{32}$ in. wide at the periphery, and $^3/_{32}$ in. deep, is located at the bottom of all lenses, except those having no prismatic structure, to insure correct location of the lens and prevent turning under vibration.

TAIL AND SIGNAL-LAMP LENS DIMENSIONS. S.A.E. standard for tail-light lenses provides that their diameter shall be 3 in. The minimum light opening shall be 2 $^1/_2$ in. Lens diameters for stop lights shall be 4 $^1/_2$ and 6 in., the minimum light opening in the lamp door being 3 $^1/_2$ and 5 in., respectively.

INCANDESCENT LAMPS. S.A.E. standards for incandescent lamps for automotive use provide that the nominal voltage shall be 6–8 or 12–16, for use respectively with three-cell and six-cell batteries. It is also provided that all such lamps for use in head lamps shall be of the gas-filled type and of 21 or 32 cp. Various filament forms in use are illustrated in Fig. 25. S.A.E. standard dimensions for incandescent lamps are given in Table

Table VI. Electric Incandescent Lamps

Dimension	G–6	S–8	S–10 *	Dimension	G–6	S–8	S–10 *
A—Aver...	3/4	1	1 1/4	C † Aver...	3/4	1 1/8	1 1/4
B—Aver...	1 7/16	2	2 3/8	D Max. ..	0.320	0.320	0.320

* The corrugations on electric incandescent lamps for headlight service shall be of sufficient depth to break up the filament image.

The spacing between the filaments of the depressed-beam or two-filament type of incandescent lamp shall be 0.140 in. ±0.016 in.

† Light-center length and axial alignment tolerances for headlight lamps are ± 3/64 in.

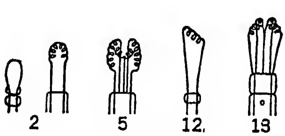


FIG. 25

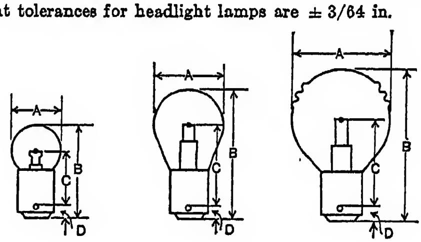

FIG. 26

VI, which refers to the dimensions shown in Fig. 26. Some lamps are provided with dual filaments one of which is so disposed in reference to the reflector as to give a depressed beam from a headlamp. As shown in Fig. 26, the S10 bulb is provided with corrugations which are intended to break up the filament image resulting from the use of a spherical surface. Bases are of the bayonet type, and some have single and some double contacts. Triple-contact bulbs are also used in connection with double-filament lamps. Standard bases, sockets, plugs, caps, and connectors are standardized by the S.A.E. Data on incandescent lamps published by the S.A.E., but not incorporated in its standards are given in Table VII. Bulb types refer to Fig. 26 and filament form to Fig. 25.

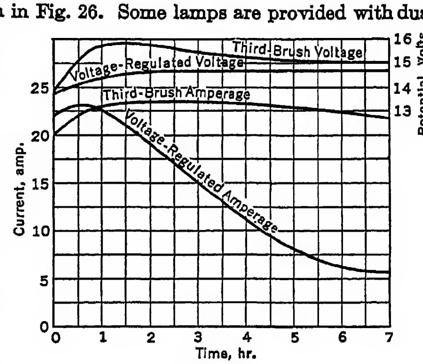

FIG. 27

Incandescent Lamps, Operating Characteristics. Although an increase of voltage from 6 to 7 increases the candlepower from 16.2 to 27, the life of the lamp is decreased to 45 per cent of its rated life if it is operated continuously at 7 volts. Extensive surveys

of automobile headlamp voltage indicate an average socket voltage of 6.35. The greater the lamp amperage, the lower is the line voltage, as the line drop is higher. Thirty-two-candlepower lamps give rated life and light output at 6.00 volts, and side and rear lamps at 6.85 volts. Because of the pronounced effect of voltage changes upon lamp life, close regulation of the voltage is desirable. That much closer regulation is obtained when the generator has a voltage regulator than when a third brush alone is depended upon for maintaining the desired output, is indicated by Fig. 27, which gives comparative curves of the two types in the case of 12-16-volt machine. The renewal rate is estimated at 3 to 4 lamps per car per year.

Table VII. Electric Incandescent Lamp Data

Candle-power	Voltage	Maximum Amper-age *	Bayonet-Base Contact †	Bulb Type	Bulb Diam-eter, in.	Maximum Overall Length, in.	Light Center Length, in.	Filament Form ‡

* Improvements in lamp design and manufacture from time to time make possible changes in ampere ratings. The figures given are therefore maximum and are for use in calculating wire sizes and battery capacities. For test purposes the exact amperage should be obtained from the lamp manufacturer.

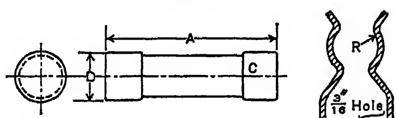
† S—Single-contact. D—Double-contact.

‡ C indicates a coiled-wire fiament.

21. INSTRUMENTS, FUSES, ETC.

FUSES AND FUSE CLIPS. S.A.E. standards for fuses and fuse clips provide, among other requirements, that fuses for circuits of 40 volts or under and 30 amp or less shall be of the closed type and so constructed that inspection will show whether or not they are burned out. The voltage (*V*) and the current capacity (*C*) shall be plainly marked on one ferrule. Fuses of the same dimensions as those of the National Electric Code shall be marked according to the requirements of that code. Fuses shall carry indefinitely, at a temperature of 75 deg fahr, a current 10 per cent above their rated capacity. A current

Table VIII



Capacity, amp	Length, in. (A)	Ferrule Diameter, in. (D)	Clip Radius (R)
5	1 1/4	1/4	3/32
10	1 1/4	1/4	3/32
15	1 1/4	1/4	3/32
20	1 1/4	1/4	3/32
30	1 1/2	13/32	5/32

50 per cent above rating shall cause the fuse to melt within 1 min. The temperature of the exterior of the fuse shall not rise more than 125 deg fahr above that of the surrounding air when the fuse is carrying its rated capacity. Fuse clips shall be so made that the fuse cannot slip out accidentally and shall be fastened to a base that cannot turn.

Standardized dimensions of fuses and clips are given in Table VIII.

INSTRUMENT DIMENSIONS. S.A.E. recommended practice relating to electrical instruments includes body diameters, drilling, and binding post sizes.

22. STARTING MOTOR

Starting motors for automotive engines are series-wound machines, designed to produce high torque at comparatively low speed and for use during only short time intervals. Consequently the motors are smaller and lighter than series motors for most other applications. Characteristic curves of a starting motor are given in Fig. 28, taken from a paper

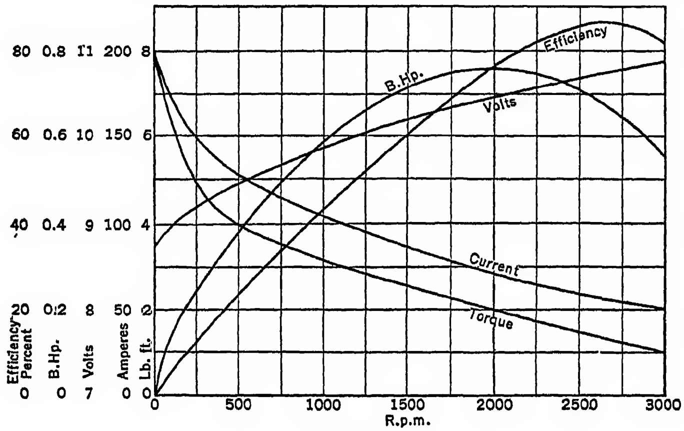


Fig. 28

entitled Electric starting and lighting equipment, by A. C. Burgoine (*The Automobile Engineer*, February, 1924). As this figure indicates, the torque is a maximum at zero speed, where, of course, the current drawn is a maximum. Both torque and current fall off rapidly with increase in speed. The power output increases with the speed, and in the motor in question reaches a maximum at about 2000 rpm, at which point the efficiency is approximately 76 per cent. Since motors of this class are rarely used for more than 1 min of continuous running, high efficiencies are not of special importance and ratings can be considerably higher than for series motors designed for continuous use. For the same reasons, the allowable rate of temperature rise may be much greater in the starting motor. High torque output is required, not alone to overcome the inertia of the parts put into motion, but also to break down the resistance or shear of the oil films in engine bearings and cylinders and to overcome the load imposed by compression of the charge in engine cylinders. Although a part of the energy used in compressing the charge is returned on the expansion stroke, even before ignition occurs, much of it is lost through wire-drawing of the gases and dissipation of the heat of compression to the cylinder jackets. Torque requirements vary during each revolution of the engine, the variation increasing as the number of cylinders in the engine decreases. Other factors also affect the torque required, one of the most important being the viscosity of the engine lubricant, which varies in turn with engine temperature, and is highest with a given oil when it is new and undiluted by fuel which passes the pistons. Chiefly because of higher oil viscosities in cold weather, low temperature starting imposes some of the most difficult limiting conditions in starter design. Comprehensive starting motor tests are reported in Low-Temperature Starting Development of Automobile Engines, by P. J. Kent (*S.A.E. Journal*, August, 1931, p. 141), from which some of the following particulars are abstracted.

A minimum cranking speed of 40 rpm is desirable. Fig. 29 illustrates the results of cranking tests of an eight-cylinder engine with two different starting motors and three combinations of starting motor and battery. Starting torque is a direct function of starting motor current, and the speed is a direct function of the terminal voltage minus the *IR* drop

in the motor. Above the starting motor voltage curve, Fig. 32, is a curve showing the required battery voltage for corresponding cranking speeds, calculated by adding the drop in the car-ground circuit and the starting motor cables. The resistance of this circuit in the average Chrysler car is 0.0012 ohm, which, when multiplied by the current, gives the drop in the line. Discharge curves of the batteries under consideration (based on a 5-sec discharge at 0 deg fahr) are also given in Fig. 29. The intersection of these curves with the curve of required battery voltage gives the cranking current for the particular battery, and projecting this point on the cranking speed curve gives the speed at which

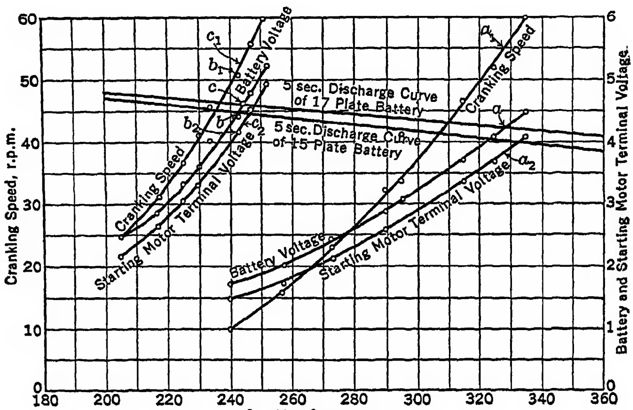

FIG. 29

the battery will crank the engine with the particular starting motor and gear reduction used. Fig. 29 applies to oil diluted with 15 per cent of kerosene. The various combinations tested are as follows:

Combination	*a*	*b*	*c*
Gear-reduction type	Direct	Back Geared	Back Geared
Ratio	9:115	11:115 and 14:29	11:115 and 14:29
Plates in battery	17	15	17
Cranking current, amp	328.0	242.5	244.0
Starting-motor voltage	3.85	4.15	4.25
Cranking speed, rpm	55.0	51.5	53.0

The intersection of the 5-sec battery-discharge curves with the battery-voltage curves at *a*, *b*, and *c* (Fig. 29) gives the battery voltage for the corresponding combinations tested. Projecting these points to intersect the cranking-speed curves at a_1, b_1, and c_1 and the starting-motor terminal-voltage curves at a_2, b_2, and c_2 gives the speed at which the engine would be cranked and the starting-motor terminal voltage for the corresponding battery, starting-motor and great-reduction combination; and on the base-line the cranking current is indicated.

Such data are sufficient to determine the correct equipment so far as initial cranking speed is concerned. Fig. 30 shows the results of three cranking capacity tests with the combinations indicated, the batteries first being tested to make sure that they are up to specifications. The engine is then cranked continuously until the potential across the starting motor terminals is reduced to 3 volts. Although the initial cranking speeds are not greatly different, the time that the engine can be cranked with the different combinations is shown to vary considerably. The current is less and the voltage at the starting motor (as well as that available for ignition) is greater in the back-geared motors. From the data in the cranking-speed tests, Fig. 29, the power required to crank the engine at various speeds can be determined, and if different starting motors and batteries are to be considered, and the performance curves of each motor with each battery are available, an ideal gear reduction can be selected and the cranking speed that each combination will give can be determined accurately. The horsepower required to crank the engine can be computed from the following formula:

$$\text{hp} = 2\pi NRT \div 33{,}000$$

where N is the cranking speed of the engine, R is the speed reduction ratio between the starting motor and flywheel gear, and T is the torque of the starting motor in pound-feet. If the actual engine cranking power is required, allowance must be made for the mechanical loss in the gearing. It is not necessary to know the loss in the gears, however, to determine the best gear reduction, if the torque has been measured with the gears in use. The power required to crank the engine, computed by the above formula, is plotted against cranking

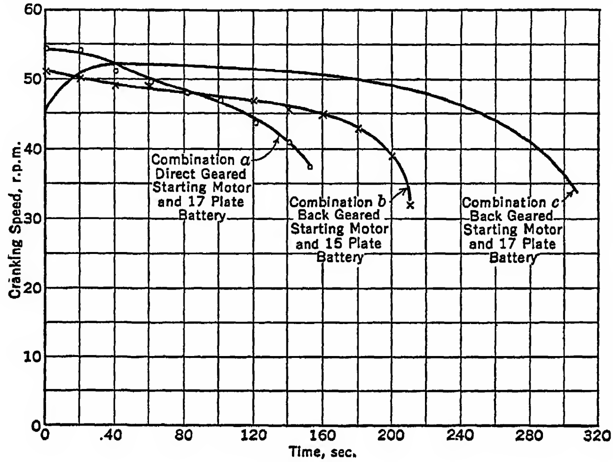

FIG. 30

speed as shown in Fig. 31. Tests of the torque *at the flywheel*, as developed by the starting motor, for different current values, are observed, using for each run a voltage at the starting motor terminals equal to the 5-sec discharge voltage of the battery minus the line loss. From these data the available power is computed and the complete performance curves of the motor are plotted. For accurate work, the starting motor should be tested at 0 deg fahr, or the normal temperature test results should be corrected to that tempera-

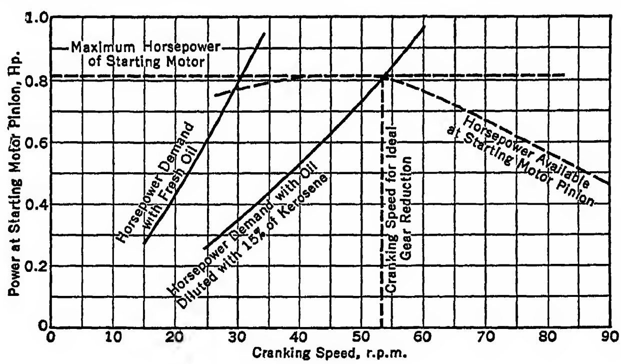

FIG. 31

ture, as was done in the curves plotted in Fig. 32. From the starting motor horsepower curve the maximum power available is determined. If this be transferred to horsepower-demand curve, Fig. 31, a line dropped to the base line, as indicated, gives the maximum cranking speed available from the particular motor and battery combination under consideration. This speed divided into the speed of the starting motor at the point of maximum power gives the ideal gear ratio for best cranking.

In Fig. 33 the curves show the actual relation between the piston displacement and the cranking speed for five different six-cylinder engines of similar design and approxi-

mately the same compression ratio, at 0 deg fahr, the same size of 13-plate battery being used in each case. Both motors used are of the direct-geared type, the gear ratio being 9 to 115. Starting motor *A* had four poles wound and motor *B* had field coils on only two poles. From the large volume of data accumulated, the following general conclusions are drawn: (1) The larger the engine, the more difficult is winter cranking. (2) For any given starting motor, increasing the size of the battery does not add greatly to cranking speed, but materially increases cranking capacity. (3) Cranking speeds of an engine may vary between wide limits, depending upon the type of starting motor and gear reduction employed.

STARTING MOTOR CONTROL MECHANISMS. Control mechanisms for starting motors are of three types: (1) Automatic engagement and disengagement of pinion (Pinion

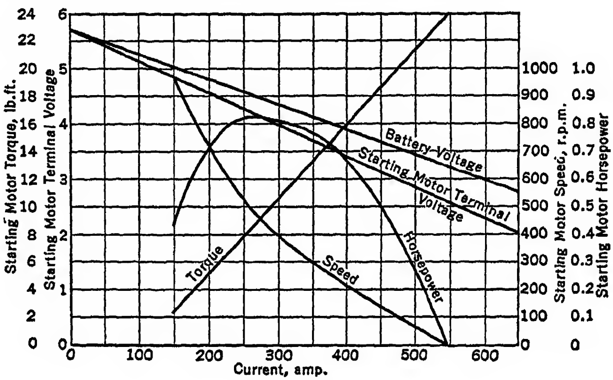

FIG. 32

type). (2) Pedal (or manual) engagement and automatic disengagement (**Bendix** type). (3) Pedal (or manual) engagement and disengagement in combination with an over-running clutch to release the armature at intervals between the time when the engine starts firing and that at which pedal disengagement occurs.

STARTING MOTOR CIRCUITS. S.A.E. standards provide that the starting motor circuit shall be so designed that the difference between the voltage of the storage battery terminals and that at the starting motor terminals shall not exceed 0.12 volt per 100 amp with the circuit at a normal temperature of 68 deg fahr.

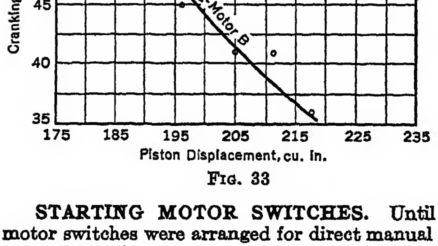

FIG. 33

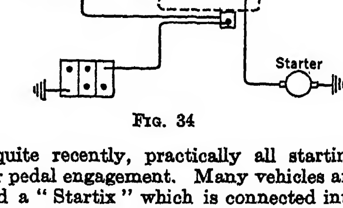

FIG. 34

STARTING MOTOR SWITCHES. Until quite recently, practically all starting motor switches were arranged for direct manual or pedal engagement. Many vehicles are now equipped with a relay starting switch termed a " Startix " which is connected into the starting system in the manner shown in Fig. 34. The Startix is so connected that the engine is started instantly and automatically when the ignition switch is closed and is automatically restarted in the event that it stalls; hence, to start the engine, the operator

need only turn the ignition key, without operating any supplementary switch or starting mechanism. The Startix is applicable, however, only to engines equipped with the Bendix drive, which automatically engages the starter pinion when the starting motor circuit is closed, and automatically disengages the starter pinion when the engine begins to fire. When the ignition key is turned on, current from the battery passes through the main switch solenoid of the Startix and closes this switch, whereupon the starter pinion is engaged and the engine is cranked. When the engine starts, the pinion is disengaged, a relay solenoid in the Startix is energized, and the inward travel of this plunger deflects a vibrator arm assembly which in turn interrupts the current through the main switch solenoid and thus breaks the starting motor circuit. When the engine starts, a second coil on the relay solenoid is energized, attracting a lever interconnected with the vibrator mechanism. If the engine stops, the lever is released along with the vibrating arm and the starting cycle is repeated. The vibrator introduces a time factor such that the engine starter will not be re-engaged until the engine comes to rest. A thermostatic safety device forming a part of the Startix is arranged to automatically open the starter circuit in the event that the starter pinion jams or fails to release. In this case the Startix produces a distinctive clicking sound until the ignition switch is turned off.

STARTING MOTOR PERFORMANCE DATA. Tests normally applied to starting motors in service and maintenance, as well as in factory inspection work, provide for measuring the current and speed at 5 or 6 volts (for 6–8 volt machines) and the current, voltage, and lock-torque when the armature is stalled and connected across a battery such as that with which it is normally employed, or some equivalent power source. The following table gives the performance data covering a number of Delco-Remy starting motors such as are widely used in automotive applications:

Model No.	No-load Test			Lock Test			Direction * of Rotation
	Amp	Volts	RPM	Amp	Volts	Torque, lb-ft	
710 C, AC	65	5	4500	450	3.70	10.0	CW
712 E, F	70	5	5000	450	3.60	11.0	CW
713 F, G, H, J	65	5	5000	475	3.63	12.0	CW
714 A, B, C, D, AX	65	5	5000	475	3.63	12.0	CW
716 A	70	5	3000	450	3.70	15.0	CW
717 A	70	5	5000	450	3.60	11.0	CW
720 J, K, L, M	65	5	6000	570	3.15	15.0	CW
720 N, P, Q, R, S, T, U, V, W, QX	65	5	6000	570	3.15	15.0	CW
723 A, B	70	5	1000	600	3.25	70.0	CW
724 C, D, E, F	70	5	3500	600	3.00	22.0	CW
725 A	65	5	6000	600	3.00	15.5	CC
732 B, C	65	5	2000	600	3.00	32.0	CW

* CW = clockwise, CC = counter-clockwise, when viewed from driving end.

23. WIRING

WIRING SYSTEMS. Although both double-wire and single-wire starting and lighting systems have seen extensive use, the single-wire type is by far the more general because of its lower cost and greater simplicity. In this system the frame and other metal parts of the car form a part of the circuit, either the positive or the negative terminal of the battery being grounded permanently to the frame or some other metal part of the car. For lighting circuits wires varing from No. 16 to No. 10 B. & S. gage are usually employed. Starting circuit cables usually range in size from No. 4 to No. 0 B. & S. gage, and their length is made as short as feasible to minimize voltage drop.

S.A.E. recommended practice for automobile grounded wiring systems is outlined in a code of which the following is an abstract:

INSULATED CABLE. Conductors should not be of smaller size than No. 16 B. & S. gage, and the potential loss at normal load should not exceed 3 per cent. Terminals on other than starting motor cable should be clamped to the insulation and soldered to the conductor.

CONDUIT. Insulated cables should be protected by metal armor or unpacked metallic or non-metallic covering unless otherwise protected or not in contact with metal. Ferrules having rounded edges should be used at open ends and at junction boxes. Wires not protected by conduit should be cleated at intervals not exceeding 28 in. When protected by conduit, metal clips secured by bolts or wood screws should be placed at intervals of not

less than 36 in. Staples should not be used. Cables not in conduit should be bushed with rubber where they pass through holes in metal.

GROUNDING. All ground connections should be accessible for repair. Ground return connections should be made to the chassis frame or to a substantial part firmly attached to the frame. The positive side of the battery should be grounded when a voltage control system is used. The surface on which grounding terminals make contact should be tinned and free from oxide or paint.

OVERLOAD PROTECTIVE DEVICES. Current to all low-tension circuits except starting motor and ignition circuits should pass through protective devices connected to the battery-feed side of switches. Circuits should be so arranged that the opening of a protective device will not extinguish all lights.

COLORING OF CABLES. To simplify the installation and connection of wiring and to afford a positive means of identification of the principal circuits, the following coloring is recommended:

Passenger car wiring, where cable is bought in coils: Red for unprotected live wires, and yellow for protected live wires.

Passenger car wiring where cables are bought in the form of a harness: Red for unprotected live wires; red with yellow tracer for low-tension or primary ignition; red with black tracer, ammeter to battery; yellow for protected live wire; brown with black tracer from lighting switch to junction block (parking lamp) and for all ground connections except battery ground; black, lighting switch to tail lamp; black with red tracer to bright headlamps (or upper beam); green to dim headlamps (or lower beam) and from switch to signal lamp.

Motor-coach and truck wiring (assumed to be bought in bulk coils): Red for unprotected live wires; yellow for protected live wires; brown with black tracer for generator cut-out or regulator to ground and all ground connections except that of battery; black for bright headlamps (or upper beam) and for bodylamp feed wires, switch to lamp; black with red tracer for dim headlamps (or lower beam); green from switch to signal-lamp and to signal-lamp indicator or pilot.

INSULATED CABLE. The following is an abstract of the S.A.E. standard specifications for insulated cable:

General Specifications. Conductors. Conductors shall be bunched or stranded as specified in each section below, and shall be of tinned annealed copper wire complying with specification No. B3-15 of the American Society for Testing Materials.

Rubber Insulation. Rubber insulation shall adhere closely but strip rapidly from the conductors, leaving them reasonably clean. It shall contain not less than 20 per cent by weight of good-grade new hevea rubber.

Varnished-cambric Tape. It shall not be less than 0.005 in. thick for wires of No. 10 A.W.G. and smaller, nor less than 0.007 in. thick for No. 8 A.W.G. and larger wires. In no case shall the thickness exceed 0.013 in. The instantaneous puncture voltage shall not be less than 750 volts per mil thickness.

Braids. Braids shall consist of closely woven cotton yarn not less than $^1/_{64}$ in. thick and shall be impregnated with at least two coats of insulating varnish or enamel resistant to heat, oil, and water, or with black water-proof wax compound that thoroughly saturates the braid and gives a smooth finish. When wound on reels, adjacent layers of cable shall not stick to each other at any temperature below 105 deg fahr.

Armor. Armor shall be solid D-shaped of either galvanized or sherardized dead-soft steel, soft brass, aluminum, or copper, applied in a close helix without overlapping turns, with dimensions as in Table IX.

Table IX. Armor Thickness and Width Dimensions

Armor	Thickness, in.			Width, in.		
	Minimum	Nominal	Maximum	Minimum	Nominal	Maximum
Small............	0.014	0.017	0.020	0.045	0.050	0.055
Large............	0.017	0.020	0.023	0.095	0.100	0.105

TESTS. Tinning Tests. A.S.T.M. standard two-cycle test.

Physical Tests. A 6-in. or longer sample of rubber insulation shall have marks placed on it 2 in. apart and shall be stretched until these marks are 6 in. apart at a stretching rate of 12 in. per min and immediately released. Thirty seconds after release the marks shall not be more than 2 $^1/_2$ in. apart. The specimen shall then be stretched until the marks are 7 in. apart without rupture. The tensile strength of rubber insulation shall not be less than 600 lb per sq in., based on original sectional area. Tests to be made at a

temperature between 50 and 90 deg fahr and sample to be cut with uniform cross-section. These physical tests apply to cables having a wall thickness of 0.045 in. or more. For thinner sections the initial and ultimate stretch shall be 5 and 6 in. respectively, and the tensile strength not less than 500 lb per sq in.

Oil Test for Braided Cables. This test shall be made on all cables, both high-tension and low-tension, having either a varnished or enameled braid covering. After submersion of all but the ends of a sample in a shallow dish containing equal parts of engine oil and gasoline for 24 hr it shall be shown that no oil has penetrated to the rubber and that the varnish or enamel does not show signs of softening or absorption.

HIGH-TENSION IGNITION CABLE. Conductors shall be of tinned copper wire and either plain rubber covered, rubber covered and varnished cambric taped and braided, rubber covered with single braid, or rubber covered with double braid, as ordered. Waxed braid shall not be used for this type of cable. When varnished-cambric strips are used, there shall be a 25 per cent overlap. Dimensions shall be as given in Table X, and when braided shall be varnished or enameled to withstand the oil test outlined above. The 7-mm size is recommended for all high-tension cables.

Table X. High-tension or Secondary Ignition Cable

Nominal Size		Number of Wires in Strand	Nominal Size of Wires in Strand, A.W.G.	Maximum Outside Diameter, in.	Minimum Outside Diameter, in.	Minimum Thickness of Rubber Wall, in.		
Mm	In.					Plain Rubber Covered	Single Braid	Double Braid
7	0.2756	12 19	26 (0.0159) 27 (0.0142)	0.285	0.265	0.097	0.081	0.066
9	0.354	19	27 (0.0142)	0.364	0.344	0.135	0.119	0.104

LOW-TENSION IGNITION CABLES AND STARTING-MOTOR AND LIGHTING CABLES. Conductors shall be bunched or stranded and insulated in one of the following seven ways: (1) plain rubber covered; (2) rubber covered and single-braided; (3) rubber covered and double-braided; (4) two layers of varnished cambric tape and single braid; (5) same as 4, but double-braided; (6) rubber covered with rubber-faced tape and single braid (for starting motor cables only); (7) rubber covered with rubber-faced tape and double-braided (for starting motor cables only). The braid shall be varnished, enameled, or weather-proofed, as provided above. The dimensions of low-tension ignition cable shall be as shown in Table XI.

Table XI. Low-tension Rubber-insulated Ignition Cable (Not Braided)

Nominal Size	Number of Wires in Strand	Nominal Size of Wires in Strand		Maximum Outside Diameter, in.	Minimum Outside Diameter, in.
		A.W.G.	In.		
5 mm (0.197 in.)	19	27	0.0142	0.207	0.187

The above cable is recommended as a grounding cable for short-circuiting magnetos.

Conductors of primary, lighting, and starting motor cables shall be of the sizes and construction given in Table XII. Conductors of cables composed of Nos. 16 to 10 A.W.G. inclusive shall be of tinned copper wire when rubber insulation is used and may be bunched or stranded as desired. For No. 8 A.W.G. and larger cables, conductors shall be stranded and may be of concentric or rope lay. In rubber-insulated cables, either tinned copper wires or bare copper wires with suitable separators may be used.

The total circular mil area of any strand shall not vary more than 2 1/2 per cent from the actual figures given.

Tolerances for the diameter of the rubber shall be as follows: No. 16 to No. 10 A.W.G. inclusive, plus or minus 0.005 in.; No. 8 to No. 00 A.W.G. inclusive, plus or minus 0.010 in.

The nominal diameter of the wires in the strands and the nominal circular mil area agree with figures issued by the Bureau of Standards in Circular 31, Table VIII.

When low-tension cables are insulated with varnished cambric and without rubber, there shall be two or more layers of overlapping cambric with alternate layers laid in opposite direction with 25 per cent overlap, and either tinned or bare copper wire may be used.

ARMORED LIGHTING CABLES. Cables of this class shall be insulated with: (1) two or more layers of varnished cambric with 25 per cent overlap and alternate

	259	23	0.0226		131,936			

layers laid in opposite directions; (2) rubber; or (3) rubber and varnished-cambric tape. All cables shall have one or two treated braids, and armor over the braid.

FLEXIBLE STEEL CONDUIT AND TUBING. S.A.E. recommended practice in reference to flexible steel conduit and tubing is covered by a specification which provides that it shall be of the square locked type made by helical coils of formed steel strip. It is rated by nominal inside diameter. Standard dimensions are given in Table XIII.

Installation. To protect electric wires from abrasion and to prevent conduit from unwinding, exposed ends should be bussed with suitable ferrules soldered to the conduit. Where taps or joints are made, junction buses should be used and conduit ends carefully bushed.

ELECTRIC AUTOMOBILES

By W. P. Kennedy

There are two types of electric automobiles, namely the battery vehicle and the "gasoline-electric" vehicle. The former type carries a storage battery from which energy is delivered to the driving motor; the latter type, in most instances, carries no battery, but electric energy is supplied to the motor by a generator which is itself driven by a gasoline engine. Formerly, storage batteries were used in combination with a motor-generator connected to the engine. Thus the machine was driven by energy from either battery or engine. The battery vehicle only is discussed in this article.

25. DEVELOPMENT

The first battery-driven automobile in this country was built by Fred M. Kimball in Boston in 1888. This machine had 6 cells of lead storage battery and could travel 10 miles on good roads at an average speed of 5 mph. In 1891 there was exhibited at the Mechanics'

Fair in Boston an electric surrey built by the Holzer-Cabot Electric Co. Little more was done in the development of electric automobiles until about 1897 when the passenger vehicle was developed in two directions: one for pleasure took the forms of victorias, runabouts, dos-à-dos, and surreys, and the other for business purposes in the form of public taxicabs or vehicles for hire. The latter development expanded during the following four years to the use of fleets of 100 to 400 cabs and broughams in New York, Boston, Philadelphia, Washington, Buffalo, and Chicago for public service on a hired basis; these disappeared from use about 1902 or shortly afterwards, largely for financial reasons, but also on account of the fact that large solid or pneumatic tires were not well developed at that date and storage batteries had not progressed beyond the heavy types used for stationary equipment in power stations.

From 1900 to 1903 the commercial type of electric truck began to be employed for merchandise delivery and progressed gradually but steadily until 1910, when the electric light companies recognized in it a desirable " off-peak " power consumer. The Electric Vehicle Association of America with considerable activity materially furthered the use of electric vehicles, both passenger and commercial, until 1914, when there were 37,000 in use; 25,000 passenger cars and 12,000 trucks (*Elec. World*, Jan. 3, 1914). The average price of the former at that date was $2200 and the latter $2800; this represented $88,000,000 invested by the public in this type of automobile. Following 1914 there was a rapid decline in the rate of production of electric vehicles owing largely to general business conditions, but principally to the competitive influence of mass production in the gasoline vehicle industry; although the electric still maintains its superiority in economic operation. In 1920 there were but three manufacturers of each type aggressively conducting production in their respective fields, but shortly afterwards passenger-car manufacture ceased. Another class of the electric vehicle, in the form of indoor industrial material and freight handling trucks, has been in progressive development since 1904. See Industrial Electric Trucks.

26. APPLICATIONS OF ELECTRIC TRUCKS

The three types of vehicles which are at present available for urban street haulage are the horse-drawn wagon, the gasoline motor truck, and the electric battery truck. In comparing these three types for use in any given service, the chief factors to be considered are relative speed, distance between stops, number and length of stops required by the service, expense per vehicle, and reliability (i.e., number of days per year upon which the vehicle can be depended for operation). The first three of these factors may be determined by trial or by observation.

The electric truck has found its widest commercial application in city services where the hauls are of moderate length, say from 2 to 10 miles, and where the daily service does not exceed 30 miles on the average, with occasional daily mileages of 40 to 50. For very short hauls where the standing time of the vehicle is a large proportion of the working time, so that the work per day of each delivery unit is not largely influenced by the speed of the unit, the horse-drawn wagon can perform the work cheaper than any motor vehicle. For the so-called " long hauls " the gasoline truck would be expected to work to better advantage than an electric truck because of higher running speed or greater distance capacity in a day, or both. The effect of hills or poor pavements would decrease both speed and mileage in electric trucks. Systems of operating in which discharged batteries are exchanged for charged batteries during the day in order to increase the mileage capacity beyond the rated value have been used with signal success in a few instances, but in general the battery equipment is usually of sufficient capacity to perform the daily service required, or is in some cases supplemented by high-rate boosting charge during the noon hour or other convenient period.

Design

The necessity of producing cars which would travel at moderate speeds with a low rate of energy consumption has forced the designers of electric automobiles to use equipment which would meet this requirement. Thus tires of low-energy consumption, batteries with large capacity per unit of weight, and " anti-friction " bearings in transmission and axles are used almost universally.

WEIGHT AND SPEED. In the design of an electric battery vehicle the two primary features are the total weight and the speed under normal conditions. In special instances a car may be built to meet unusual requirements of distance traveled per charge, in which case either the speed or weight must depart from the limitations of common practice. Any decrease in the total weight will result in an increase in either speed or

distance capacity or both; or if the weight is brought back to the original value by the use of additional battery capacity, the speed or distance may be still further increased. This has been one of the chief considerations leading to the adoption of lighter batteries, such as the Edison and " thin " pasted lead plate, in place of the heavier type lead plate batteries commonly used where their additional weight is not a critical factor. General practice as regards weight and speed for various types of electric automobiles is indicated in Table I.

Table I. Speeds and Weights of Electric Trucks

Rated Capacity of Truck	Approximate Weight in Pounds, Including Body and Load	Approximate Speed, miles per hour	Chassis Weight without Battery or Body, lb
1,500-lb truck	5,000	15 to 20	2800
2,000-lb truck	6,500	13 to 15	3500
4,000-lb truck	8,000	12 to 14	4000
6,000-lb truck	10,500	12 to 14	4800
8,000-lb truck	13,500	12 to 14	5300
10,000-lb truck	22,000	12 to 14	6400
12,000-lb truck	26,000	10 to 13	7600
15,000-lb truck	32,000	10 to 12	8500

Load Efficiency. By load efficiency of a motor truck is meant the ratio of the load on the machine to the gross weight of the machine, including chassis, body, and load. Thus, from the above table, a representative value for the rated load efficiency of a 5-ton capacity electric truck is $\frac{10{,}000}{10{,}000 + 22{,}000} = 0.31$. The rated load efficiencies for gasoline trucks of large capacity, 2 tons or more, are practically the same as the values for electric trucks, but small-capacity gasoline cars of good design may have a rated load efficiency as high as 30 per cent as compared to about 24 per cent for electric cars with the customary lead battery equipments.

MOTORS. Four-pole series motors are now used almost exclusively for electric automobiles. In the majority of cases but a single motor is used on each vehicle. The field coils are usually arranged in two groups which may be connected first in series and then in parallel. Motors will carry their normal rated load continuously with a maximum temperature rise of 65 deg cent above the surrounding air at 25 deg cent or will carry 2 1/2 times their rated load for 1 hr with a maximum temperature rise of 75 deg cent. Ratings are based on bench tests, so that when the motor is installed in a car the overload capacity is usually increased owing to the improved ventilation. Large overload capacity is necessary to meet severe street and grade conditions, and unusually good commutating characteristics are required.

An automobile motor must also operate satisfactorily over the varying range in the voltage furnished by the battery in the charged and discharged conditions. The motor speeds which are used with single reduction drives range from 750 to 1000 rpm; the speeds which are used with double reduction drives range from 1000 to 2000 rpm.

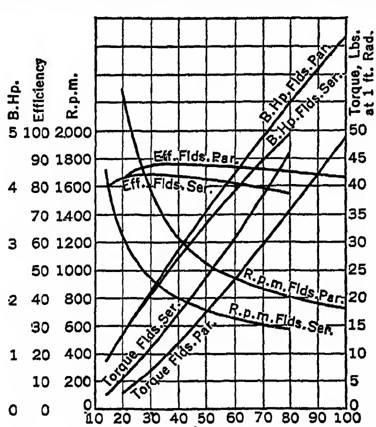

FIG. 1a

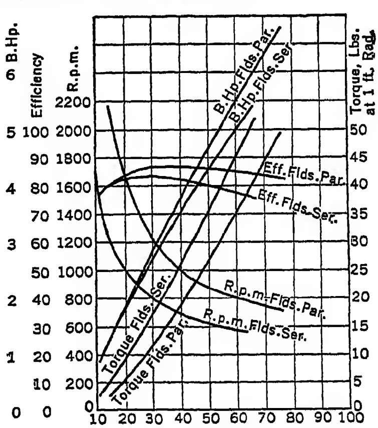

FIG. 1b

Number of Motors. Most electric trucks are now being equipped with a single motor. It was formerly common practice to use two motors on the larger trucks on account of flexibility in control, but a single motor is now being used on account of space limitations, saving in weight and better electrical efficiency.

The characteristic curves for a typical motor with the 60-volt and 80-volt windings are given in Figs. 1*a* and 1*b*. The relatively small change in efficiency for overload with the field coils in parallel is noteworthy. The "torque ratio" of this motor, i.e., the ratio of torque at 2 1/2 times rated current to torque at rated current, is approximately 5 with both windings.

Before recommending motor equipment for automobile service the motor manufacturers usually require that the purchaser submit data upon the weight, speed, battery, wheel dimension, etc., for the vehicle on which the motor is to be used.

SIZE OF MOTOR REQUIRED. In selecting the size of motor the voltage should be chosen on the basis of 1.9 volts per cell for lead batteries and 1.0 volt per cell for Edison batteries. The average discharge voltages of both types of batteries at their normal rates are higher than these values, but it has been found desirable to install motors on the basis of these values so that at high rates of discharge the terminal voltage may not fall too far below the rated motor voltage.

The current rating of the motor (and also of the battery) should be approximately the value of the current required to drive the car at the rated speed on hard level asphalt. The current input into a vehicle motor when driving a car at constant speed is given by the expression

$$I = \frac{2vWr}{E\epsilon}$$

where v = speed of car in miles per hour.
W = total weight of car and load in tons.
r = car resistance in pounds per ton of total car weight.
E = motor terminal voltage.
ϵ = overall efficiency of motor, controller, and transmission.

The value of ϵ at the rated speed is the product of the efficiencies of motor and transmission, usual values falling between 60 and 75 per cent. For value of r see next paragraph.

Car Resistance. The car resistance depends upon the following conditions: speed, grade, diameter of wheels, load per square inch of tire contact or per inch of tire width, construction and composition of tire, and road surface. The effect of speed is to change r in a manner dependent upon the type of tire, the value of r having a minimum usually at a speed between 6 and 10 mph; air resistance varies approximately as the square of the speed and need not be considered for speeds of less than 20 mph. The effect of up-grades is to increase r by 20 lb per ton for each per cent grade. The car resistance with pneumatic tires on hard, level asphalt is from 15 lb per ton for special tires to 35 lb per ton for the standard type of tire used on gasoline cars; the resistance is greatly affected by the air pressure, increasing rapidly as the air pressure is reduced.

Effect of Road Surface. Values of relative car resistance on various level road surfaces as compared to the value on hard, level asphalt are given in the Table II.

Table II. Relative Values of Car Resistance

Road Surface	Ratio	Road Surface	Ratio
Asphalt, hard	1.0	Snow, packed	1.3
Wood block	1.1	Snow, fairly hard, without chains	1.7
Macadam	1.15	Snow, fairly hard, with chains	1.9
Granite block	2.0	Snow, soft, about 3 in. deep	2.1
Dirt road	1.3	Sand	20.0
Brick	1.4		

27. TRANSMISSION SYSTEMS

The transmission systems between motor and wheel which are now in common use are gear drives. A single-speed reduction is used in a few makes of cars, but a double reduction is used on a majority of machines.

SHAFT OR GEAR DRIVE. With shaft drive the motor is usually mounted lengthwise of the car, and either a single- or double-speed reduction is used. For single reduction both bevel and worm gears are used as the connection between propeller shaft and differential in the rear axle. For double reduction the motor is usually connected to the pro-

peller shaft by spur gear, herringbone gear or silent chain, and the propeller shaft is connected to the differential by a bevel gear.

WORM DRIVE. There has recently been a decided tendency among designers of trucks to use the single-reduction worm gear instead of the double-reduction bevel or chain arrangements, the advantages claimed for the worm being better transmission efficiency and less trouble from adjustment.

WALKER BALANCED GEAR. In the trucks built by the Walker Vehicle Co. the motor is built into the rear axle, which is made hollow and of a sufficient diameter to contain the motor. The armature shaft is also hollow, so that the drive shafts may extend through from the sockets of the differential to the center of each rear wheel. The wheels are driven by a spur-gear reduction mounted inside the wheels. The wheels have steel-plate sides instead of spokes, so that the gears may run in oil and are thoroughly protected from dirt.

28. BATTERIES

There are three types of batteries in general use in electric vehicles, namely, the pasted lead, the "Iron-clad" lead, and the Edison. The performance characteristic (except life) of the first two are identical and are described in Section 7, Art. 7; the characteristics of the Edison battery are described in Section 7, Art. 13.

Number of Cells; Number of Plates. Practice among electric automobile manufacturers is now practically standardized upon the installation of 42 cells of lead battery and 60 to 72 cells of Edison battery. There are, however, in use old designs of cars in which from 24 to 38 lead cells are used, and the small-capacity delivery wagons in which 48 Edison cells are also employed. A 24-volt to 48-volt battery is used on industrial trucks.

Table III. Useful Data on the Edison Storage Battery

Cell Type	Normal Discharge Rate, amp		Rated Capacity	
	3 1/2 Hour	5 Hour	Ampere-hours	Watthours
A4	.....	30.0	150.0	180

G14	105.0	.....	350.0	420
G18	135.0	.....	450.0	540
Average voltage	1.2	1.2		

1. Type C, new in 1930, same area as A, but 5 in. higher. Capacity of C is therefore 50 per cent greater than A. Thus: A6—225 amp-hr, C6—337 1/2. Or A12—450 amp-hr, C12—675.

2. Trucks for city streets usually have 60, 64, 66, 70 or 72 cells. For high-speed trucks 80 cells are employed. Types A and C are used for ordinary service; type G is applied in special cases where greater capacity is required.

29. CONTROLLERS

Controllers are usually of the drum type with two running positions, known as the "field-series" and the "field-parallel" positions. The motor field coils are arranged in two groups for connection either in series or in parallel. The cells of the battery are connected permanently in series. In starting, either two or three resistance notches are used before the "field-series" notch is reached. A shunt on the fields is frequently used between the "field-series" and the "field-parallel" notches. For normal full-speed running the two groups of field coils are in parallel. An emergency speed is obtained by shunt-

Height given is from bottom of jar to top of intercell connector, except where vertical diagonal connector is used, when height should be increased 7/8 in.

ing a resistance around the fields when connected in parallel. It was formerly customary to split the battery into two groups which could be operated in series-parallel in order to obtain four economical running speeds, but trouble was experienced from the unequal discharge of the two halves of the battery. In the magnetic type of control which is used to some extent the changes in connection are affected by relays operated by an auxiliary electric circuit. Mechanical cam and spring type contactor controllers are also in successful use, avoiding the use of solenoid circuits.

TIRES. Tires for use on electric automobiles are generally more resilient than the standard types of tires commonly used on gasoline automobiles. "High efficiency" or special electric tires, both solid and pneumatic, have been developed by most of the tire manufacturers in response to a demand by the operators of electric vehicles for tires with low consumption of energy. Standard types of tires may consume as much as 100 per cent more energy than the special electric tires. Experience has shown that the smooth starting characteristic of an electric motor produces much less abrasion than the uneven acceleration with a gasoline motor, so that the rubber compounds in tires for electric cars are usually softer than the compounds in tires for gasoline cars and yet the lives of both types, expressed as distances traveled, are approximately the same.

30. PERFORMANCE; ENERGY CONSUMPTION

The energy consumed by an electric automobile will depend very largely upon the care of the driver in coasting up to stops instead of braking directly from full speed; other important factors in determining the energy consumption are efficiencies of battery and driving mechanism, tire equipment, nature of roads and grades, number of stops and miles per day, etc. However, for a car which is operated under similar conditions day after day, the energy consumption per mile should be reasonably uniform, so that any considerable increase in energy consumption may indicate either careless driving or poorly adjusted mechanism, as for instance a dragging brake.

31. OPERATION

In the operation of electric automobiles particular attention should be paid to the proper care of the storage batteries. The battery manufacturing companies issue complete instructions for the proper handling of their cells. The manufacturers of the battery, as well as the manufacturers of the vehicles, are usually ready to confer with the operator to

the end that he may obtain satisfactory service from his machines. They should be consulted on the first indication of trouble in their respective portions of the equipment, should the cause of the trouble not be understood.

The following points upon the care and operation of electric vehicles should be observed:

1. A battery must always be charged with direct current and in the right direction.
2. Never bring an exposed flame near a battery while charging or immediately afterwards.
3. Do not allow the battery temperature to exceed 110 deg fahr.
4. Keep the cells filled to the proper level by adding distilled water only. Never, under any circumstances, put acid in an Edison battery.
5. Keep the outside of the cells free from foreign substances, both solid and liquid.
6. For boosting a lead battery during a specified short period, the maximum current rate I which may be used without reaching the gassing point is the quotient of the ampere-hours Q previously discharged (read from ampere-hour meter), divided by 1 plus the hours H available for boosting, viz., $I = \frac{Q}{1 + H}$.
7. The mechanism of a car should be inspected carefully at least once in two weeks.
8. A car should be entirely overhauled at least once each year, in order that worn parts may be located and replaced.

ELECTRIC PROPULSION OF SHIPS

By W. N. Zippler

33. FUNDAMENTAL PROPULSION REQUIREMENTS

Practically all vessels are now propelled by " screw " type propellers, the side wheel and stern wheel having generally passed out of use except for vessels operating in very shallow waters, as for instance in some parts of the Mississippi River. With the existing propeller designs, the best efficiencies are obtained at relatively low rpm. Propellers seldom exceed a speed of 400 rpm and are generally operated between 100 and 200 rpm. The propellers are usually driven by either reciprocating steam engines, steam turbines, or internal-combustion engines.

A ship may be equipped with one, two, three, or four propellers. The depth and speed of the vessel are, in general, the principal factors in determining the number of propellers. As the speed is increased, the power requirement increases very rapidly, and in order not to obtain a poor propeller efficiency, the area of the propeller must be increased with increased power. The limit of area per propeller is determined by the diameter that can be suitably accommodated with the external dimensions of the vessel. It is advantageous to have the propeller submerged at all conditions of draft and yet not project below the keel of the vessel to interfere with " dry-docking " or shallow-water operation—therefore, the necessity for more than one propeller. Maneuverability of a vessel is improved by the use of two propellers instead of one, owing to the " turning " force that can be obtained by operating one propeller in the ahead direction and the other astern. No accurate data have been obtained indicating there is a gain in four propellers over two in this respect.

PROPELLER CHARACTERISTICS. Fig. 1 shows the relation between the speed and torque of a propeller when the ship is being driven at constant speeds in smooth water and also when the ship is held stationary in the water. It will be noted that the running propeller torque increases approximately as the square of the speed. The power to drive a ship, therefore, increases approximately as the cube of the speed. The exact values, however, vary with each type of propeller design.

TORQUE REQUIRED TO STOP AND REVERSE. When the driving power is removed from a propeller with the ship traveling at a high speed, the propeller will continue to revolve in the same direction, being driven by the water. In order to stop the ship in the shortest time, or to maneuver quickly, it is necessary not only to stop the propeller against the action of the water but also to drive it in the reverse direction.

An experimental determination of the relation between the speed and torque of the propeller while being stopped and reversed with the ship traveling at constant speeds was made in the Model Tank at Washington, and later these data were found to agree approximately with tests taken on the U.S.S. *Jupiter* and the U.S.S. *New Mexico*. Fig. 2 shows such a propeller characteristic as obtained in the Model Tank.

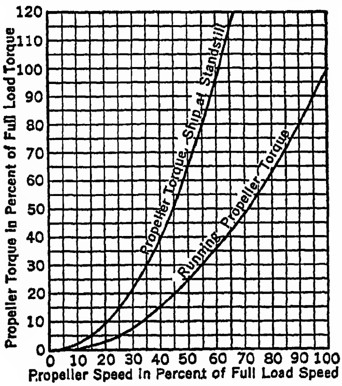

Fig. 1

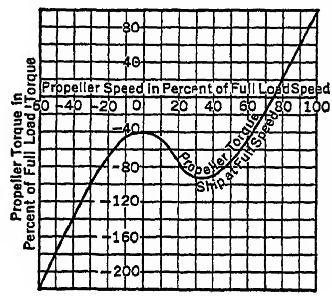

Fig. 2

Directly the power is removed, the propeller begins to slow down to approximately 73 per cent of its original speed, and, if power is now applied to the shaft, tending to stop the propeller, the torque of the propeller mounts up to approximately 100 per cent of the forward driving torque. This maximum torque is attained at between 35 and 40 per cent of normal propeller speed. From this point on, the torque decreases as the propeller speed decreases, until it comes to rest, when approximately 40 per cent torque is required to hold it stationary. If the propeller is now reversed, with the ship proceeding ahead at full speed, 100 per cent torque is attained at a propeller speed of about 30 per cent of the full-ahead revolutions. From this curve, therefore, it will be noted that it takes approximately 100 per cent torque to break the propeller away from the water, but only about 40 per cent torque to hold the propeller stationary after being stopped.

From experience obtained to date, it would seem that machinery for high-speed ships, having two or more propellers, should give 100 per cent reversing torque to bring the propellers quickly to rest when reversing from full speed. On lower-speed ships, indications are that the maximum stopping torque is considerably less than 100 per cent. On single-screw cargo boats, the stopping torque is probably quite low.

VARIATION OF PROPELLER TORQUE WITH PITCHING OF SHIP. The General Electric Co. has made a number of elaborate tests to determine the variation of the propeller torque when the ship is in a sea-way. An illustration of the variation which may be expected in moderately rough sea is shown on Fig. 3. Although the ship was only pitching 4 deg, the increase in torque varied from no load to 175 per cent of normal load.

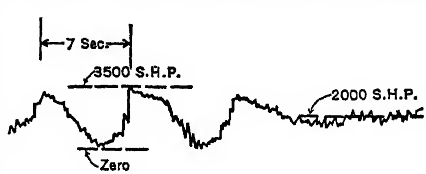

Fig. 3

These results were obtained on a cargo ship equipped with double reduction gearing. This turbine equipment did not have a governor, and the variation in torque may, in part, be due to the variation in speed of the propelling machinery.

Under worse conditions of sea, it may be expected that this variation in torque would be considerably increased.

It was observed that, when the propeller approached the surface of the water, the load was quickly released and was again gradually increased as the propeller went deeper

into the water. The record was taken with the ship in ballast, and it was observed that the propeller did not break water. This variable condition of torque has been confirmed on electrically driven ships by observing the variation of load by electrical instruments.

The electric motor is an ideal piece of machinery for absorbing these shocks without deterioration. As there is no mechanical connection between the turbine and the propeller, this shock is absorbed in the air gap of the motor, it being necessary only to give the electrical machinery a sufficiently strong magnetic bond to hold the generator and motor together. This bond is increased by simply increasing the degree of excitation. If the motors drop out of step with the generators, then, to bring them in step again, it is necessary only to reduce the turbine speed and increase the excitation. Then the turbine speed can again be increased to normal. No harm is done if these motors are left out of step for short periods as the generator is so proportioned that the increase in current cannot greatly exceed the normal.

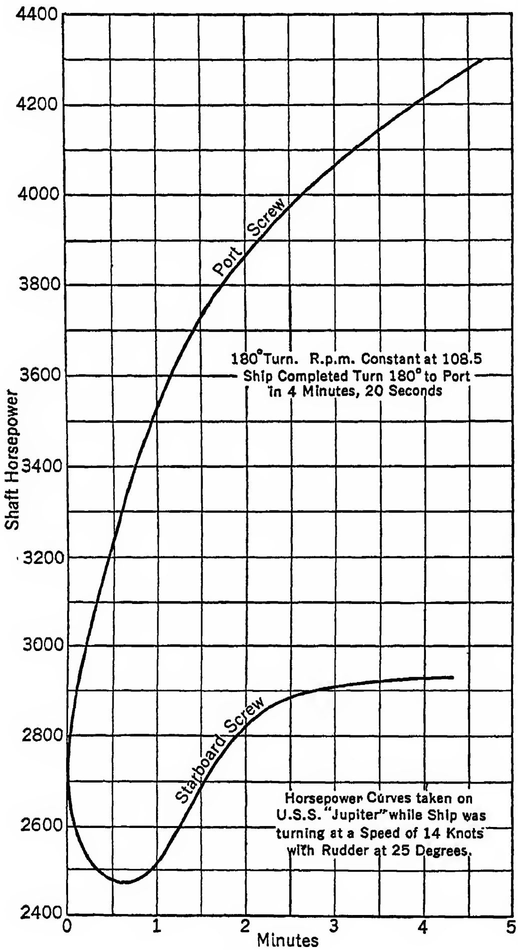

Fig. 4

Turning. Another condition of maneuvering that affects the design of electric propelling machinery is "turning." Most marine engines are not fitted with speed governors, the control of speed being entirely dependent upon the load and position of the throttle. With constant throttle opening, the reciprocating engine or turbine will develop practically constant torque regardless of the load on the propellers. Thus without a governor, the power varies directly with the revolutions. In the electric drive, the turbine is fitted with a speed governor which will hold the speed fairly constant, regardless of the load.

Commander S. M. Robinson, in his book, Electric Ship Propulsion, states:

"When turning a vessel, which is driven by a turbine, equipped with a constant speed governor, the power in the screw on the outboard side of the turning circle drops, and that on the screw on the inboard side of the turning circle rises. After a short time, the power on the outboard screw also rises. Fig. 4 shows how, in the case of the electric ship *Jupiter*, the power first drops on the outboard screw, reaching a minimum when the ship has turned through about 20 degrees; it then begins to rise, reaching its original value when the ship has turned through about 40 degrees, and reaching a constant value when the ship has turned through about 140 degrees. The power rises on the inboard screw from the beginning to the end of the turn. Thus in the case of the *Jupiter*, turning at 14 knots with the rudder at 25 degrees, at the completion of the turn, the increase of power on the outboard screw was 4.6 per cent and on the inboard screw 53 per cent, making a total increase of power of 29 per cent."

Although these figures vary with vessels of different size and speed, the data at least give a rough indication of what may be expected in all prime movers equipped with constant-speed governors.

It is for this reason that means are provided on governed turbines to limit the steam flow, thus producing a decrease in speed when the power exceeds a predetermined point.

34. STEAM TURBINE DRIVE

The relative light weight, small size, and high steam economy of high-speed steam turbines, compared with reciprocating engines, naturally suggest the use of such turbines for the propulsion of ships. Since the steam turbine has its best efficiency at a high speed and the propeller the best efficiency at a low speed, some means of speed reduction must be provided to obtain the best overall efficiency. At present, two means of reduction are available, namely: mechanical reduction gears and "electric gearing." Mechanical gearing, as used on ships, generally consists of a single or double set of spur, herringbone, or spiral-toothed gears, The "electric gearing" consists of a high-speed generator directly connected to the turbine and electrically connected to a low-speed motor, which is direct-connected to the propeller. By these two methods, speed reductions as high as approximately 40 to 1 may be obtained. Ships equipped with "electric gearing" are commonly referred to as being electrically propelled. There are many advantages and disadvantages for each type of reduction gearing.

The turbine has also permitted the use of much higher steam pressures and steam temperatures than had ever been considered for reciprocating engines. Some of the recently contemplated high-speed light-weight vessels are designed for steam temperatures as high as 850 deg fahr and 600 lb per sq in. gage pressure. Most merchant vessels of the present date operate with pressures of 275 to 300 lb per sq. in. gage and superheat temperatures of approximately 150 to 200 deg fahr. As is the case with the land steam plant, in recent years much more consideration has been given to increased pressures and temperatures; the increase, however, has been much slower in the marine plant than in the stationary plant. The German merchant marine boasts of an experimental cargo vessel that operates with a pressure of 1200 lb per sq in. gage, the boilers being of the "Benson flash type.".

Slow-speed turbines, which in comparison with high-speed machines are relatively inefficient, have been used for a number of years for driving ships. These turbines are directly connected to their propellers. In some large ships, a combination of reciprocating steam engines and a low-pressure turbine have been installed.

When the turbine is connected to the propeller by mechanical reduction gears, the drive is commonly called "geared turbine drive." Although as previously stated it is possible to obtain a turbine to propeller gear ratio as high as 40 to 1 by the use of a double set of gears, the ratio commonly used for passenger and cargo vessels seldom exceeds 25.

As is well known, superheat greatly improves the efficiency of steam turbines by reducing the friction and windage loss of turbine blades and disks. There is also a considerable gain due to increase in the available energy of the steam incident to increase in temperature. Steam consumption is reduced at least 1 per cent for every 12.5 deg fahr of superheat. With some installations, there is also a gain in boiler efficiency caused by increased heating surface exposed to the flue gases. Superheated steam also increases the life of the turbine blades and nozzles.

In America, superheat has, for a number of years, been extensively used in central stations, but only during the last few years has it come into extensive use on American merchant steamships.

TURBINES VERSUS RECIPROCATING STEAM ENGINES. Aside from questions of weight and cost, the higher steam economy of high-speed turbines is of itself ample in most cases to justify the adoption of the turbine for ship propulsion. The steam engine of the triple or quadruple expansion type, owing to the limitations in size of the low-pressure cylinder, cannot be made having a steam expansion ratio greater than about 16 to 1 or 20 to 1.

The reciprocating engine also cannot be used with highly superheated steam, on account of the difficulties in properly lubricating the cylinder walls and in obtaining a type of design and materials that can withstand the large stresses produced in the cylinder walls by the high pressures and temperatures.

The steam turbine has no such limitation and is capable of using, efficiently, steam expanded to any practicable extent. Where turbines are used, a vacuum of 28.5 in. is quite common, and 29.5 in. is being recorded on some vessels during winter months. The economy due to high pressure, high superheat, and large expansions is indicated by a comparison of the available energy of a pound of steam when expanded from boiler pressure to various degrees of vacuum, viz.:

200 lb pressure to 24-in. vacuum = 220,000 ft-lb
200 " " " 26-in. vacuum = 238,000 " "
200 " " " 28-in. vacuum = 265,000 " "
200 " " " 29-in. vacuum = 289,000 " "
600 " " 486 deg fahr (saturated) to 29-in. vaccum = 334,000 ft-lb
600 " " 850 deg fahr to 29-in. vacuum = 428,000 ft-lb

These figures give an indication of the saving that can be expected by the turbine which can use, efficiently, steam expanded to a low degree. Little advantage, however, is gained with a reciprocating engine when the expansion is carried below 24-in. vacuum. This greater available energy per pound means a saving not only of fuel, but also in the size and weight of boilers, auxiliaries, etc. Because of the above facts, the reciprocating engine has gradually passed into obsolesence.

LOSS DUE TO INCORRECT TURBINE AND PROPELLER SPEEDS. In many turbine-geared equipments, it has been considered advisable to depart from the most desirable propeller and turbine speeds so as to reduce the speed ratio of turbine and propeller and thus obtain a simple gearing. This sacrifice of turbine and propeller efficiency in some cases has caused an increase of fuel consumption amounting to 25 to 30 per cent. With electric propulsion a speed ratio as high as 40 to 1 can be used, the exact ratio being determined by the diameter of the motor that can be placed in the vessel, the output of the turbine, and the minimum number of poles that can be provided in the generator.

REVERSING. The propelling machinery of a ship must, of course, be capable of backing the ship as well as driving it forward. With reciprocating steam engines, there is no difficulty in this respect. A steam turbine, however, cannot be reversed. Consequently, when a ship is equipped with turbines directly connected to the propeller shafts, or connected thereto through mechanical gearing, each shaft must be equipped not only with a forward-driving turbine, but also with a turbine whose normal direction of rotation is opposite to that of the forward-driving turbine. Such turbines are called "reversing turbines" or "astern turbines." When the ship is driven forward the reversing turbine is driven backward, no steam being admitted to it. To reverse the direction of motion of the ship, the steam supply is cut off from the main turbine and admitted to the reversing turbine, the main turbine then being driven backward.

With electric gearing, reversing turbines are, of course, unnecessary, since the direction of rotation of the motors connected to the propeller shafts can be reversed merely by operating suitable switches, and the torque astern is equal to the torque ahead. This is a decided advantage of electric propulsion over direct-connected or mechanically geared turbines.

Losses in Reversing Turbines. Experiment has shown that a turbine forced in a direction opposite to its normal direction of rotation has about 10 times as much friction loss as when driven in its normal direction. This friction loss in a reversing turbine, which is always present when the ship is in motion, may amount to 1 per cent or more of the rating of the ahead turbine. This value varies with the rating and number of stages in the astern turbines.

TWO EFFICIENT SPEEDS. The propelling machinery of a war vessel should be capable of driving the ship efficiently not only at full speed but also at cruising speeds, which are usually from 40 to 70 per cent of full speed. The same is also desirable in certain passenger ships. As the power required to propel a ship varies approximately as the cube of the speed, this means that, at cruising speeds, the propelling machinery will be running at less than one-third of its maximum load. Since a steam turbine is most efficient at or near maximum load and at full speed, it follows that, when directly connected or mechanically geared turbines are employed, there is a sacrifice in efficiency at cruising speed, which is the speed at which a warship is driven by far the greater part of the time.

Cruising Turbines. To avoid this difficulty, it is possible to provide, in addition to the main turbines, auxiliary high-speed turbines geared to the propeller shafts, the speed reduction being such as to give the desired cruising speed. Provision is generally made for disconnecting the auxiliary turbines when the ship is driven at full speed by the main turbines. These auxiliary turbines are usually referred to as "cruising turbines." In all modern naval and merchant vessels, where long periods of operation at reduced power are contemplated, cruising turbines are generally provided.

With electric propulsion two efficient speeds are readily obtained without any such complication. All that is necessary is to change the ratio of the number of poles of the motors to the number of poles of the generators, which is readily accomplished by a simple switching operation. Since the propeller torque required at half speed is only about one-quarter that required at full speed, the voltage applied to the motors at cruising speed can also be reduced, thus keeping the motors operating at relatively high efficiency at reduced speed. U.S.S. *New Mexico,* which was the first electrically propelled battleship, being put

into commission in 1918, and all subsequent electrically propelled battleships and airplane carriers are arranged for pole changing. With reference to the *New Mexico*, Commander S. M. Robinson has stated: " In conclusion, it may be said that the performance of the *New Mexico* since commissioning has been entirely satisfactory in every way and that the expectations of those who were responsible for its installation have been more than realized."

GEAR LUBRICATION. In order to lubricate and carry away the heat generated in the reduction gears, large volumes of lubricating oil must be continually circulated through the gear case. This requires storage tanks, piping, oil pumps, and oil coolers. Sea water is used for cooling the oil. A storage tank is usually located above the machinery so as to insure an oil flow for several minutes upon failure of pump, thus allowing sufficient time to stop the gears before damage.

With turbine electric drive, a much smaller volume of lubricating oil is required because it is used only for lubricating the three or four turbine generator bearings and the two motor bearings.

35. TURBINE ELECTRIC DRIVE

Two Chicago fireboats, *Graeme Stewart* and *Joseph Medill* were equipped with electric propulsion in 1908. The first large ship equipped with electric propulsion for the U. S. Navy was the cutter *Jupiter*, which was placed in service in 1913. The latest example is the French Liner *Normandie*, which was completed in May, 1935, and is equipped with four turbine generating sets and four synchronous motors having a total output of 160,000 shaft horsepower.

The essential elements required for electric transmission between the turbines and the propellers of a ship are the generators, the motors, the cables connecting these two, and the switching and control devices.

ALTERNATING VERSUS DIRECT CURRENT. Where generators are driven by turbines, a-c apparatus is usually adopted for ship propulsion in preference to direct current. There are, however, a few cases where direct current is used when small powers are involved, and also when Diesel engines are used as prime movers.

Alternating current has many advantages over direct current, the chief of which may be stated as follows:

1. The combined transmission losses of the generator and motor, when a-c apparatus is used, is from 5 to 8 per cent less than with d-c apparatus.

2. High-speed prime movers and generators can be used with alternating current, whereas with direct current, when a high-speed steam turbine is used, it is necessary to have a reduction gear between this and the low-speed d-c generator. High-speed apparatus is cheaper and lighter.

3. A-c apparatus is, generally speaking, more reliable than d-c. As the distance between the generator and motor on shipboard is short, there is no advantage in using high-voltage transmission, as is the case on land. Lower voltages, therefore, are usually adopted. The range of potential is from 1100 to 6000 volts. The General Electric Co.'s records, over long periods of years and covering such electrical apparatus as is used on ships, show that only about $^1/_{10}$ of 1 per cent of machines of such voltage give any electrical trouble in a period of ten years. This electrical apparatus includes all motors and generators installed in all kinds of service.

TYPES OF MOTORS SUITABLE FOR ELECTRIC DRIVE. Five types of a-c motors have been used for ship propulsion:

1. Induction motors equipped with slip rings and external resistors.

2. Induction motors without slip rings, but with two squirrel-cage rotor windings. A high-resistance rotor winding is placed in the slot near the periphery of the rotor and beneath this a low-resistance winding. During normal running, when the current alternates slowly in the rotor, the low-resistance winding carries the current. When, however, there is a high-frequency current flowing in the rotor, as during reversals of the propeller, the self-induction of the low-resistance winding forces current into the high-resistance winding, and this produces a high torque.

3. Induction motors without slip rings but with one squirrel-cage rotor winding, consisting of deep, narrow bars. The action of this motor during reversal is similar to that of the double squirrel-cage motor.

4. Induction motors equipped with slip rings but no external resistors. The rotor is wound with a low-resistance winding near the periphery of the rotor, and beneath this a high-resistance squirrel-cage winding. The low-resistance winding is connected to the slip rings. To make the high-resistance winding carry the current during reversal of propeller, the low-resistance rotor winding is opened by means of contactor switches connected across

the slip rings. If this motor is wound to give two different speeds the slip rings can be made neutral for high-speed running and thus need not carry heavy current. All reversals are accomplished with low-speed connection.

5. Synchronous motors, the periphery of the poles being equipped with a low resistance bar winding. With this type of motor the propeller is brought to rest during reversal by reversing the phases with the circuit " dead " and then applying a strong field on the motor, leaving the field off the generator. The propeller thus drives the synchronous motor as a generator, being loaded on the turbine generator. Sufficient torque is developed to bring the propeller approximately to rest. Field is now applied to the main generator and removed from the motor. If the turbine governor has previously been set for a slow speed, the motor will now reverse and quickly reach approximate synchronous speed, at which time the field is again supplied. A small and simple air-cooled resistor can be switched in multiple with the generator during the stopping period. If this is done a higher torque can be developed with less excitation and with lower current flowing between the machines.

The following advantages are claimed for the synchronous motor over the induction motor:

1. A higher transmission efficiency due to operating at unity power factor.
2. Larger air gaps can be provided.
3. The generator and motor are lighter and cheaper.

The induction motor is better if two different numbers of poles are desired for running at different speeds, as in warships.

TYPES OF TURBINE GENERATORS SUITABLE FOR ELECTRIC DRIVE. The a-c propulsion turbine generator is of the conventional rotating-field central-station type, except as follows:

(*a*) It is designed for continuous operation at practically any speed from approximately 25 to 100 per cent of rating. In order to accomplish this requirement satisfactorily, it is necessary to design the turbine generator rotating parts so that there will be no serious critical speeds within the operating range. In the central-station unit, owing to operation at only one speed, it is only necessary to eliminate " criticals " in a narrow speed band.

(*b*) The field windings must withstand the large current required to prevent collapse of the generator voltage when starting the propulsion motor with the turbine operating at approximately 25 per cent speed. As soon as the motor locks into synchronism with the generator, the field current is reduced to normal. Approximately double normal excitation is used during this starting period.

(*c*) The governor must be designed to maintain approximate constant speed at any setting from 26 to 100 per cent. Since the a-c generators are not operated in parallel, it is not essential to have the turbine govern within the limits required for central-station equipment.

(*d*) It is also generally necessary, in a twin or quadruple propeller ship, to provide a steam limit device on the turbine to prevent overloading the electric equipment to the " pull-out point " when the ship is turned at full power. The increased power requirements are discussed in the paragraph on Turning. The steam limit simply limits the steam flow to the unit so that, when the overload occurs, the propeller and the turbine generator connected thereto will slow down, thus maintaining approximately constant torque.

The following are considered desirable turbine speeds (for the impulse type of turbine) for the corresponding generator output:

Horsepower	Rpm	Poles of Generator	Cycles per Second
7,000	3600	2 poles	60
10,000	3000	2 poles	50
16,000	2400	2 poles	40
29,000	1800	4 poles	60
65,000	1200	4 poles	40

CONTROL EQUIPMENT. The control equipment is usually placed in a wire mesh enclosed cell with a steel or aluminum panel front. All the operating equipment and meters are located on the front of the panel. The switches, rheostats, current transformers, potential transformers, and other high-voltage parts are enclosed in the control cell. The entrance door to this cell is equipped with an interlock which prevents application of excitation to the generators when the door is open.

All switches are of the air-break type, thus eliminating the fire hazard encountered with the oil-immersed type.

The connections are arranged so that the a-c generators cannot be operated in series or parallel, but either one, two, or four motors, depending on the number installed, can be

operated from one generator. When two or four motors are operated from one generator, all motors must operate at the same speed, in the same or opposite directions, due to the speed being determined by the setting of the turbine. The equipment in a four-propeller vessel is connected so that the two port motors are operated at the same speed and direction from a single control lever, and similarly for the starboard units. In all four-propeller vessels, it is customary to operate the port propellers as one unit and the starboard propellers as one unit, with provisions for operating the port and starboard units singly or from a single control lever.

When ready for operation, the turbine generator is started up by opening the hand throttle. All electrical circuits are open, and the turbine speed lever on the control board is at the minimum setting. The minimum speed setting is usually about 25 per cent of rated speed. When the throttle is wide open the governor takes charge and maintains approximately constant speed regardless of load.

After the " set-up " has been made, i.e., the selection of the motors and generators that are to be operated, the motor is started by operating the field control switch. The first step of this control closes the generator field circuit, applying approximately double normal current to the generator field windings. This condition is maintained until the motor or motors reach approximately constant speed; the field control lever is then moved to the next position, which applies current to the field of the synchronous motor. (This step is eliminated when induction motors are used.) As soon as the motor locks into synchronism, the load current decreases and the field control lever is moved to the next position, which reduces the generator field excitation to normal.

From this point on, the speed adjustment is made by operating the speed control lever which adjusts the governor setting of the turbine, the motor speed following the turbine speed.

The speed control lever and the field control lever are interlocked, so that the turbine speed cannot be increased until the field control lever is in the run position and the field cannot be removed until the speed control lever is in the minimum speed condition.

The motor reversing switches are also interlocked, so that they cannot be operated until turbine speed lever is in the minimum speed position and the field control lever is in the off position.

The operation of the overload device opens the generator field circuit, and, therefore, under no condition of operation is it possible to open or close the main circuit switch without first removing excitation from the generator fields.

VENTILATION OF ELECTRICAL APPARATUS. It is very important to ventilate the electrical apparatus in such a way that it will not collect moisture when shut down or running. To prevent this, the temperature of the apparatus must not be lower than that of the surrounding air. In order to prevent spray and water from being carried to the equipment, the ventilating air should be taken from the same room in which the apparatus is placed, except in Diesel engine rooms where other conditions affect the situation. Suitable dampers can be provided to prevent the engine room from becoming uncomfortably cold during the winter weather by recirculating some of the air.

In most recently constructed electric drive vessels, the closed system of ventilation is used, in which cases the air after leaving the generators and motors is passed around finned cooling tubes through which sea water is circulated. After passing the cooler, the air is returned to the generators or motors. Motor-driven fans are usually required for circulating the air in the motor cooling system, owing to the large size and low speed of the motor. Thus the same air is used continually. This method eliminates the large ducts leading from the upper decks of the ship and also insures the use of clean dry air at all times. These coolers can be made quite small for this purpose.

In order to keep the temperature of the internal parts of the motors and generators above the surrounding air during shutdown, steam or electric heaters are generally provided adjacent to the windings.

36. ADVANTAGES OF ELECTRIC PROPULSION

Some of the advantages of electric propulsion have already been noted. This subject has been very fully treated by Mr. W. L. R. Emmet in numerous papers (see Bibliography), and the following parts in quotation have been taken from his papers.

RELATIVE WEIGHTS OF ELECTRIC DRIVE AND GEAR DRIVE. Under some conditions, when properly designed, the weight of the machinery required for electric drive is but little in excess of the weight required for single reduction gear drive. Generally, the full theoretical advantage of the electric drive cannot be realized, because the dimensions of most vessels at the stern are insufficient to accommodate the large motor diameter required by a large speed ratio without excessive slope of the propeller shaft.

EFFICIENCY OF ELECTRIC TRANSMISSION. The greatest advantage for the electric transmission, from an efficiency standpoint, is in the higher powers, because the efficiency of motors and generators increases with increased ratings at a greater rate than with mechanical gears.

In the case of the 180,000 shaft horsepower airplane carriers, the overall motor and generator efficiency at full power, including excitation, power input to vent fans, control losses, etc., is approximately 92.7 per cent. A reputable manufacturer of large-powered reduction gears guarantees an efficiency of approximately 97.5 per cent for a set of double reduction gears having approximately the same ratio as provided for the electric transmission. From test data taken on turbines operating in the reverse direction, we may expect a loss of approximately 1.2 per cent in the reversing turbine when steaming ahead. This leaves a net difference in efficiency of 3.6 per cent in favor of the geared drive at full power for this particular installation.

When operating at reduced power and speed the reduction in efficiency of the electric drive shows a smaller decrease than the gear drive, owing to inherent characteristics of electric machinery in having a nearly uniform efficiency within certain limits of voltage reduction. In central-station generating equipment, the efficiency at reduced load shows a greater reduction because the voltage and speed are maintained at a constant value. In addition to this advantage, the electric drive permits the operation of a lesser number of turbines at the reduced power by virtue of its ability to operate more than one propeller from the same turbine. In the equipment specifically mentioned above, the overall efficiency at approximately 30 per cent power is only $^1/_2$ per cent less than at full power. Since in the turbo-electric drive the turbine speed is reduced in the same proportions as in a geared drive, the efficiency of the turbine would be the same in both.

In the example cited above, the motors are of the induction type; if synchronous motors had been used, the difference in overall efficiency at full load would have been reduced to approximately 2.5 per cent in favor of the geared drive.

GAIN IN EFFICIENCY AT LOW SPEEDS BY OPERATING AT REDUCED VOLTAGE. Electric motors for shore purposes usually operate at approximately constant voltage regardless of the load carried. At light loads, therefore, they are relatively inefficient owing to the iron losses remaining approximately constant. Motors, however, used for propelling ships usually obtain their power from a generator whose voltage can be varied to suit the motor's load. At reduced speeds, therefore, in an electrically driven ship, the voltage can be reduced; this reduction has the effect of materially reducing the losses in the iron laminations of both motor and generator. Thus, at reduced loads, the percentage of power lost is nearly the same as at full load, whereas with gears, the transmission loss remains quite high at reduced speeds. Also the percentage loss of power in the gears increases when the gears have become worn, but the efficiency of electric machinery is not affected by use.

LOCATION OF PROPELLING MACHINERY. When vessels are equipped with turbine electric propulsion, the driving motors can be placed as far aft as convenient, thus shortening the propeller shafting. The turbine-generator units can be placed near the boilers at any desired level, reducing to a minimum the length of steam piping and other piping systems. The controlling mechanism, as in an electric locomotive, can be placed at any convenient position.

EASE OF DISCONNECTION AND REPAIR OF PROPELLING MACHINERY. The following is quoted from Mr. Emmet: "In a geared equipment, each shaft has a system of turbines, gears, bearings, thrust-balancing devices and lubricating systems all mechanically locked together. With high-speed machinery any kind of trouble with any of these parts will almost certainly necessitate the immediate stoppage of the whole system. To keep a high-speed turbine running out of balance or with bearing trouble is impossible, and the gearing part would present almost equal difficulty. In the event of mechanical trouble of such character, a ship would have to be stopped until the damage could be cleared. The work necessary to uncouple and disconnect any part of such very heavy apparatus would be a serious matter involving much time, including that required to stop the ship.

"If it was found impracticable to make this disconnection, and the damage was such that the shaft could not be allowed to revolve, it would be necessary to lock the shaft to hold the propeller. This locked propeller acts as a very serious resistance to a vessel traveling at even moderate speeds. In fact, such a dragging screw may add 20 per cent to the horsepower and would in addition, materially reduce the maneuvering qualities of the vessel.

"In the electrically driven ship there is no mechanical connection of the shaft to anything but the rotors of motors. These are self-contained, iron-clad structure and cannot by any possibility be subject to mechanical interference. The shafts are subject

to the same possibilities of bearing or thrust trouble as shafts in other ships, but the presence of the motors does not increase this danger and the speed being low it is remote in any case. With this equipment any motor, generator or turbine, if in any kind of trouble, can be instantly disconnected without stopping the ship and with only a small loss from the highest speed capacity. Such a disconnection is made by simple switches."

Referring specifically to 180,000-hp, 33-5-knot airplane carriers now in the service of the U. S. Navy, Mr. Emmet continues: "Such interchangeability as this power of disconnection gives, constitutes one of the most important advantages of electric drive in such a ship. With one motor out of eight in trouble, only one-eighth of the maximum capacity is lost and the ship's maximum speed is impaired by only about 1 knot. If a generator or turbine is in trouble, the maximum speed is reduced only about 2 knots. With two generating units and four motors out, the ship can make 25 knots, and with three generators and four motors out, she can make 19 knots. If parts give trouble, they are simply cut out and repaired at leisure or as opportunity offers. The value of this interchangeability in a warship can hardly be over-estimated. It largely overcomes the military danger incident to accidents to the driving power, a danger which has always been of primary importance."

MUD IN CONDENSERS. In addition to the foregoing, there is a great advantage when maneuvering an electrically propelled vessel in shallow or muddy water in and around harbors, provided the ship is equipped with more than one turbine and condenser. Under these conditions, only one turbine generator is needed to drive the ship, and in case the condenser of this unit is plugged with mud, it can be immediately switched off and another turbine switched on to the driving motors.

In cases where turbines are mechanically connected to their respective propellers, under similar conditions of operation, it would be necessary to use all the turbines together with their condensers. If such a ship ran into mud, all condensers might become plugged at once but, if only one became plugged, the maneuvering qualities of the ship would be dangerously impaired. Commander Robinson states: "As an actual experience the *New Mexico* while entering New York harbor had to shift main generators twice owing to the plugging of her condensers with mud, and these shifts were made so quickly that they did not affect the operation of the ship at all."

BACKING POWER. Again quoting Mr. Emmet: "In geared turbine-driven ships, it is necessary to provide backing turbines which must run idle in the reverse direction when the ship is going ahead. These backing turbines involve complications which are very objectionable, and if these are reduced to a desirable minimum, the backing power will be greatly reduced to that easily provided with electric drive. Experiment has shown that a turbine forced in an opposite direction involves about ten times as much friction loss as when driven in its normal direction. This loss, therefore, is very appreciable in the backing turbines of ships. There are also serious difficulties and dangers in high-speed apparatus incident to the abrupt and wide changes of temperature where steam is suddenly admitted to a cold reversing or ahead turbine. With electric drive, the turbine never need be stopped when the ship is underway."

CRUISING ECONOMY. With the electric design, the number of motors and turbines used can, to a certain extent, be adapted to the demand for power, while with the other types all parts must be kept running. This gives very important gain in economy at all speeds below the maximum. At 18 knots (in the 180,000 hp airplane carriers for the U. S. Navy), only one turbine is required to drive the ship, and electrical arrangements are made by which the turbine can be run at full speed instead of running at half speed, as it would if the ratio was fixed as by gearing. Thus, the steam efficiency of the turbine at 18 knots, a desirable cruising speed, is equal to the best attainable at any speed, and the overall efficiency from turbine input to power developed at propeller shaft is only slightly less than at full power. The use of a cruising turbine will increase the efficiency over that developed by the main turbine at reduced speed, but in order to equal the electric drive, the efficiency of the cruising turbine must be sufficiently better than the main turbine to overcome the reduced efficiency of the reduction gear and the losses in the idling main turbine. Cruising economy gives increased cruising radius without renewal of fuel supply. This has always been considered a matter of the greatest importance in warships.

FLEXIBILITY OF INSTALLATION. A military advantage of great importance in connection with electric propulsion is the "flexibility of installation." The following is quoted from Commander Robinson (*Gen. Elec. Rev.*, April, 1919):

"The tendency in building modern capital ships is to provide for more and more torpedo protection and it becomes necessary to crowd the machinery away from the sides of the ship as much as possible. This arrangement is also desirable from the point of protection against gunfire for a similar reason. In this respect, electric drive has an enormous advantage over any other type of machinery in which the prime mover is mechanically con-

nected to the propelling shaft. The main turbine-generators may be placed in any part of the ship that is most desirable; they may be placed in compartments forward of each other and they may be raised up enough to place the main condenser underneath them—in fact, there is practically no limit, other than the head-room, as to the position of the main turbine-generators in the ship. This gives an enormous advantage to electric drive over all other types of machinery and enables the Naval Constructor to give far more adequate protection to the ship and machinery against damage by torpedo and gunfire. Those parts of the machinery—the main motors—which it is necessary to connect mechanically to the shafts, are comparatively small and take up only a small space so that they can be placed in small isolated compartments which will not menace the ship in case of flooding; since no main auxiliaries are required for the motors, the flooding of a motor room will not entail any loss in that respect. Also, the motors may be placed very much farther aft than can steam driven turbines and, therefore, the length of the main shafting may be very materially reduced. This constitutes a big advantage; both on account of less liability to derangement of the shafting itself, due to injury to the ship, and also of less danger to the ship itself because of the shafting not having to pierce a number of watertight bulkheads. These advantages of installation constitute the real and main reason for the adoption of electric drive for capital ships and any other advantages are minor compared with them. Utilizing these advantages to the fullest extent makes it possible to build capital ships which are far superior to any others fitted with any other form of machinery. In addition to advantages from the point of view of protection, there are also the advantages from an engineering standpoint. The shorter lengths of shafting make it easier to keep the shafts in line; the grouping of boilers around the machinery makes short and direct steam pipes with a consequent reduction in weight and complication and a smaller drop in steam pressure. The same may be said of practically all the other piping systems of the ship, such as feed lines, oil lines, exhaust lines, etc."

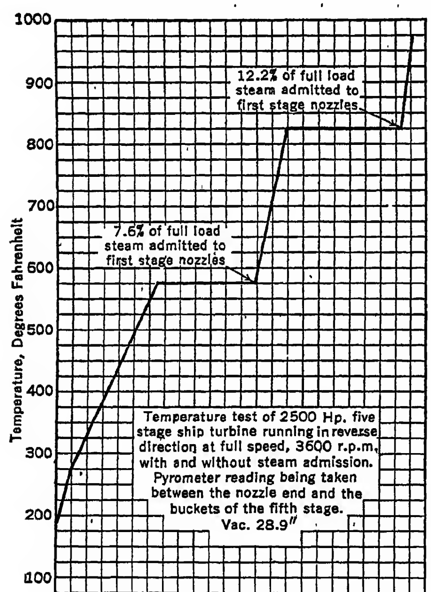

FIG. 5

SUPERHEAT AND REVERSING TURBINES. Whereas high superheat is beneficial to the operation and life of turbines, it has caused serious trouble in reversing turbines owing to expansion strains set up by rapid changes in temperature, and reversing turbines are necessary when mechanical connections between turbine and propeller are adopted. When steam expands without doing work, its temperature remains nearly constant, and if work is done upon it by a reversed turbine, this temperature is considerably increased. With superheated steam, these temperatures may be extreme and might be injurious to the main turbine as well as the reverse turbine, since it also must be used for reversal of direction and since the two often occupy the same casing.

Fig. 5 illustrates the possible steam temperatures which may be reached when maneuvering a ship equipped with reversing turbines. The turbine in this test was first run at full speed in the extremely high vacuum given on the record until a constant temperature was shown by the pyrometer. A little steam was then admitted and a constant temperature was again reached at 825 deg fahr, when more steam was admitted and the temperature then rose so quickly that the steam had to be shut off. In the General Electric Co.'s shops, it has been discovered that the reversing wheels of marine turbines turn blue with heat when operated at normal speed in a vacuum of 20 in.

When high superheat is used in combination with a reversing turbine, precautions can be adopted to preserve the turbine from damage. Various arrangements have been

proposed. One is to reduce the steam temperature before it enters the reversing turbine by injecting a spray of water, or by passing the steam through a cooler. Another method is to install a steam pipe connected between the boiler drum and the superheater—this also requires special maneuvering valves. With this latter method, greater care must be taken to prevent the superheaters from overheating during maneuvering operations. These complications are eliminated by the adoption of electric drive, which abolishes the astern turbine.

ELECTRIC DRIVE FOR AUXILIARIES. A source of considerable loss in the operation of many ships is the use of steam-driven auxiliaries. With electric drive, it is necessary to maintain a d-c electrical supply independent of the main generators for purposes of excitation. This same source can be used for lighting and driving electrical auxiliaries. If turbine units are chosen for this auxiliary power, the steam from these units can be exhausted into a suitable stage of the main turbine, and, by automatic means, exhausted into the main condenser when the load is removed from the main turbine. A more simple method is to design the auxiliary turbines as condensing units and connect their exhaust directly into the main condenser. This is the usual method of design. An auxiliary condenser is provided for use in port. In certain cases, it may be desirable to use a few steam-driven auxiliaries, such as boiler-feed pumps, and the exhaust from these can be utilized for feed heating. If necessary, this steam can be supplemented by either "bleeding" the main turbine or using part of the exhaust from the auxiliary units. In some installations, practically all feed-heating steam is bled from main turbine.

Some few ships are equipped with auxiliaries driven by a-c motors which receive their power from the main generating unit. In some of these installations, reduced speeds of the ship are obtained by running the turbine generator at approximately full speed and reducing the motor speed by means of an external resistance. The fuel consumption during these reduced speeds is greater with this method than when the turbine speed can be reduced, as there is a large loss of power in the external resistance.

In other installations, where the turbine speed varies with the propeller, the alternating current is taken from the main propulsion generator when the propulsion generator is operating between 66 and 100 per cent of rated speed. Since direct current is used for most auxiliaries, the alternating current taken from the propulsion generator operates an a-c motor which is directly connected to a d-c generator. The d-c generator is designed to give 100 per cent voltage at approximately 66 per cent speed. Since the speed of the a-c motor follows the propulsion generator, an automatic voltage regulator is provided to vary the generator field excitation automatically and thus maintain constant voltage at all speeds within the range from 66 to 100 per cent. When the propulsion generator is not in operation or the speed is below 66 per cent, the motor-generator set is driven by a steam turbine which is connected to it through reduction gears. The change-over from motor drive to turbine drive is done automatically when the propulsion turbine speed is reduced below 66 per cent. The change from turbine drive to motor drive is manual. When the a-c motor is driving the motor-generator set, the turbine is operated under vacuum with the steam supply shut off. This latter arrangement was adopted in the five U. S. Coast Guard vessels built in 1929.

In a few of the Coast Guard vessels, some of the auxiliaries, where the load varies with the speed of the vessel, are driven by a-c motors. These motors are supplied direct from the propulsion generator through step-down transformers or from the synchronous motor of the motor-generator set which may be operated as a generator when the motor-generator set is being driven by the steam turbine.

37. INTERNAL-COMBUSTION ENGINE DRIVE

DIRECT-DRIVE DIESEL ENGINE. For very small pleasure boats on inland waters and bays, the internal-combustion gasoline engine is used almost exclusively. Gasoline fuel is very expensive and presents a great fire hazard on a vessel. In recent years, the development of the heavy oil Diesel internal-combustion engine has progressed to such a state that it now finds many applications in overseas cargo and passenger vessels of the smaller sizes. The number of such applications is much greater on vessels of European registry than for the United States. The largest single Diesel engine in operation at the present day is of the double-acting four-cycle, type and has a rating of 6700 hp at 125 rpm.

As in all other types of prime movers, the weight, cost, and space required per horsepower for an internal-combustion engine decrease as the speed is increased. The use of reciprocating parts, however, limits the speeds far below those obtainable with the steam turbine, but speeds are obtained which are above the best propeller performance Therefore, in

this case, it is also possible to use the electric reduction gearing, the speed ratio for the larger size engines generally not exceeding approximately 5 to 1. Although some Diesel-engine-driven vessels have been equipped with reduction gears, the standard application is direct drive or through the electric reduction gear.

With the direct-drive Diesel, the engine must be stopped, started, and reversed many times during a vessel's entry into port. The general method of starting and reversing a Diesel is by operating it on compressed air until sufficient compression pressure is obtained in the cylinder to ignite the injected fuel oil. Since sometimes, during the docking of a vessel, orders may be received for as many as 30 starts, including reversals, it is very essential to have a large supply of compressed air, for without this, the engine is incapable of being started. This is one of the major disadvantages for the direct-drive internal-combustion-engine type of equipment. The fuel consumption per shaft horsepower-hour for the Diesel engine is slightly better than in the most modern high-pressure, high-temperature steam plant, but the present cost of Diesel fuel oil is much greater than for the grade of oil required in the steam plant. Because of this, the fuel cost per shaft horsepower-hour at present prices is about equal to or at least within debatable limits of equality with the modern steam plant.

In estimating the operating cost for a Diesel engine, some consideration must be given to the lubricating oil which is consumed; in the turbine plant the loss is practically negligible. Owing to the greater contamination and larger quantities of lubricating oil, the Diesel plant must be equipped with more purifying apparatus than is required by the turbine plant.

A review of the operating data of several direct-drive Diesel-engine-driven cargo vessels fails to indicate that the operating cost for a Diesel ship of American registry is materially less than for a modern turbine plant. The data also indicate that the maintenance cost increases very rapidly after the cylinder sizes exceed a certain dimension, owing to the increased difficulty in handling the parts in the limited space available on a vessel. For the large engines, it is generally necessary to have an outside contractor provide additional men and equipment in order to make a general overhaul of the machinery. This, of course, greatly increases the operating cost of the vessel and, in many cases, requires an arrangement of ship schedules which will allow a greater time in port.

The cost of these large Diesel engines (4000 hp or over) in the United States is also much greater than for some other types of machinery, because the quantity constructed is small, and the applications to date are so varied that each job is one of special design and construction. Stationary or industrial engines, except in special cases, are not applicable to marine installations on account of their higher speeds, constant direction of rotation, etc.

DIESEL-ELECTRIC DRIVE. The internal-combustion engine, when electrically connected to the propeller, is commonly known as the "Diesel-electric drive," and this type of installation overcomes several of the objections of the direct-drive Diesel.

The Diesel electric drive, like the turbine electric drive, consists of a generator directly connected to the Diesel engine and the propeller directly connected to an electric motor. In this case, the electric machinery is usually of the d-c type. This electric reduction gear removes the requirement for a very slow-speed engine, yet permitting a relatively slow-speed propeller. By the use of the d-c system, the speed ratio between the engine and propeller is readily changed from maximum design to zero and the propeller motor reversed with very little difficulty. The procedure is so easily accomplished that, in most Diesel electric installations, the speed of the propeller is adjusted and controlled directly on the bridge instead of the usual procedure of the bridge passing an order to the engine room where the actual speed adjustments are made.

In the Diesel electric installations, more than one engine can be used for each propeller with no operating difficulties. This permits the installation of more and smaller Diesel engines. The greater quantity reduces the cost per engine, and the smaller engine reduces the size of the parts to be handled, facilitating maintenance and repairs. The multiple engines also facilitate routine overhauls, in that, for multiple-engine ships, one engine can be switched out of the circuit and the ship operated on the remaining engines with only a slight reduction in speed.

The electric equipment for Diesel electric installations usually is arranged as follows:

A shunt-wound, separately excited, d-c generator is directly connected to each Diesel engine and a shunt motor directly connected to the propeller shaft. The propeller motor is frequently of the double type, i.e., it consists of two independent armatures on a single shaft with two bearings and two electrically independent field structures, to give increased reliability. If one motor is damaged for any reason, the vessel can still operate on the other motor at a reduced speed.

In addition to the propulsion generators, one or more exciters are usually installed. These exciters are either in tandem with and driven by the propulsion generator engines

or a separate unit directly connected to a separate Diesel engine. These exciters operate at constant voltage in most cases and supply excitation to the propulsion generators and propulsion motors and supply direct current to the other ship's auxiliaries, including lighting.

In order to keep the size of the motors and generators to a minimum and to insure uniform heat distribution in the equipment, both the motors and generators are usually force-ventilated. In some cases, the supply of air is taken from the engine room and discharged out the top of the vessel. This, however, is not the best practice, for invariably in a Diesel engine room there is considerable oil vapor in the air and, when it is forced through the motor and/or generator, the ventilation passages act as oil condensers, with the result that the windings are soon saturated with oil. The supply of this cooling air from outside the engine room is, therefore, essential, and except for the disadvantage to operating personnel, because of the high temperature that is produced, could be discharged to the engine room. The best installation, therefore, requires both supply and discharge ducts with careful design at the air intakes at the top of the vessel, to prevent water and spray from being carried into the electric equipment.

In one installation that the writer has been associated with, air coolers have been provided for the generators and motors. These coolers consist of finned tubes which are cooled with sea water, and the air is continuously circulated through motor and cooler, and generator and cooler, by motor-driven fans. No air is taken from the outside. This arrangement has the objection that, even with the most carefully designed ventilation systems, dust from the carbon brushes is circulated and eventually closes the ventilation passages through the windings unless frequently cleaned. This, of course, can be overcome by filters, but this adds equipment which requires space and increases the weight of the installation. Space is at a premium, because every cubic foot taken by machinery means a corresponding reduction of space available for revenue-producing passengers or cargo. The air ducts of the air cooler installation usually have an enlarged cross-section at one point, so that the air velocity will be reduced to such an extent that most of the carbon particles will drop to the bottom of the duct, where they can readily be cleaned out.

Since the d-c equipments permit a variable speed ratio between generator and motor, the Diesel engines for this type of equipment are automatically operated at practically constant speed by a governor. The engine is, therefore, never reversed and never started under load. This procedure reduces the starting air requirements, as the engine is not stopped until the vessel is securely fastened to the dock.

Since the armature circuits of the generators and motors are all connected in series, each generator is provided with a special switch which has two positions. The off position opens the armature circuit of the associated generator and at the same time keeps the propulsion armature circuit complete for the remaining equipment. This will permit operation with one, two, three, or four generators in series, depending on the number available. All switching equipment is interlocked, so that it is impossible to open or close any of the main power circuits without first opening the generator field circuits, thus reducing the terminal voltage of the generator to residual and preventing heavy arcs by breaking large currents. The main power circuit switches are provided with arcing tips to facilitate renewal from any burning that may be encountered.

In order to control the speed and direction of rotation of the propelling motors, a potentiometer-type reversing generator field rheostat is provided in the wheel house or adjacent thereto, with mechanical connection to a handle, wheel, or lever adjacent to the steering wheel. This field rheostat controls the amount and direction of the field current to the generators that have been "switched" into the propulsion circuit by the engineer in the engine room. This arrangement will permit operating the vessel at reduced speed with practically full-speed fuel consumption per horsepower-hour, provided the speed is selected so that the connected generators will be operated at rated load. For instance, in a vessel having four generators in series for full power operation, the fuel consumption per shaft horsepower hour for $^1/_4$, $^2/_4$, and $^3/_4$ full power will be approximately the same as for full power. This result is obtained because the generator always operates at the same speed, and with $^1/_4$ power and one generator operating, the generator voltage is the same as full-load. Therefore, the efficiency of the Diesel engine and generator is the same as for full load, the only additional loss being the difference in motor efficiency. The variation of motor efficiency from $^1/_4$ load to full load is considerably less than with the usual type of d-c motor because the reduced power is obtained at reduced speed which is procured by a reduction of the motor applied voltage and motor field excitation. If we assume that each generator has a rated voltage of 300 volts, then for $^1/_4$ power, one generator gives motor voltage of 300, $^1/_2$ power requires two generators with a motor voltage 600, etc.

The shunt fields of the generators are operated in parallel and each generator switch has sufficient contacts to close the circuit to the generator field at the same time the generator armature is connected to the power circuit.

Unfortunately for the electrical system, the power required to drive a propeller does not vary directly as the revolutions, but is generally rather close to the cube power. For example:

100% power—100% speed—100% voltage—100% current
75% power— 90.9% speed— 75% voltage—100% current
50% power— 79.4% speed— 50% voltage—100% current
25% power— 63.0% speed— 25% voltage—100% current

Since the generator is designed for the voltage required at full load, any increase in generator voltage to obtain a higher motor speed when operating with reduced number of generators would mean an increase in the cost and weight of the generators. Therefore, in order to absorb full power at a voltage corresponding to the sum of the ratings of the operating generators, the motor field excitation is reduced for each generator removed from the circuit.

In a four-generator installation, the characteristics of the motor may not permit a sufficient reduction of the field to give the speed required for 1/4 power without the motor becoming unstable. This is overcome in a double-motor installation by using only one motor armature for the one generator condition.

Since the Diesel engines are operated at rated rpm for all propeller speeds and electric machinery has the inherent characteristics of being able to withstand very great current overloads for short intervals of time, torques as great as 300 per cent may be developed by the propelling motor during the reversing period without overloading the Diesel engines—that is, with reduced motor speed and voltage, the current can be increased so that the product of the two approaches the rated horsepower of the engine. This high torque is not possible with any other type of drive.

In order to keep the voltage to ground and between wires to a minimum in a double-motor installation, each half of the double motor is connected between half the generators; i.e., in a four-generator installation with a double motor, the circuit is through two generators, one half the motor, the other two generators, then the other half of the motor. This arrangement is of no consequence where the applied voltage is relatively low.

The Diesel electric drive introduces an additional power loss between the prime mover and propeller, but this loss may be partially or even wholly made up in some particular cases by the better fuel consumption of the higher-speed engine and the increased efficiency of the lower-speed propeller. As the fuel consumption is approximately the same per horsepower-hour at full, 3/4 and 1/2 power, it requires only a very short period of operation at reduced power to effect a saving of fuel over that required for direct-drive Diesel equipment. In the direct-drive plant the fuel consumption increases quite rapidly per shaft horsepower-hour as the power and speed are reduced.

At the present time, there are many very successful Diesel electric installations, the greatest number of applications being in tugs, small harbor craft, etc., where maneuverability and pilot-house control are of great importance. One of the largest installations on a commercial cargo vessel consists of:

One 4000-hp separately ventilated 60-rpm 1500-volt, double-unit propulsion motor.

Four 800-kw, 375-volt, 250-rpm generators, each direct connected to an 8-cylinder 1200-bhp, Diesel engine.

The U. S. Army engineers have used Diesel electric equipment in some of their hopper dredges. In this type of vessel, the propeller and the dredge pump are each directly connected to a motor. When dredging, the propulsion generator is connected to the dredge pump motor and a smaller generating unit is connected to the propulsion motor. The speed of the vessel is very low when dredging; therefore, the power required to operate the propelling motor is very small. After the hoppers are filled, the pump motor is shut down and the propulsion generator connected to the propelling motor. This permits a reasonable speed of propulsion when proceeding to the dumping grounds with the minimum of idle equipment. This type of equipment makes it very easy to place the entire control of the dredging and maneuvering operations under one man on the bridge. It is understood that, with this type of dredging equipment, the cost per cubic yard has been considerably reduced over that obtained with other types of equipment.

This double use of the propulsion generator has also been adopted in a fire boat, the propulsion generator being connected to operate the fire pumps when at a fire and to the propulsion motor when on the way to the fire.

Summary of Advantages. The advantages of the electric reduction gear for Diesel engine installation are as follows:

(a) Direct control of vessel on bridge.
(b) Quicker reversal of propeller.
(c) Greater torque during reversing.
(d) Higher-speed Diesel engines.
(e) Less air tanks and smaller compressors.
(f) Small engines with small reciprocating parts.
(g) Less chances of sea or port detention, since failure of one engine will not prevent operation of vessel and repairs may be made at sea without stopping vessel.
(h) In some cases, fuel consumption at full load is same as for direct-drive Diesel.
(i) Practically same fuel consumption per shaft horsepower-hour at certain reduced speeds as at full speed.

Summary of Disadvantages.

(a) More equipment required than for direct-drive Diesel.
(b) In some cases, initial cost, and weight may be slightly more.

At the present time, the output per shaft with this type of drive is limited to about 8000 hp per propeller. This is due to the present limits of motor design and the inability to get the large-diameter motor in the vessel without producing too much slope in the propeller shaft.

38. TYPICAL ELECTRICALLY PROPELLED SHIPS

The following is a partial list of the more important turbine-electric-propelled ships:

Name	Type	No. of Propellers	Total Shaft Horsepower, Full Speed	Type of Motors	No. of Ships This Class	Reference
U.S.S. *Tennessee*	Battleship	4	28,000	Induction	5	1
Rodman Wanamaker	Ferry	2	2,200	Induction	2	2
U.S.S. *Lexington*	Airplane carrier	4	180,000	Induction	2	3
California	Pass.-cargo	2	17,000	Synchronous	3	4
Chelan	Coast guard	1	3,000	Synchronous	5	5
City of Saginaw	Car ferry	2	7,200	Induction	2	6
Morro Castle *	Pass.-cargo	2	16,000	Synchronous	2 *	7
President Coolidge	Pass.-cargo	2	26,500	Synchronous	2	8
Talamanca	Pass.-cargo	2	10,500	Synchronous	6	9
Corsair	Yacht	2	6,000	Synchronous	1	10
Normandie	Pass.-cargo	4	160,000	Synchronous	1	11

A partial list of representative Diesel-electric propelled ships is as follows:

Golden Gate	Ferry		750	D-c shunt	2	12
A. Mackenzie	Hopper dredge		1,600	Special	4	13
J. W. Van Dyke	Tanker		2,300	D-c shunt	1	14
N. Y. C. No. 34	Tug		650	D-c shunt	2	15
Fresno	Ferry		1,250	D-c shunt	6	16
Courageous	Cargo		4,000	D-c shunt	3	17

* The *Morro Castle* was burned in 1934.

ELECTROCHEMICAL PROCESSES

By M. de K. Thompson

(See also Electrochemistry.) The principal industrial electrochemical processes are the following:

Electroplating.
Galvanoplasty, including electrotyping.
Electrolytic refining of metals.
Electrolytic extraction of metals.
Electrolytic oxidation and reduction.
Electrolysis of sodium and potassium chloride solutions.
Electrolysis of water.
Electric-furnace processes (see Electric Furnaces).
Production of ozone.
The Fixation of Nitrogen.

Some of the more important of these various processes are briefly described below.

1. ELECTROPLATING

Electroplating consists in covering a conducting surface (usually metallic) with a thin, smooth, compact, well-adhering layer of metal, by depositing this metal electrolytically from an aqueous solution of one of its salts. Usually the anode of the electroplating vat consists of rods or plates of the same metal as that of the salt in solution and is connected to the positive terminal of the source of electricity. For some metals, for example, chromium, unattackable anodes are used. The object to be plated forms the cathode, and is usually connected to the negative terminal. The anode dissolves approximately to the same extent that the cathode gains, so that the amount of the metal ions in the bath remains nearly constant. There are cases in which this does not hold; for example, in brass plating. This results in a continuous change in the composition of the bath.

SUSPENSION OF OBJECTS TO BE PLATED. The cathodes are always suspended in the bath between two rows of anodes, so that they will be plated uniformly on both sides. When the cathode is of irregular shape, or very large, it must be turned frequently during the plating in order to get a uniform deposit. The cathodes and anodes are suspended by copper wires from horizontal metallic tubes, the ends of which rest on the edge of the plating vat. The metallic tubes are permanently connected to the source of the electricity, so that, as soon as the cathodes are suspended in the bath, electrolysis begins. Small objects, such as tacks, pins, and screws, are suspended in the vat in a wire basket, which is, of course, plated simultaneously. To get a uniform plated surface the objects should be well shaken during electrolysis. The anodes are removed from the bath only when they are nearly used up and have to be replaced.

CONSTRUCTION OF VATS. Large plating vats are made of wood or concrete lined with some specially prepared substance resembling pitch, with lead, or with rubber. Small tanks for silver or gold plating are usually porcelain lined.

VOLTAGE AND CURRENT DENSITY. Electroplating tanks are always connected in parallel, so that they will be electrically independent of each other.

Low-voltage generators of from 5 to 6 volts are, therefore, used in plating, and each tank must be connected directly to the generator through a rheostat in order to regulate the voltage.

The proper current density in any plating process is that density at which a good deposit is formed. This may vary within certain limits for a given solution and temperature; it is a function of the temperature and the nature of the solution.

WASHING AND PICKLING. In order to make the metal adhere well to the surface to be plated, the surface must be perfectly clean. Grease is removed by dipping it into a hot alkaline bath containing 10 per cent, by weight, of sodium carbonate or sodium hydrate. After washing off the alkali, the object is dipped into a bath called a " pickle," the purpose of which is to remove any oxide that may have been produced by the alkali, and to give a

bright surface. The pickle is then washed off with water and the object is suspended immediately in the electroplating vat. Degreasing by Trichlorethylene is a more recent method. (W. Burden, Metal Cleaning and Finishing, 1935, Vol. 7, p. 504.)

Pickling Solutions. The pickle varies with the nature of the metal treated. Cast iron and wrought iron are pickled in a solution consisting of 15 parts, by weight, of water to 1 part of concentrated sulfuric acid. A suitable pickle for zinc is dilute sulfuric or hydrochloric acid. Copper, brass, bronze, and German silver are pickled first in a bath consisting of 200 parts, by weight, of nitric acid of specific gravity 1.33, 1 part of common salt, and 1 part of lampblack. The lampblack is intended to form some nitrous acid from the nitric acid. The object is then washed in boiling water and is immersed in a "bright dipping bath," to give a bright surface. This bath consists of 75 parts, by weight, of nitric acid of specific gravity 1.38, 100 parts of concentrated sulfuric acid, and 1 part of common salt.

After the plating is finished, the object is removed from the plating bath, washed in hot water, and placed in warm sawdust or in a drying closet.

ELECTROLYTIC CLEANING. In electrolytic cleaning the object is made the cathode in a hot alkaline solution. A current density of 10 amp per sq ft (1 amp per sq dm) is used, which requires 6 to 10 volts. This emulsifies the grease. The time required is 3 to 5 minutes. The current may then be reversed for 10 to 15 seconds to dissolve any metallic deposit of zinc, lead, or tin that may have formed. This also tends to make the deposit more adherent. (De la Rive used electrolytic cleaning in sulfuric acid in 1842.) A suitable solution is 8 oz per gal (60 grams per liter) of sodium carbonate, and 2 oz per gal (15 grams per liter) of sodium hydroxide.

SIMULTANEOUS CLEANING AND PLATING. The object is electrolyzed as cathode in alkaline copper cyanide. The alkali removes the grease, and a thin film of copper is deposited where the surface is clean. The advantage is that the deposited copper shows when the surface is clean. It is chiefly used in the large-scale production of cheap articles, or for the preliminary coating of iron and steel with copper. The following solution may be used:

	per liter
1/2 lb H. V. Winkle's XXX lye	60 g
2 oz copper carbonate	15 g
4 oz ammonium carbonate	30 g
4 oz potassium cyanide	30 g
1 gal water	1000 g

(*Trans. Am. Electrochem. Soc.*, Vol. 27, p. 142, 1915.) If deposit of brass is desired, add 2 oz of zinc carbonate to this solution.

PLATING BY DIPPING. A thin film of metal may be deposited on a metal by dipping it into a solution of a salt of a metal which is electropositive (see Principles of Electrochemistry) with respect to the metal to be plated, e.g., by dipping iron into a copper-sulfate solution. A small amount of iron dissolves and an equivalent amount of copper is deposited on the remaining iron. Of course, only a thin film can be produced in this way, for, as soon as the iron is covered with copper, the action ceases. No external electric current is needed in this process.

PLATING BY CONTACT. When the metal to be plated is electropositive with respect to the metal to be deposited on it, the electrodeposition can be obtained by connecting the former to a zinc rod. In this case, the solution must be of a complex salt, in order to reduce the deposition of the metal in solution on the zinc itself. For example, silver may be deposited on copper by connecting a zinc rod or plate to the copper object by a wire and dipping both into a potassium-silver-cyanide solution; the zinc dissolves and silver is deposited on the copper, while some silver is also deposited on the zinc. No external current is needed in this process.

NICKEL PLATING. Numerous formulas for nickel-plating solutions are in use. The following is an example:

	Approximate Normality	Grams per Liter	Ounces per Gallon
$NiSO_4 \cdot 7H_2O$	0.75	105	14
NH_4Cl	0.25	15	2
$NiCl_2 \cdot 6H_2O$	0.13	15	2
H_3BO_3	0.25 molal	15	2

Hydrogen-ion concentration: $pH = 5.3$.
(Blum and Hogaboom, Electroplating and Electroforming, p. 259, 1930.)
Current density 0.5 to 2 amp per sq dm (5 to 19 amp per sq ft).

The following fluoride solution gives a fine-grained deposit:

		Grams per Liter	Ounces per Gallon
$NiSO_4 \cdot 7H_2O$	2 normal	281	37.5
NaF	0.2 normal	8.4	1.1
H_3BO_3	0.5 molal	31	4.2

Nickel anodes of at least 99 per cent purity should be used. The salts should be free from zinc and copper.

In recent years high-speed nickel plating with low *pH* (below 3) and high-current density (up to 18 amp. per sq. dm.) has been used (O. P. Watts. *Trans. Am. Electrochem. Soc.*, 1931, Vol. 59, p. 379; M. Ballay, ibid., 1932 vol. 62, p. 91.)

The Madsenell process of plating ductile and well-adhering layers of nickel and other metals consists in " degasification " of the base metal, such as iron or steel by treating as anode in 96 per cent sulfuric acid at 50 amp per sq ft. (F. M. Dorsey, *Ind. Eng. Chem.*, 1928, Vol. 20, p. 1094.)

COPPER PLATING. The metals on which copper is usually plated, such as zinc, iron, and tin, are more electronegative than copper. On dipping any of these metals into an acid copper-sulfate bath, they would become covered with a layer of copper, which in some cases is spongy and does not adhere well. In order to reduce the velocity with which this reaction takes place a solution of the double cyanide of copper and potassium, $KCu(CN)_2$, is used. This can be made by dissolving cuprous cyanide in potassium cyanide to form a 3 to 8 per cent solution,* with an excess of 0.2 per cent of potassium cyanide. This bath is generally heated to 50 to 60 deg cent. The proper current density at the cathode is about 0.5 amp per sq dm (4.6 amp per sq ft) which requires about 3 volts at room temperature. For further details, see Circular of the Bureau of Standards, No. 52.

Surfaces that have already received a thin coating of copper in a cyanide bath are sometimes thickened in an acid copper-sulfate bath. The cyanide must be washed off on transferring to the sulfate bath. A sulfate bath may be made by dissolving 150 grams of copper sulfate $CuSO_4 \cdot 5\,H_2O$ and 50 grams of concentrated sulfuric acid in 1 liter of water. The proper current density is about 0.7 amp per sq dm (6.5 amp per sq ft) which requires less than 1 volt.

Small springs are very much weakened by copper plating in a cyanide bath, and are very likely to break while suspended, slightly stretched, in the bath during plating. This may be due to absorbed hydrogen. See *Met. and Chem. Eng.*, Vol. 16, p. 83, 1917; *Trans. Am. Electrochem. Soc.*, 1917, Vol. 32, p. 247, and 1918, Vol. 33, p. 169. A copper sulfate-oxalate bath has been recommended as a substitute for copper cyanide (C. G. Fiuk and C. Y. Wong, *Trans. Am. Electrochem. Soc.*, 1933, Vol. 63, p. 65).

ZINC PLATING. Electrolytically deposited zinc is of a dull color and is not as pleasing in appearance as layers obtained by dipping in melted zinc, but electrolytic zinc has been shown to protect iron better for a given thickness of deposit than a coating made from melted zinc. (Burgess, *Electrochem. and Met. Ind.*, Vol. 7, p. 17, 1905.) A suitable solution consists of 240 grams of zinc sulfate, $ZnSO_4 \cdot 7\,H_2O$, 15 grams of ammonium chloride, 30 grams of aluminum sulfate $[Al_2(SO_4)_3 \cdot 18\,H_2O]$, and 1 gram of licorice per liter of solution. Enough sulfuric acid is added from time to time to keep the *p*H value from 3.5 to 4.5. The current density in the cathode is 5 amp per sq dm (47 amp per sq ft), which requires from about 1 to 2.5 volts. Zinc anodes are used. A little more zinc is dissolved than is deposited, owing to the free acid. The resistance may be reduced by warming the bath to 40 or 45 deg cent. A finer-grained deposit, and therefore better protection, are furnished by deposits from alkaline solutions. The following formula has been found satisfactory at the Bureau of Standards:

	Normality	Grams per Liter	Ounces per Gallon
ZnO	1.0	45	6
NaCN	1.5	75	10
NaOH	0.3	15	2

The current density is from 1 to 2 amp per sq dm (9.3 to 19 amp per sq ft), and the temperature is 40 to 50 deg cent (104 to 122 deg fahr).

Zinc anodes containing 0.5 per cent aluminum and 0.3 per cent mercury have been found superior to pure zinc anodes. (*Metal Ind.* 1933, Vol. 31, p. 195.)

* An *n* per cent solution of a substance contains *n* parts, by weight, of that substance in 100 parts, by weight, of the solution.

BRASS PLATING. If an acid solution of zinc and of copper sulfates were electrolyzed, only copper would be deposited. In a cyanide solution of zinc and copper, however, these metals are deposited simultaneously in the form of an alloy. (Spitzer, *Zeit. f. Electrochemie*, Vol. 11, p. 367, 1905.) The copper is deposited more easily than the zinc, so that at a low current density, 0.1 amp per sq dm (0.93 amp per sq ft), only a small amount of zinc is deposited, but at 0.3 amp per sq dm (2.8 amp per sq ft), the deposit contains only 80 per cent of copper. Increasing the current density changes the composition of the deposit only slightly.

A suitable bath for brass plating is made by substituting zinc cyanide for half of the copper cyanide in the solution given above for plating. Brass anodes are used. Other brass baths that have been found to give good deposits are the following:

	Normality	Grams per Liter	Ounces per Gallon
$CuCN$	0.30	27	3.6
$Zn(CN)_2$	0.15	9	1.2
$NaCN$	1.10	54	7.5
Na_2CO_3	0.60	30	4.0

(Blum and Hogabroom, Electroplating and Electroforming, p. 385, 1930.)

The temperature is 32 to 45 deg cent (90 to 113 deg fahr), and the current density 0.2 to 0.3 amp per sq dm (2 to 3 amp per sq ft). An important property of brass containing 65 per cent copper is that rubber can be made to stick to it with great tenacity. For this reason, brass plating is used extensively in the rubber industry.

SILVER PLATING. The double cyanide of potassium and silver is generally used for silver plating on account of the smooth deposit obtained with this solution. The deposit from a nitrate comes down in the form of isolated crystals, which do not cover the surface completely. The solution contains from 1 to 5 per cent silver as potassium silver cyanide, $KAg(CN)_2$, with 0.5 per cent of free potassium cyanide. Too much or too little free cyanide gives a bad color to the deposit. A good silver plating bath may be made up as follows:

20 grams potassium silver cyanide.
10–12 grams potassium cyanide, 99 per cent.
1 liter water.

The current density is 0.3 amp per sq dm, at about 1 volt. (Schlötter, Galvanostegie, 1. Teil, p. 149, 1910.) The anodes are silver.

In order to make thick deposits of silver adhere well on metals which alloy with mercury, a thin deposit of mercury is produced by dipping these metals in a "quicking bath," consisting of a solution of 30 grams of potassium mercury cyanide, $KHg(CN)_2$, and 30 grams of potassium cyanide in 1 liter of water. On removal from the quicking bath, articles are washed and placed immediately in the silvering bath.

At least two different silvering solutions are used. The first is called a "striking" solution, or "strike." It contains more cyanide and less silver than the regular silvering bath, for the purpose of reducing the silver-ion concentration in order to prevent deposition by immersion. In some cases a second striking solution is used.

The silver deposit from the solution given is not bright, but the addition of a small amount of the solution saturated with carbon bisulfide makes it so.

Silvering solutions of silver iodide dissolved in sodium iodide have recently been put into practice (C. W. Fleetwood and L. F. Yntema, *Ind. Eng. Chem.*, 1935, Vol. 27, p. 340.)

GOLD PLATING. The solution used in gold plating contains from 0.35 to 1 per cent of gold as the double cyanide of gold and potassium, $KAu(CN)_2$, with twice as much free potassium cyanide. The current density on the cathode is about 0.2 amp per sq dm (1.9 amp per sq ft), which requires about 1.5 volts. The anodes are pure gold. The solution may be used hot or cold. The deposit from a hot solution is more dense, more uniform, and of a richer color. The color of the gold deposit may be influenced by simultaneously depositing some other metal. Green gilding may be obtained by adding a little silver cyanide to the bath, until the desired tint is obtained. The solution should be cold. To give the deposit a red tint, a little copper cyanide is added to the solution.

CHROMIUM PLATING. In recent years chromium plating has become common. The following two formulas are in use:

	Grams per Liter	Ounces per Gallon
1. Chromic acid, CrO_3	250	33
Concentrated H_2SO_4	2.6	0.34
2. Chromic acid, CrO_3	400	54
Concentrated H_2SO_4	4	0.55

A good current density is 11 amp per sq dm (100 amp per sq ft), at 40 deg cent (104 deg fahr). Lead anodes are used. The deposit is bright.

PLATING ON ALUMINUM frequently does not wear well, on account of the difficulty in getting a perfectly clean aluminum surface on which to plate. This is due to the rapidity with which a thin invisible film of oxide or hydroxide forms on aluminum when exposed to the air or to any solution. One method of overcoming this difficulty is to immerse the aluminum in a solution of potassium hydrate until hydrogen is evolved, and then dip without previous washing in a potassium silver cyanide solution. The aluminum is immediately covered with a layer of silver. It is still better to amalgamate by dipping into a 0.5 per cent solution of mercuric chloride immediately after treating with hydrate. The chloride is rinsed off, and the object again treated with potassium hydrate and then immediately suspended in the silvering bath. (Langbein, Electrodeposition of Metals, 4th ed., p. 409, 1902.)

Burgess (*Electrochem. Ind.*, Vol. 2, p. 85, 1904) recommends cleaning first with dilute hydrofluoric acid, then with a mixture of 100 parts of sulfuric acid and 75 parts of nitric acid, both concentrated. After rinsing with water the surface is immediately plated with zinc, as this metal is found to adhere better than many others. Starting with the zinc surface, other metals are readily deposited.

OTHER PLATING PROCESSES. Plating with the following metals is also used: cobalt, cadmium, platinum, tin, lead, rhodium and iron. It has recently been found that tungsten can be deposited from aqueous solutions in a smooth, hard, coherent deposit, with a high luster. (Fink and Jones, *Trans. Electrochem. Soc.*, 1931, Vol. 59, p. 461).

2. GALVANOPLASTY

Galvanoplasty is the art of reproducing by electrolysis articles of various kinds, or of making finished products, such as set-up type, copper tubes, etc. "Electroforming" has been used as a substitute name for galvanoplasty.

ELECTROTYPING. The object is to make a copper plate which shall be an exact duplicate of type which has been set up ready for printing. First an impression of the type is made in wax, which is then covered with a thin layer of graphite, by dusting the fine powder over the wax surface with soft brushes. A thin layer of copper is then formed by sprinkling the surface with iron filings and pouring over the surface a solution of copper sulfate. The iron goes into solution, depositing copper on itself and on the graphite. The wax plate is then washed in water and suspended in an acid bath of copper sulfate, where copper is deposited electrolytically until a thin sheet that can be stripped from the wax has been formed. After removing the copper sheet from the wax plate, a melted lead-antimony alloy is poured on its reverse side, making a plate approximately 0.5 in. thick. This is then used for printing in place of the original type. Phonograph records are made by the same method.

The current density ranges from 1 to 2 amp per sq dm (0.9 to 1.8 amp per sq ft) and the volts per cell from 0.75 to 1.5.

Nickel is also used for electrotyping. The thickness of the deposit is 0.05 mm (0.002 in).

TUBES, ETC. Copper Tubes are made by the Elmore process by depositing copper on a conducting cylinder which rotates in an acid copper sulfate bath. The surface must be conducting, but the copper must not stick so firmly that the cylinder cannot be slipped out of the tube when finished. In order to keep the outer surface of the tube smooth, it is frequently polished during the deposition of copper. Copper sheets may be made by making tubes of large diameter and cutting them open. Copper sheets 1120 ft long, 31 in wide and 1.35 mils thick are now made by depositing on a rotating lead-covered copper cylinder, partly immersed in the solution, and stripping as the deposit emerges from the bath. The rate of deposition is such that 1120 ft are produced by one tank in a day. If greater thickness is desired, the sheet is passed through a second tank. (W. M. Shakespeare, *Trans. Am. Inst. Min. & Met. Eng.*, 1934, Vol. 106, p. 441.)

Spongy copper is being made electrolytically. This is mixed with graphite and is compressed to form self-lubricating bearing metal.

Electrolytic Iron Tubes were made for a number of years at Grenoble, but this has been given up.

Metallic Foil may be made by the electrolytic deposition of a thin metallic layer on a surface from which it can be removed.

3. ELECTROLYTIC REFINING

The method of refining metals electrolytically is as follows. The impure metal is made the anode of an electrolytic bath, the electrolyte of which is, at the start, a solution

of a pure salt of the metal to be refined, and the cathode is a sheet of the refined metal or of a metal from which the refined metal can be stripped. On passing the current, metal dissolves, along with certain of the impurities. The impurities which are electronegative with respect to the principal metal dissolve; those electropositive with respect to the principal metal remain adhering to the anode. When the latter finally drop from the anode they may be dissolved by the free acid, in which case they would be precipitated again on coming in contact with the anode or the cathode. Some metals are precipitated as an insoluble salt as soon as they dissolve, and are thus removed from the further action of the current.

When it goes into solution, the principal metal is, therefore, separated from those metals which are electropositive with respect to it. When it is deposited on the cathode, it is separated from those metals which are electronegative with respect to it. The bath thus becomes contaminated with certain of the impurities in the anode, and these would eventually be deposited on the cathode if the bath were not purified from time to time.

The metals which do not dissolve drop to the bottom of the tank forming the **anode mud.** It is from this mud that the platinum, gold, and silver are recovered in copper refining. For methods of working up anode mud, see Kern, *Met. and Chem. Eng.*, Vol. 9, p. 417, 1911.

COPPER REFINING. The object in refining copper electrolytically is to obtain as pure copper as possible for electric conductors and to obtain the precious metals contained in the crude copper. A representative composition of crude copper anodes for American refineries is the following:

Copper	98–99.5 per cent.
Silver	0–300 oz per ton.
Gold	0–40 oz per ton.
Arsenic	0–2 per cent.

The refined copper is about 99.95 per cent copper. The electrolyte is a solution of $CuSO_4$ and H_2SO_4 containing about 16 per cent of free acid and about 3 per cent of copper. The current density ranges from 0.43 to 4.8 amp per sq dm (4 to 45 amp per sq ft) of cathode surface, and the volts per cell range from 0.1 to 0.3. The electrolyte circulates slowly from tank to tank. The cathodes, called *starting sheets*, are thin sheets of refined copper.

Multiple and Series Systems of Arranging the Electrodes. The tanks for holding the solution and electrodes are made of wood or concrete and are lined with lead or asphalt. There are two methods of arranging the electrodes. In the " multiple system " all the cathodes of one tank are connected together, and likewise the anodes, the cathodes having an anode on each side, as shown in Fig. 1.

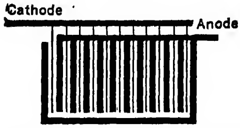

FIG. 1. Multiple System of Electrodes

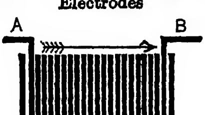

FIG. 3. Series System of Electrodes

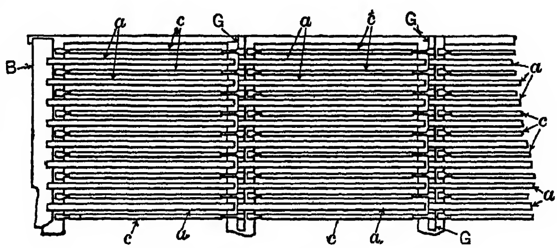

FIG. 2. Walker Multiple System

The most economical method as regards the use of copper of connecting tanks in the multiple system with each other is that devised by Walker (U. S. Pat. 687,800, 1901). In this system the current flows from tank to tank without being collected in a single bus-bar in this passage. The *cathodes* of the first tank rest on a conducting bar *G* (Fig. 2) on which the *anodes* of the second tank also rest. The figure shows three tanks so connected. *B* is the leading-in bus-bar; *a* are anodes, *c*, cathodes, and *G* is a copper bar connecting cathodes to anodes. A more recent improvement is to have the cathodes of a tank make direct contact with the anodes of the adjacent tank.

In the " series system," the electrodes are arranged as shown in Fig. 3. The impure copper plates are suspended in the solution at equal distances apart, only the end

ones being connected to the dynamo. The current enters at the electrode *A*, which dissolves, and on flowing through the tank passes through the intermediate plates. Pure copper is deposited on the sides of the plates facing *A*, and dissolved from the opposite surfaces facing *B*. Some conducting preparation is painted over the sides of the intermediate electrodes facing *A*, so that the copper deposited can be separated from the impure copper. When a certain amount of the impure copper has been dissolved, the electrodes are removed, the pure copper is separated from the impure, and the latter is melted and cast into new electrodes. This method is in use at the large plant of the Nichols Copper Co., Laurel Hill, N. Y., and at the Baltimore Copper Smelting & Rolling Co., Canton, Md. All others use the multiple system.

Comparison of the Two Systems. The energy required in the series system is about 70 per cent of that required in the multiple system. Contacts give more trouble in the multiple than in the series system. The electrodes in the series system cost more to prepare than those in the multiple system. The investment in a series plant of given capacity is less than in a multiple plant. Since lead-lined tanks cannot be used in the series system, the maintenance expense of a series plant is greater than that of a multiple plant. For recent improvements in the series system, see *Trans. Electrochem. Soc.*, 1930, Vol. 57, p. 231.

NICKEL REFINING. The International Nickel Co., Inc., extracts nickel from nickel-copper ore by flotation, top and bottom smelting, grinding, roasting, and smelting. The nickel thus made is 95 per cent pure, and this is cast into anodes and refined by the Hybinette process. Originally, the Hybinette process used anodes containing only 65 per cent nickel, when it would be considered an extraction process. Nickel starting sheets are used, and these are separated from the anodes by a canvas diaphragm.

Nickel sulfate solution circulates to the cathode and passes through the diaphragm, and copper is dissolved from the anode with the nickel. The copper is removed from the solution leaving the anode by cementation with nickel. The product is 99.9 per cent nickel and cobalt. The cobalt content is 0.4 per cent.

SILVER REFINING. Two cases arise: (1) the separation of silver from copper in an alloy consisting mainly of these two metals, and (2) the separation of silver from relatively small amounts of gold and platinum.

Dietzel Process. One method of separating silver and copper is the Dietzel process. This consists in dissolving both of the metals as anode in a weakly acid solution of copper nitrate. The solution is then transferred to another vessel and the silver is precipitated by metallic copper, following which the copper is deposited electrolytically.

The current density is about 1.5 amp per sq dm (14 amp per sq ft) of cathode surface, and the voltage per cell from 2.5 to 3.5 volts.

Moebius Process. Silver is separated from small amounts of other metals by the Moebius process. In this process, the anodes consist of the impure silver, the cathodes of thin sheet silver, and the electrolyte is a slightly acid dilute silver nitrate solution. In the earlier type of apparatus the cathodes were stationary; in the later type the cathode is a rotating sheet of silver. In both the pure silver is scraped off as crystals.

The current density is about 3 amp per sq dm (28 amp per sq ft) of cathode surface, and the voltage per cell from 1.4 to 1.5 volts. Another type is the Balbach-Thum cell (*Met. and Chem. Eng.*, Vol. 9, p. 444, 1911).

GOLD REFINING is carried out in a slightly acid solution of gold chloride. Gold anodes do not dissolve in a solution of gold chloride, $AuCl_3$; or of chloroauric acid, $HAuCl_4$, but the chlorine liberated comes off in the gaseous form. If some free alkali chloride or hydrochloric acid is present, the gold dissolves. The resulting gold is never less than 999.8 fine, and frequently is 1000 fine.

The baths contain about 3 per cent of free hydrochloric acid with 30 to 40 grams of gold as chloroauric acid per liter. The bath is heated to 60 or 70 deg cent, and the current density is about 10 amp per sq dm (93 amp per sq ft) at about 1 volt.

LEAD REFINING is carried out by the Betts process. The electrolyte is a solution of lead fluosilicate ($PbSiF_6$) containing 60 to 70 grams of lead and 120 to 130 grams of SiF_6 per liter, and 0.1 per cent of glue. The object in refining lead is to recover the copper, antimony, bismuth, gold, and silver. Tin cannot be separated from the lead electrolytically, on account of its proximity to lead in the electrolytic series.

The current density ranges from 1.3 to 1.7 amp per sq dm (12 to 16 amp per sq ft) of cathode surface, and the voltage per cell from 0.30 to 0.38 volt.

IRON REFINING has been carried out by different companies, as at Hawthorne, Ill., by the Western Electric Co., and at Grenoble, but has been given up at both places. (*J. Ind. & Eng. Chem.*, 1912, p. 752; *J. Iron & Steel Inst.*, Vol. 90, pp. 66–80, 1914; *Trans. Am. Electrochem. Soc.*, Vol. 29, pp. 357–367, 1916.)

TIN REFINING was carried out by the American Smelting and Refining Co. at Perth Amboy, N. J., but was given up several years ago. The solution contained 6 to 8 per cent sulfuric acid, 3 per cent of stannous tin, and 4 to 8 per cent of cresol-phenol sulfonic acid.

4. ELECTROLYTIC EXTRACTION OF METALS

The attempts that have been to extract metals directly from their ores or from mattes are based on the same principle as that underlying metal refining. These attempts have not been successful until recently, however, on account of the large amount of impurity that gets into the bath and on account of mechanical difficulties. The best known of such attempts are the following.

MARCHESE PROCESS. In the Marchese process it was attempted to obtain pure copper from a matte containing principally copper, lead, iron, and sulfur, by electrolyzing this matte as an anode in a sulfate bath. The process seemed a success at first, but finally failed.

SIEMENS AND HALSKE PROCESS. The Siemens and Halske process for extracting copper consists in electrolyzing a solution of iron sulfate and copper sulfate in a cell in which the anode and cathode are separated by a linen diaphragm. The anode was carbon; the cathode pure copper. In the cathode compartment the solution loses copper by deposition on the cathode. The solution then circulates to the anode compartment, where the ferrous sulfate is oxidized to ferric sulfate. See below, under Electrolytic Oxidation. From here the solution circulates to another vat where fresh ore, consisting of copper pyrites ($Cu_2SFe_2S_3$) that has been roasted so as to change the iron sulfide to oxide, is treated. The ferric sulfate dissolves the cuprous sulfide as follows:

$$Cu_2S + 2Fe_2(SO_4)_3 = 2CuSO_4 + 4FeSO_4 + S$$

This solution, enriched in copper, is then conveyed to the cathode compartment, and the cycle is completed. This process also failed when tried on a commercial scale.

HOEPFNER PROCESS. In the Hoepfner process the copper ore, consisting of copper sulfide, is dissolved in a cupric chloride solution containing a relatively large amount of sodium chloride. The reaction is as follows:

$$Cu_2S + 2CuCl_2 = 4CuCl + S$$

The cuprous chloride, insoluble in water, is held in solution by the sodium chloride. The anode and cathode of the electrolytic cell are separated by a diaphragm. The solution first circulates to the cathode compartment, where part of the copper is deposited, and then to the anode, where the cuprous chloride is oxidized to cupric chloride. The solution from the anode then circulates to fresh ore.

COPPER HYDROMETALLURGY AT CHUQUICAMATA. A process is being used by the Chile Exploration Co. for extracting copper directly from the ore of the Chuquicamata copper mine, in Chile. The ore is dissolved in dilute sulfuric acid in leaching tanks. The solution is then conducted to the electrolyzing tanks where the copper is deposited, using insoluble anodes and copper cathode starting sheets. Originally fused magnetite anodes were used, but these were replaced by *duriron* (ferrosilicon containing 12 per cent silicon), and duriron has been replaced by an alloy of copper, iron, and silicon.

COPPER HYDROMETALLURGY AT KATANGA AND MIAMI, ARIZONA. A similar process is used at Katanga in Central Africa. (F. Kroll, *Metall und Erz*, Vol. 25, p. 154, 1928.) A plant of the Consolidated Copper Co. at Miami, Arizona, leached mixed sulfide and oxide ore with acid ferric sulfate, and electrolyzed with lead anodes. (Van Arsdale, *Trans. A.I.M.E.*, Vol. 73, p. 58, 1926.)

SALOM PROCESS. Lead was at one time extracted from galena (PbS) by the Salom process, consisting in electrolyzing the powdered galena as cathode in sulfuric acid. The hydrogen deposited on the galena combines with the sulfur, forming hydrogen sulfide and leaving the lead as lead sponge. This process was given up, partly, at least, on account of the poisonous action of the hydrogen sulfide. (*Trans. Am. Electrochem. Soc.*, Vol. 1, p. 87, 1902; Vol. 4, p. 101, 1903.)

ELECTROLYTIC ZINC. Within recent years a large quantity of high-grade electrolytic zinc has been produced in the United States and Canada by a process similar to that used for copper at Chuquicamata. Sulfate solutions are used, with lead anodes and aluminum cathodes, from which the zinc is stripped in sheets $^1/_{16}$ in. thick. The solution must be free from impurities in order to get good deposits. See Hansen, *Bull. Am. Inst. Mining Eng.*, Vol. 135, p. 615, 1919; T. French, *Trans. Am. Electrochem. Soc*, Vol. 32, pp. 321–328, 1917; *Met. and Chem. Eng.*, Vol. 18, pp. 549–550, 1918.

DETINNING TIN SCRAP AND OLD CANS. The two principal methods of recovering tin from tin scrap and old tin cans are due to Goldschmidt. The first consists in

electrolytically dissolving the tin and depositing it in the metallic state; the second method, which, however, is not electrolytic, converts the tin into tin tetrachloride by treating with dry chlorine.

In the electrolytic method the solution consists of a sodium hydrate solution, containing a certain amount of carbonate, absorbed from the air, and sodium stannate. The best concentrations are: 10 to 12 per cent alkalinity, not over 7 per cent free alkali; carbonate not over 3 per cent; stannate not over 5 per cent. Temperature, 60 to 70 deg cent. About one-tenth of the solution must be replaced every week.

The tin scrap is suspended in the solution in baskets (39 by 35 by 18 in.) of perforated sheet iron, containing 100 to 130 lb of scrap. Old cans are cleaned, compressed, and then cut up. The cathodes are sheet iron 39 by 35 inches. The tin dissolves from the anode and is deposited as spongy tin on the cathode. The scrap is left in the bath for 3 hours. The spongy tin is compressed by a hydraulic press into cylinders weighing 6 lb; these are subsequently melted in a furnace in sealed tubes. This sponge contains 50 per cent tin and 50 per cent ash. The ash is subsequently reduced with carbon in an open-hearth furnace, yielding 70 per cent of the tin.

Very careful working is necessary to remove the tin so completely that the iron can be sold to open-hearth plants. Even then the iron contains 0.1 to 0.5 per cent tin.

The cathode current density is never over 0.75 amp per sq dm (7 amp per sq ft), at 2 to 3 volts per cell. (*Electrochem. and Met. Ind.*, Vol. 7, p. 79, 1909; *Met. and Chem. Eng.*, Vol. 10, p. 202, 1912.)

5. ELECTROLYTIC OXIDATION AND REDUCTION

Electrolytic oxidation and reduction are frequently carried out on substances in solution. One of the advantages of the electrolytic method is that no other substance has to be added to the solution. In carrying out an electrolytic oxidation or reduction a porous diaphragm is used to separate the anode and cathode compartments. The substance to be reduced is placed in the cathode compartment, where the whole or a part of the hydrogen that would be evolved by the current while in the nascent state acts on the substance in question. The intensity of the reduction may be varied by varying the potential difference between the solution and the cathode. This is accomplished either by increasing the current density on the cathode, or by making the cathode of different metals on which the overvoltage (see Principles of Electrochemistry) is different. It frequently happens that the metal composing the cathode has a marked accelerating effect on the velocity of the reduction. Thus the reduction may be much more complete on one metal than on another, though the potential difference between the metals and the solution is the same in both cases. The same considerations apply to oxidation on the anode.

TYPICAL REDUCTION AND OXIDATION PROCESSES. Examples where electrolytic reduction has been found useful are: in the manufacture of white lead by corroding a lead anode in a suitable solvent, e.g., the Sperry process; in the preparation of the lower salts of vanadium, molybdenum, and titanium. Examples where electrolytic oxidation has been employed are: in the oxidation of the lower cerium sulfate, $Ce(SO_4)$, to $Ce(SO_4)_2$, the latter being useful as an oxidizing agent; in oxydizing potassium manganate, K_2MnO_4, to permanganate, $KMnO_4$; in the oxidation of potassium ferrocyanide, $K_4Fe(CN)_6$, to the ferricyanide, $K_3Fe(CN)_6$; and of chromium sulfate to a chromate.

Sodium permanganate has been made on a semi-commercial scale by electrolyzing ferro-manganese anodes in sodium carbonate or hydrate solutions (*Trans. Am. Electrochem. Soc.*, Vol. 35, pp. 371–384, 1919). Potassium permanganate has been made in the same way (*Chem. and Met. Eng.*, Vol. 21, pp. 680–681, 1919).

6. ELECTROLYSIS OF SODIUM OR POTASSIUM CHLORIDE

The electrolysis of sodium or potassium chloride may yield several different products, depending on the kind of cell employed. In the following discussion the reactions for sodium chloride are given; these reactions also apply to potassium chloride when K is substituted for Na.

PRODUCTION OF ELECTROLYTIC BLEACH. If there is no diaphragm and the solution is kept cool, the chlorine and hydrate react on each other to form principally sodium hypochlorite or "electrolytic bleach," according to the equation

$$2NaOH + Cl_2 = NaOCl + NaCl + H_2O$$

As soon as hypochlorite is formed, it begins to change to chlorate, but at first not as rapidly as it is formed. As the concentration of the hypochlorite increases a larger and

larger proportion changes to chlorate, until finally the concentration of the hypochlorite reaches a limit, which depends on the temperature, original salt concentration, current density, and other factors. The hypochlorite then changes to chlorate as rapidly as it is formed.

The reactions by which hypochlorite changes to chlorate are two: (1) the action of the discharged ClO ion on water:

$$6ClO + 3H_2O = 2HClO_3 + 4HCl + 1^1/_2\, O_2$$

and (2) in a slightly acid solution:

$$2HOCl + NaOCl = NaClO_3 + 2HCl$$

If the solution is warmed to about 50 deg cent the conditions are so changed that the limiting concentration of hypochlorite is much lower than when cold. Sodium and potassium hypochlorites are used only in solution, but the chlorates are crystallized out.

By further electrolysis of a cooled sodium (or potassium) chlorate solution, perchlorate, $NaClO_4$, is produced by the action of the liberated ClO_3 ion on water:

$$2ClO_3 + H_2O = HClO_4 + HClO_3$$

and

$$HClO_4 + NaOH = NaClO_4 + H_2O$$

In most of the cells used for producing hypochlorite, a vessel is divided into a number of narrow compartments by bipolar or intermediate electrodes, consisting of carbon plates (Hass and Oettel) or platinum-iridium wire wound on glass plates (the Kellner cell). The solution is cooled by circulation. There is no essential difference between a hypochlorite and a chlorate cell, except that the latter is used at a higher temperature. (See numerous volumes in the Engelhardt Monographs.)

PRODUCTION OF CHLORINE AND CAUSTIC. If the anode and cathode are separated by a diaphragm of some kind, sodium hydrate is produced at the cathode by the removal of hydrogen ions, leaving an excess of hydroxyl ions, while at the anode chlorine is set free, which may be used to make bleaching powder.

Various devices are used to separate the hydrate and chlorine in cells intended for these products. In the McDonald cell (*Electrochem. Ind.*, Vol. 1, p. 387, 1903) and others a porous diaphragm is used. In the Hargreaves-Bird cell (U. S. Pat. 655,343, 1900; 596,157, 1897), the porous diaphragm is supported by a heavy copper wire screen cathode, which is wetted only by the solution percolating through the diaphragm. In the "bell jar process" the anode is inside an inverted nonconducting, nonporous bell jar, and the cathode is a conducting ring outside. Two important diaphragm cells are the Allen-Moore cell and the Nelson cell (*Trans. Am. Electrochem. Soc.*, Vol. 35, pp. 239–249, 1919.)

In the Castner cell the compartments are separated by a mercury diaphragm, acting as an intermediate electrode; and in the Solvay and the Whiting cells a mercury cathode is used, which, when charged with sodium in the electrolytic cell, is decomposed by water in a different compartment. The sodium amalgam reacts with water like metallic sodium. (See the Engelhardt Monographs.)

7. ELECTROLYSIS OF WATER

The electrolysis of water is carried out on a commercial scale for the production of hydrogen and oxygen. The electrolyte is usually a 15-per cent sodium hydrate solution. The cells generally use asbestos cloth diaphragms to prevent the mixing of hydrogen and oxygen.

In the cells of the Electrolabs Co. of Pittsburgh the anodes and cathodes are cobalt plated. The International Oxygen Co., of Newark, N. J., uses cast-iron nickel-plated anodes and cast-iron cathode.

Recently attempts have been made to produce hydrogen and oxygen at high pressure by electrolysis. (Noeggerath, *Zeitschr. d. V. deutscher Ing.*, Vol. 72, p. 373, 1928.)

8. OZONE

Ozone (O_3) is made by the silent discharge of electricity through dry air. The electrodes are water cooled, and protected to prevent the passage of sparks. From 8000 to 50,000 volts alternating are applied, this voltage being obtained from a small step-up transformer. For the Siemens and Halske ozonizer the concentration of the ozone is about 2 or 3 grams per cubic meter of the air which passes through it, and the yield is from 18 to 37 grams per kilowatthour. (*Electrochem. Ind.*, Vol. 2, p. 67, 1904.) Milk has been sterilized by high-tension discharges; one process being the Shelmerdine process

(*Electrical Times*, Vol. 45, pp. 502–505, 1914). Ozone is used for sterilizing the air in cold-storage warehouses and in public buildings.

ELECTRIC FURNACES AND THEIR PRODUCTS

By M. de K. Thompson

10. CLASSIFICATION

Electric furnaces may be classified as follows:

Arc furnaces.
- *a.* High-tension.
- *b.* Low-tension.

Induction furnaces.
- *a.* High-frequency.
- *b.* Low-frequency.

Resistance furnaces.
- *a.* Current conducted by the materials heated:
  1. With electrolysis.
  2. Without electrolysis.
- *b.* Current conducted by a special resistor.

In the arc furnace the heat is produced by an electric arc (see Electric Arc) usually between carbon electrodes. The low-frequency induction furnace is essentially a static transformer (see Transformers) with the low-tension "winding" formed by the material to be heated. In the high-frequency furnace, the heating is due to eddy currents. In the resistance furnace the current is supplied to the material to be heated (i.e., to the furnace "charge"), or to the special resistor, by connecting the charge or resistor directly to the source of the current supply. The heat developed in both the induction and resistance furnaces arises from the passage of the current through the resistance offered by the charge or special resistor.

The arc furnace may be considered a resistance furnace in which the resistor is a gas. Since the resistance of a gas at atmospheric pressure is greater than that of any solid resistor of the same dimensions as the arc, the amount of heat that can be produced in a small space will be greatest with an arc furnace.

11. TEMPERATURE AND DISTRIBUTION OF HEAT

The advantage in electric heating is that a higher temperature can be produced than by using fuel, that the heat is produced inside the furnace where it is needed, and that the heat can be easily and accurately regulated. In the arc the hottest part of the positive carbon is estimated to be between 3900 and 4000 deg cent absolute. (Waidner and

Burgess, *Bull. Bur. Standards*, Vol. 1, p. 123, 1905.) The temperature of the arc itself increases with the current. (Kayser, Handbuch der Spektroscopie, Vol. 1, pp. 154–160, 1900. Chaney, Hamister and Glass, *Trans. Am. Electrochem. Soc.*, 1935, Vol. 1, p. 67, preprint 18.)

The electric energy delivered to the furnace as heat is used as follows: (1) to heat the charge to the desired temperature, which involves heating up the furnace walls, if cold at the start. This energy is equal to the mass of the charge times the temperature rise times the specific heat. If the charge is melted or vaporized in the furnace, additional heat must also be supplied.. This item may be reduced by delivering the charge to the furnace already hot as in steel refining. (2) To supply the energy needed for the reaction; the energy so required cannot be reduced. (3) To supply the loss due to conduction and radiation through the walls and electrodes, and the heat carried off by hot gases. A part of the heat carried off by hot gases may be recovered in heating water in boilers, so that it is not a complete loss.

12. MAXIMUM SIZE OF ELECTRIC FURNACES

The largest workable capacity of an open-arc single hearth with a compact bundle of electrodes has been found in practice to be from 2500 to 3000 kw at 30,000 to 40,000 amp and 75 to 90 volts. These large sizes are always used with the three-phase system, so that the maximum total power absorption of a furnace is from 7500 to 9000 kw. In carbide furnaces double three-phase furnaces are used with six electrodes, in place of three, in the same shaft, and the power absorbed is from 15,000 to 18,000 kw. Great progress has been made in electric-furnace construction, by closing the furnace at the top and by having special means of feeding in the charge, thereby avoiding the dust nuisance and protecting the workmen from the heat, as well as distributing the charge more uniformly. (Taussig, *VII Int. Cong. App. Chem.*, Sec. 10, p. 24, 1910; *Trans. Faraday Soc.*, Vol. 5, p. 254, 1909; *VIII Int. Cong. App. Chem.*, Vol. 21, p. 105, 1912.)

13. DESIGN OF FURNACE WALLS

To reduce the conduction of heat through the walls and electrodes to a minimum amount, these must be properly designed. The heat flow through the walls of three different shapes may be computed by the formulas below. In all cases

k = thermal conductivity of the walls, at the mean temperature $(t_1 + t_2)/2$. This coefficient k may be expressed in any convenient unit, e.g., gram calories per centimeter cube per second per degree centigrade, or watts per inch cube per degree centigrade. See Heat and Thermal Properties for values.

H = total heat conducted per second through the walls.

t_2 = temperature of the inside surface of the wall.

t_1 = temperature of the outside surface of the wall.

HOLLOW RECTANGULAR PARALLELEPIPED.

$$H = \left(\frac{A}{\vartheta} + 0.54\,\Sigma l + 0.15 n\vartheta\right) k(t_2 - t_1)$$

where A = the area of the six inner surfaces, ϑ = thickness of wall, Σl = the total length of all the inner edges, n = the number of corners. This applies where all three inner dimensions are greater than $^1/_5\,\vartheta$. (Langmuir, Adams, and Meikle, *Trans. Am. Electrochem. Soc.*, Vol. 14, p. 53, 1914.)

HOLLOW SPHERE.

$$H = \frac{\pi k D d\,(t_2 - t_1)}{l}$$

where D = outside diameter of sphere, d = inside diameter, l = thickness of wall, all in the same unit.

HOLLOW CYLINDER.

$$H = \frac{2\pi k L\,(t_2 - t_1)}{2.3 \log_{10} \dfrac{D}{d}} + \frac{\pi k D d\,(t_2 - t_1)}{2\,l}$$

where L = mean height of inner and outer walls, D = outside diameter, d = inside diameter, and l = thickness of top and bottom walls, all in the same unit. The first term gives the flow of heat through the cylindrical walls, the second the flow of heat through the top and bottom. (Hering, *Trans. Am. Electrochem. Soc.*, Vol. 14, p. 215, 1908.)

LININGS AND COMPOSITE WALLS. The most refractory substances do not have the lowest thermal conductivities. Consequently, it is advantageous to use a highly refractory substance only for the inner part or lining of the walls, using only such a thickness that the drop in temperature will be sufficient to permit of a less refractory substance of a lower conductivity being used for the next layer. "Graded" walls of several layers may be employed. See Ray and Kreisinger, Flow of Heat through Furnace Walls, Bull. 8, Dept. of the Interior, 1912.

REFRACTORIES FOR FURNACE WALLS. The most refractory substance is carbon, which, however, is a good heat conductor. Some of the products of the electric furnace, as silicon carbide and firesand (a substance containing varying amounts of carbon, silicon, and oxygen) stand next to carbon as refractories, and do not have such high heat conductivities. (See Fitzgerald, *Electrochem. Ind.*, Vol. 2, p. 439, 1904.) The numerical values of heat conductivities of refractories at high temperatures are known for only a few substances and then only approximately. See article on Heat and Thermal Properties; also article by Hering in *Met. and Chem. Eng.*, Vol. 9, p. 625, 1911, and the table below for graphite and carbon.

14. DESIGN OF ELECTRODES

The electrodes of an electric furnace should be so designed that the energy will be carried into the furnace with a minimum energy loss. The loss due to the electrical resistance is directly proportional to the electrode's length; this should therefore be made as short as convenient. The loss due to electrical resistance will be smaller the greater the cross-section of the electrode, but the heat loss from the furnace through the electrode will be directly proportional to the cross-section. It is therefore possible to find a cross-section of a given material which will give a minimum total loss for a given length. The cross-section that would give the minimum loss on certain assumptions, only approximately true, is found from the equation

$$S = 0.346\,LI\sqrt{\frac{r}{k(t_2 - t_1)}}$$

and the loss itself, watts, is

$$h = 2.89\,I\sqrt{kr\,(t_2 - t_1)}$$

where S = cross-section of electrode; L = its length; I = the current in amperes carried by the electrode; t_2 and t_1 the temperatures, in degrees centigrade, of the hot and cold ends of the electrode respectively; r = its mean electrical resistivity in ohms per unit cube; and k = its mean heat conductivity for the mean temperature $(t_1 + t_2)/2$. If S and L are in centimeters, r and k must be per cubic centimeter; if S and L are in inches, r and k must be per cubic inch.

The values of k and r for carbon and graphite are not known accurately at high temperatures. The following values have been computed from measurements of Hering (*Trans. Am. Electrochem. Soc.*, Vol. 17, p. 166, 1910).

Material	Temperature, ° C		Thermal Cond. g-cal per cm³ per ° C per sec	Electrical Resistivity, ohms per cm³
	Hot End	Cold End		
Carbon	300	40	0.0891	0.00422
	701	50	0.124	0.00381
	902	60	0.130	0.00377
Graphite	355	66	0.399	0.000837
	516	70	0.325	0.000827
	707	87	0.309	0.000802

NOTE: For other data see the International Critical Tables.

15. SMALL LABORATORY FURNACES

A great variety of electric furnaces have been devised. A few typical laboratory furnaces will be described in this article. Some industrial furnaces are described in the next article.

Moissan's Furnace (Fig. 1). Moissan's work was carried out in a furnace consisting of two horizontal electrodes, mounted so that the distance between the two ends could be adjusted longitudinally by a screw thread. An arc was formed between these electrodes in a cavity formed by some refractory material, such as lime. The substance to

be heated was placed in a crucible under the arc as shown in Fig. 1. When the substance was not to be exposed to the gases of the arc, a furnace was made with a carbon tube passing through it at right angles to the electrodes and immediately below the arc. The substance to be heated was placed inside this tube.

BORCHERS' FURNACE (Fig. 2). A type of furnace due to Borchers consists in a carbon rod placed between two larger electrodes. The charge is either packed around

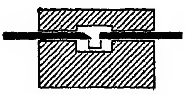

Fig. 1. Moissan's Furnace

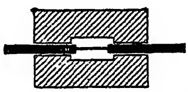

Fig. 2. Borchers' Furnace

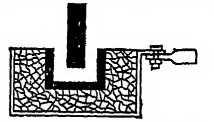

Fig. 3. Héroult Furnace

the small rod or placed under it. This type of furnace is convenient where a temperature below that of the arc is desired.

HÉROULT FURNACE (Fig. 3). A furnace that takes its name from Héroult consists in a crucible with one or more electrodes connected together above the crucible. The crucible is represented in Fig. 3 packed in carbon in an iron container. Graphite crucibles may be turned out from graphite electrodes. The charge in the crucible is usually melted by forming an arc between the crucible and the electrode above with an adjustable resistance in series with the arc. After the charge has melted the electrode may be partly immersed in the bath. In case it is desired to melt a substance in a crucible without the use of an arc, a smaller piece of carbon may be placed between the crucible and the electrode as in Borchers' furnace. If after the substance has been melted it is desired to pass the current through the bath itself, as, for example, if a salt is to be electrolyzed, the upper electrode may be raised, the thin rod removed with a pair of tongs, and the electrode then lowered into the bath. The salt will not solidify during this operation.

ARSEM FURNACE (Fig. 4). It frequently happens in the laboratory that it is desired to heat a substance to a high temperature in a vacuum or in some pure gas, such as hydrogen or nitrogen. A very convenient furnace for this purpose has been designed by Arsem (*Trans. Am. Electrochem. Soc.*, Vol. 9, p. 153, 1906), and has been extensively employed in research work. This furnace may be obtained from the General Electric Co. in two sizes. A vertical section is shown in Fig. 4. It consists of a chamber *A* and cover *B* made of a gun-metal casting turned true at the joint. A lead gasket *C*, 1/16 in. thick, forms an air-tight joint when the cover is fastened down by the cap-screws *D*. The tube *J* through which the air is removed from the furnace is soldered into the cover. The window *E* is a disk of clear white mica 0.005 in. thick clamped between lead washers *F*.

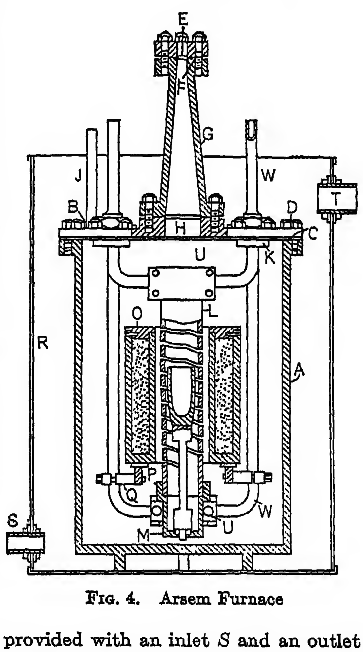

Fig. 4. Arsem Furnace

The electrodes *W* are brass tubing which are insulated from the cover. The clamps *UU* for holding the heater are copper. The heater *L* is a helix, usually of graphite, which is made by boring out a graphite electrode and cutting it along a spiral as shown. Metallic heaters may also be used. The lower end of the heater rests in the graphite cup which also holds the crucible support insulated from it by a lava ring. The screen for preventing radiation is a double-walled cylindrical box of Acheson graphite filled with graphite powder.

The water jacket *R* is a galvanized-iron tank provided with an inlet *S* and an outlet *T*. In a vacuum in the small furnace 9 to 10 kw produce a temperature of 2000 deg cent.

HIGH-PRESSURE FURNACES. The Arsem furnace may, of course, be used with the internal pressure above an atmosphere, but it is not designed for high pressures. A furnace for working up to 200 atmospheres has been designed by Hutton and Petavel. (*Phil. Trans.*, Series A, Vol. 207, p. 421, 1908, and *Electrochem. and Met. Ind.*, Vol. 6, p. 97.)

For a modified form see Pring and Fairlie (*VIII Int. Cong. App. Chem.*, Vol. 21, p. 79, 1912). For a furnace for spectroscopic work on gases at pressures up to 200 atmospheres, see King, A. S., *Astrophys. J.*, Vol. 28, p. 300, 1908.

FURNACES WITH METALLIC RESISTORS (Fig. 5). A very useful type of furnace is a tube wound in its middle portion with an electrical resistor. The ends of the tube are cooled by the air, or may be cooled by a coil of copper pipe through which water flows. The tube may be of some non-conducting substance, such as porcelain, in which case a ribbon of metal may be wound directly on the tube. Furnace tubes with grooves for winding with wire are now made by the Norton Co. of Worcester, Mass., from fused alumina. These, however, are porous and cannot be used for a vacuum furnace. Glazed German porcelain may be heated up to 1180 deg cent and a vacuum maintained. At temperatures higher than for this glazing melts and air leaks into the tube. A nickel tube may be used for higher temperatures. Muffle furnaces and pot furnaces are made on the same principle.

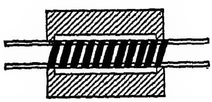

Fig. 5. Resistor Furnace

The metallic winding for carrying the current may be of platinum, nickel, nichrome, tungsten, molybdenum, or any other suitable high-resistance material (see Resistance Wires).

These furnaces are particularly useful when the temperature is to be held constant over a long period of time. For most purposes a constant current will keep the temperature sufficiently constant. For greater constancy some kind of regulator must be used (see Zabel & Hancox, *Rev. Sci. Instr.*, 1934, Vol. 5, p. 28; Henney, Electronics, 1934, Vol. 7, p. 183.

HOSKINS FURNACE. A convenient furnace for heating rather large crucibles or masses of material is made by the Hoskins Manufacturing Co. of Detroit, Mich. The heater consists of two rows of narrow, thin carbon plates which extend over two sides of the cavity which receives the substance to be heated. The contact resistance between the plates may be varied by pressure. This furnace of course requires a very large current at a low voltage.

HIGH-FREQUENCY FURNACES. These are made by the Ajax Electrothermic Corp., of Trenton, N. J. The sizes of spark-gap type are 3, 15, and 35 kv-a. Furnaces are built for use with motor generator sets from 20 to 1500 kw.

GRANULAR CARBON FURNACE (Fig. 6). A carbon or graphite crucible may be easily heated by placing it in a trough surrounded by granular gas carbon; this conducts better than coke. The current is passed through the trough, into which it is conducted by carbon rods. Clay crucibles should not be used in this way for temperatures above 1000 deg cent, as at a high temperature they are attacked by the carbon.

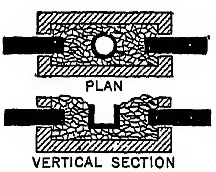

Fig. 6. Granular Carbon Furnace

GLOBAR FURNACE. The Globar Corp. of Niagara Falls, N. Y., furnished silicon carbide rods of various sizes for use as heating elements. They can be used up to 1200 deg. cent. or more if protected from the fumes of volatile materials.

16. ELECTRIC-FURNACE PRODUCTS AND INDUSTRIAL FURNACES

Some typical industrial furnaces and their products are described below.

CALCIUM CARBIDE. Willson and Horry furnaces. Calcium carbide was first made on a large scale by Willson in 1892 at Spray, N. C., by heating lime and carbon in an arc furnace. The reaction that takes place is

$$CaO + 3C = CaC_2 + CO$$

The furnace consisted of a carbon plate 3 by 2.5 ft with a carbon electrode suspended above it. The whole was surrounded by brick walls. Furnaces similar to this were at first used at Niagara Falls, with the lower electrodes mounted on a car which was removed when filled with an ingot of carbide. Later the Horry rotary furnace was used (U. S. Pat. 656,156). Carbide may be either formed in an ingot in the crucible of the furnace and removed solid, or it may be drawn off in the liquid state. When an ingot is formed it has been found better to have the current flow between two electrodes suspended over the crucible, in place of having the crucible form one electrode. (Conrad, *Electrochem. and Met Ind.*, Vol. 6, p. 397, 1908.) In practically all carbide furnaces now used the carbide is tapped. For the latest types, see Taussig, *Die Industrie des Kalziumkar-*

bides, 1930. The purity of the carbide is in the neighborhood of 80 per cent. The yield of 80 per cent carbide is about 5 kg per 24 kw hr. Söderberg self-baking continuous electrodes are used extensively in carbide furnaces. (*Trans. Electrochem. Soc.*, 1931, Vol. 60, p. 181).

SILICON PRODUCTS. Silicon Carbide. Acheson Process. Silicon carbide or carborundum was first made on a large scale by Acheson. It is produced from quartz and carbon when these substances are heated in an electric-resistance furnace, according to the reaction

$$SiO_2 + 3C = CSi + 2CO$$

The furnace has a granular carbon core around which the charge, consisting of quartz, carbon, sawdust, and sodium chloride, is packed. The latest furnaces are 9.15 meters long by 3.67 meters wide, and absorb 1600 kw. The current is 20,000 amp (*Min. Industry*, Vol. 16, p. 155, 1907; Vol. 17, p. 112, 1908). From measurements on a 750-kw furnace it was found that the carbide is formed at 1840 deg cent and decomposes when heated above 2240 deg cent. (Saunders, *Trans. Am. Electrochem. Soc.*, Vol. 21, p. 425, 1912.) The yield is about 1 kg of crystallized carbide for 8.5 kwhr. Silicon carbide is used as an abrasive and for furnace linings. (Fitzgerald, Carborundum, Vol. 13, in the Engelhardt Monographien über angewandte Elektrochemic.) For description of Norton Co.'s plant see Fitzgerald, *Met. and Chem. Eng.*, Vol. 10, pp. 519–521 (1912).

Firesand, formerly called siloxicon, is a product of the incomplete reduction of silica, and may be represented by the formula SiCO, though compounds with varying proportions of these elements are found. Firesand is used for crucible linings. It is made by heating silica and an insufficient quantity of carbon for complete reduction of the silica.

Silox is a spongy substance of about the same composition as firesand, made by the General Electric Co., by heating silica and carbon in a closed arc furnace and condensing the distillate in a large chamber. It is used for heat insulating.

Silicon is made in an arc furnace from coke and quartz. At the high temperature produced the silica is completely reduced and the melted metal is drawn off in amounts weighing from 600 to 800 lb. It varies from 90 to 97 per cent in purity (F. J. Tone, *Electrochem. and Met. Ind.*, Vol. 7, p. 192, 1900; *Min. Ind.*, Vol. 17, p. 768, 1908).

GRAPHITE. Berthelot (*Ann. de chim. et de phys.*, Series 4, Vol. 19, p. 393, 1870) defines graphite as that allotropic form of carbon which when oxidized at low temperature with powerful oxidizing agents (potassium chlorate and nitric acid) gives graphite oxide. Arsem suggests as a definition for graphite that it is that allotropic form of carbon whose density lies between 2.25 and 2.26. (*Trans. Am. Electrochem. Soc.*, Vol. 20, p. 105, 1911.)

Graphite is made by heating carbon, containing a small amount of impurity, to a high temperature in an electric resistance furnace. Anthracite coal is graphitized in bulk; electrodes and crucibles are also graphitized after molding. Acheson's theory of the formation of graphite is that the carbon first forms a carbide, which decomposes at a higher temperature, leaving the carbon in the form of graphite. This theory is not confirmed by Arsem's experiments. (See Fitzgerald, Künstlicher Graphit, Vol. 15 of the Engelhardt Monographien über angewandte Electrochemie.)

CARBON BISULFIDE is made in a specially designed furnace by heating together sulfur and carbon. Most of the disagreeable features encountered in the manufacture of this substance are thus avoided. (Taylor, *Trans. Am. Electrochem. Soc.*, Vol. 1, p. 115, 1902; Vol. 2, p. 185, 1902; Richter; *Trans. Am. Electrochem. Soc.*, 1922, Vol. 42, p. 253.)

PHOSPHORUS is a substance the production of which the use of the electric furnace has much simplified. It is made in the Readman-Parker furnace according to Wöhler's process:

$$Ca_3(PO_4)_2 + 3SiO_2 + 5C = 3CaSiO_3 + 5CO + 2P$$

(*Min. Ind.*, Vol. 6, p. 537, 1897; Vol. 7, p. 557, 1898.) Phosphoric acid is made by oxidizing the gaseous phosphorus with air, as it comes from the furnace, and absorbing the oxide in water.

ALUNDUM is the trade name of fused aluminum oxide, which is made by the Norton Co. of Worcester. Aluminum oxide is fused in an arc furnace. (*Min. Ind.*, Vol. 19, p. 28, 1910.) Fused alumina is used as an abrasive, as a refractory substance for furnace linings, and porous crucibles of this substance are used in analytical laboratories.

ALUMINUM. HALL AND HÉROULT PROCESSES. Aluminum is now produced by the electrolysis of a solution of alumina in fused cryolite ($AlF_3 \cdot 3NaF$) to which other fluorides, such as those of aluminum and of sodium, are added in some factories. The aluminum sinks to the bottom of the crucible and is drawn off. This process was discovered nearly simultaneously by C. M. Hall and Héroult. The heat developed by the current in passing through the solution is sufficient to keep the bath melted. The cathode is an iron trough lined with carbon, and the anode consists of a number of carbon rods

suspended over the crucible. The Aluminum Co. of America uses as anode for one crucible 48 carbon rods 3 in. in diameter and 15 in. long. The electromotive force applied to each crucible is 5.5 volts; the current is 10,000 amp. The yield is 1.75 lb of aluminum per horsepower-day. For further information see *Min. Ind.*, Vols. 6, 14, 15, 17, 20, Thompson & Seyl, *Trans. Electrochem. Soc.*, 1933, Vol. 64, p. 321. Aluminum is also refined by a similar process, using an anode of chromium-copper-silicon alloy. (Frary, *Trans. Am. Electrochem. Soc.*, 1925, Vol. 47, p. 275.)

SODIUM, POTASSIUM. CASTNER PROCESS. Sodium and potassium are obtained by the electrolysis of their fused hydrates, usually in the cell designed by Castner (U. S. Pat. 453,030, filed 1890; see also Becker, Die Elektrometallurgie der Alkalimettale). The production of sodium by the electrolysis of fused sodium chloride, containing additions which lower its melting point 200 to 300 deg cent, is now carried out, e.g., in the Downs cell. (U. S. Pat. 1501, 756, July 15, 1929.)

CALCIUM. Calcium is made by the electrolysis of fused calcium chloride, to which calcium fluoride is added to lower its melting point. Calcium is made at Holcomb's Rock, Va., probably in a cell devised by Seward and Von Kügelgen (U. S. Pat. 880,760, 1908; *Min. Ind.*, Vol. 16, p. 131, 1907; Vol. 17, p. 99, 1908); and abroad by the method of Rathenau (*Z. f. Elektrochem.*, Vol. 10, p. 508, 1907). In the Rathenau method the cathode is an iron rod which just touches the surface of the melted calcium chloride. The calcium solidifies when deposited on the cathode by electrolysis. As the calcium grows the rod is withdrawn so that a rod of calcium is produced. (*Trans. Am. Electrochem. Soc.*, 1920, Vol. 37, p. 465.)

BARIUM. Barium cannot be made electrolytically, because metallic barium acts on all of its fused salts. A lead alloy of barium can be made by electrolyzing barium chloride with a melted lead cathode.

ZINC. Zinc may be made by the electrolysis of fused zinc chloride. In the Swinburne-Ashcroft process sodium chloride is added to zinc chloride in such quantity that the resulting mixture contains 28 per cent zinc. The cell is a brick-lined, sheet-iron vessel. The anode is carbon, the cathode, melted zinc. Each vat takes 4.5 volts, with a cathode current density of 400 amp per sq ft. The temperature of the fused salt is 450 deg cent. (*Electrochem. and Met. Ind.*, Vol. 3, p. 65, 1905.)

MAGNESIUM. Magnesium is made by the electrolysis of fused magnesium chloride and floats to the surface. Hydrated magnesium chloride is dried in the presence of ammonium chloride ($1NH_4Cl$ to $1MgCl_2$) to prevent decomposition. The ammonium chloride is then removed by volatilization and condensed.

CERIUM. Cerium may be made by electrolyzing fused cerium chloride ($CeCl_3$). Its iron alloy sparks when filed and is used in gas lighters.

BERYLLIUM. Beryllium has been made only during recent years. It has a high modulus of elasticity and makes valuable alloys. It is also used for windows in x-ray tubes.

Beryllium can be made by the electrolysis of fused salts of beryllium, e.g., beryllium oxyfluoride and barium fluoride. (*Wiss. Veröff. aus dem Siemens-Konzern*, Vol. 8, p. 42, 1929.) The beryllium is drawn out of the bath by the method used in making calcium. The temperature is 1400 deg cent. Siemens and Halske have erected a plant in which 1 metric ton of 98.5 to 99.2 per cent beryllium is made yearly. The price is 1 mark a gram. The principal alloy made in Germany is with copper, containing 2.5 per cent beryllium. Beryllium is made by the Beryllium Corp. of America. (*Min. Ind.*, 1934, Vol. 43, p. 616.)

17. ELECTRIC FURNACES IN METALLURGY

Under special local conditions, where iron ore is plentiful, where coke is expensive, and where power is cheap, the electric reduction of iron ore is carried out commercially, as at Trolhätten and Domnarfvet, Sweden, and in Switzerland and Japan. The furnaces have a shaft resembling a blast furnace, with a crucible at the base into which the electrodes project in a slanting position. (For detailed accounts, see volumes of the *Met. and Chem. Eng.*) More recently it has been found better to have the electrodes vertical. (Taussig, *VIII Int. Congress App. Chem.*, Vol. 21, p. 105, 1912.)

Electric tin smelting has been tried on a commercial scale with apparent success (*Met. and Chem. Eng.*, Vol. 9, p. 453, 1191) as well as the smelting of copper and nickel (*Met. and Chem. Eng.*, Vol. 11, p. 22, 1913), and zinc (see volumes of the *Met. and Chem. Eng.*). The use of electric furnaces in steel refining and in the production of ferro-alloys is much more extensive for in this case power does not need to be so cheap as in the reduction of iron ore.

STEEL REFINING. Usually the steel which is refined in electric furnaces is taken from Bessemer converters or open-hearth furnaces and poured directly into the electric furnace. Steel scrap, however, is melted and refined in the electric furnace in one operation. The advantages of the electric furnaces are (Walker, *Met. and Chem. Eng.*, Vol. 10, p. 371, 1912):

1. Complete removal of oxygen.
2. Absence of oxides caused by additions, such as silicon manganese.
3. Production of electric steel ingots of 8 tons and less that are practically free from segregation.
4. Reduction of sulfur to 0.005 per cent if desired.
5. Reduction of phosphorus to 0.005 per cent as in the basic open-hearth process, but with complete removal of oxygen.

The number of electric steel refining furnaces in use was increased greatly by the war.

The recent progress in electric steel refining consists in an improvement in existing methods and in a reduction of costs. Whereas in 1911 it was considered good practice to melt and refine steel scrap in 6 hours at 750 kwhr per ton, the same operation is now carried out in 4 hours with 600 kwhr. (Héroult, *VIII Int. Cong. of App. Chem.*, Vol. 21, p. 59, 1912.)

Some of the types of furnaces used in steel refining are the following:

STASSANO STEEL FURNACE (Fig. 7). This furnace consists of a closed chamber with three electrodes connected to a three-phase system above the slag. The furnace

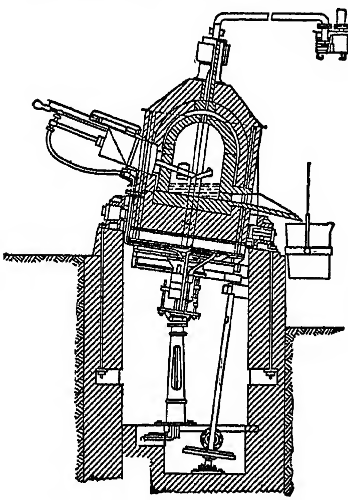

Fig. 7. Stassano Furnace

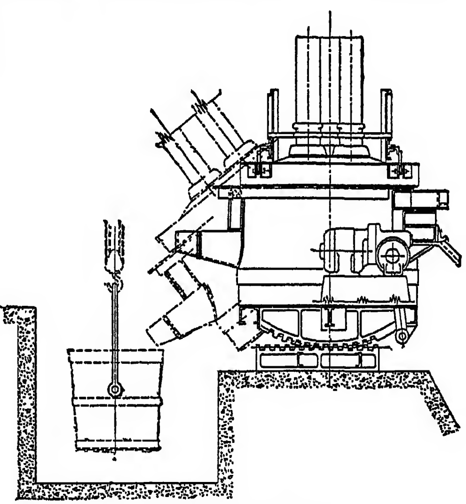

Fig. 8. Héroult Steel Furnace

rotates so as to stir all the metal. This furnace is used in Italy, Odessa, and Newcastle-on-Tyne (*Met. and Chem. Eng.*, Vol. 10, p. 66, 1912.)

HÉROULT STEEL FURNACE (Fig. 8). This furnace consists of a crucible lined with refractory material. Carbon electrodes project into it through the roof. An arc is formed where the current passes from each electrode into the slag. The power is regulated by an electrical automatic regulator which moves the electrodes up and down as required. These furnaces are made by the American Bridge Co.

GIROD STEEL FURNACE. This furnace consists of a crucible with several soft-steel rods projecting through the base. These form one electrode; the other is one or more carbon rods suspended from above. The steel electrodes of course melt several inches below the surface of the refractory lining of the crucible. The furnaces were formerly sold by C. W. Leavitt and Co., 30 Church St., New York, from whom the following data have been obtained.

These furnaces require from 65 to 70 volts at frequencies from 25 to 50 cycles. The power factor is about 80 per cent, and the duration of heat when the metal is charged in the melted state is 1 1/2 to 2 1/2 hours. The number of electrodes is from 1 to 3, according to the capacity of the furnace. For a furnace of about 12 tons' capacity, the maximum

power required is 1200 kw measured at the terminals of the electric generator; the energy consumption when the metal is charged cold is 900 kwhr per ton of steel; with a melted charge, from 150 to 250 kwhr. The electrodes are so designed that the current does not exceed 5 amp per sq in. of cross-section. The number of consecutive heats possible without repairs is:

	Linings	Cover	Electrodes
With cold charge....................	30 to 40	20 to 30	10
With melted charge..................	60 to 90	40 to 50	20

To handle the furnace 6 persons are necessary: a melter, 2 assistant melters, 2 workmen, and a boy.

Other Arc Furnaces more or less similar to the Héroult furnace are the Keller furnace (*Trans. Am. Electrochem. Soc.*, Vol. 15, p. 96, 1909), the Nathusius furnace (*Met. and Chem. Eng.*, Vol. 10, p. 227, 1912) and the Snyder furnace (*Trans. Am. Electrochem. Soc.*, Vol. 28, pp. 221–230, 1915).

LOW-FREQUENCY INDUCTION FURNACES. These furnaces are transformers in which a melted ring of steel is the secondary. The Kjellin furnace, Fig. 9, consists of a single deep ring of metal. It has only a small area of contact between the metal and slag, and the slag is not easily heated. The use of this furnace is therefore restricted in its application (Kjellin, *Trans. Am. Electrochem. Soc.*, Vol. 15, p. 175, 1909).

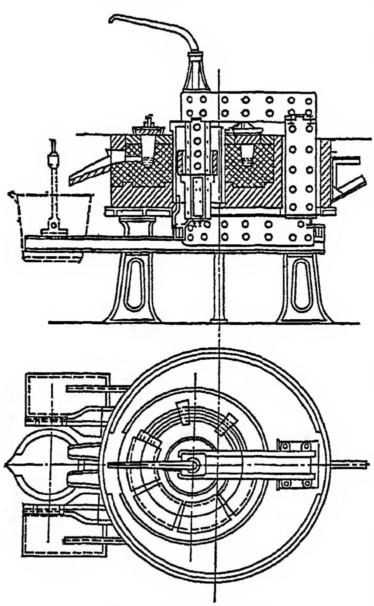

Fig. 9. Kjellin Furnace

A modified form of induction furnace is the Röchling-Rodenhauser furnace. This furnace has two annular rings combined in the form of a figure 8. The central portion carries the currents induced in both circuits, as well as a current from electrodes supplied by extra secondary coils. This current passes through the lining of the furnace, which has sufficient conductivity when hot.

These furnaces, as well as another modification, known as the Frick furnace, can be obtained from Siemens and Halske, represented in this country by Dr. G. K. Frank, New York. Another design of induction furnace is due to Hiorth (*Trans. Am. Electrochem. Soc.*, Vol. 20, p. 293, 1911).

PINCH EFFECT IN INDUCTION FURNACES. The magnitude of the current which can be sent through a trough of melted metal is limited by the so-called pinch effect (*Trans. Am. Electrochem. Soc.*, Vol. 11, p. 329, 1907). On account of the attraction of the current elements for each other, a compressing force is exerted on the metal which causes a decrease in the cross-section at some point. If the current is too great the metal may be entirely separated momentarily and the circuit broken.

FERRO-ALLOYS. Ferro-alloys were originally made from iron ore, the oxide of other metal, carbon, and flux, but on account of impurities, scrap iron and steel shavings are now used in place of iron ore (*Met. and Chem. Eng.*, Vol. 8, p. 133, 1910). Arc and resistance furnaces similar to those used for steel refining are used. For detailed information see Keeney, *Bull. Am. Inst. Mining Eng.* No. 140, pp. 1321–1373, 1918.

Ferrosilicon is the most important of the ferro-alloys. It is made from iron, quartzite, and carbon. At the Keller-Leleux works at Livet it has been found practicable to turn out 20 tons of 30 per cent ferrosilicon with 4000 hp during a day. (See preceding reference.) For an account of the uses of the other ferro-alloys, see *Electrochem. Ind.*, Vol. 1, p. 583, 1903; *Electrochem. and Met. Ind.*, Vol. 4, p. 247, 1906.

BRASS MELTING. Electric furnaces are now used to a considerable extent for brass melting. (St. John, H. M., Electric brass melting, *Elec. J.*, 16, 373, September, 1919.) Some of the types of furnaces used are the Booth rotating furnace (*Trans. Am. Electrochem. Soc.*, Vol. 33, p. 247, 1918); the Rennerfelt furnace (*Met. and Chem. Eng.*,

Vol. 12, p. 275, 1914; *Trans. Am. Electrochem. Soc.*, Vol. 29, p. 497, 1916; Vol. 31, p. 87, 1917); the Ajax-Wyatt induction furnace (*J. Franklin Inst.*, Vol. 190, p. 817, 1920); the Helberger furnace (*Met. and Chem. Eng.*, Vol. 12, p. 644, 1914, and Globar furnaces.

18. FIXATION OF ATMOSPHERIC NITROGEN

One of the most important applications of the electric furnace is the fixation of atmospheric nitrogen. The various processes employed are described below.

CARBIDE METHOD. In this method calcium carbide is heated in pure nitrogen, forming calcium cyanamide according to the reversible reaction

$$CaC_2 + N_2 \rightleftarrows CaCN_2 + C$$

The carbide is heated in iron drums by a thin carbon conductor running through the center of the drum. Heat is evolved by the reaction. The product is called "nitrolime" or "lime-nitrogen," and contains 12 to 15 per cent nitrogen. (*Met. and Chem. Eng.*, Vol. 5, p. 78, 1907.) It is used directly as a fertilizer, or may be converted into ammonia by superheated steam. The yield in nitrogen by the carbide method is about 51.6 grams per kilowatthour, including the manufacture of the carbide.

DIRECT OXIDATION METHOD. In this method the nitrogen and oxygen in air are caused to combine in a high-voltage arc accordnig to the reversible reaction

$$N_2 + O_2 \rightleftarrows 2\,NO$$

On cooling the NO is further oxidized to nitric dioxide. The nitric dioxide on treatment with water gives nitric and nitrous acids:

$$2NO_2 + H_2O = HNO_3 + HNO_2$$

Only about 1 to 3 per cent of the air treated is oxidized. The yield in the Birkeland-Eyde furnace is 12.7 grams of nitrogen fixed per kilowatt hour. (*Trans. Faraday Soc.*, Vol. 2, p. 98, 1906.) Furnaces of three different designs are now in operation for oxidizing nitrogen: that of Birkeland and Eyde, that of Schönherr, and that of H. and G. Pauling.

DIRECT SYNTHESIS OF AMMONIA. In this method, due to Haber, ammonia is formed directly from a mixture of nitrogen and hydrogen by passing over a catalyzer between 500 and 700 deg cent at 200 atmospheres, according to the reversible reaction

$$^1/_2\,N_2 + {}^3/_2\,H_2 \rightleftarrows NH_3$$

(*Zeit. f. Elektroch.*, Vol. 16, p. 244, 1910; Vol. 19, p. 53, 1913.) In the Claude process the pressure is increased to 1000 atmospheres, which gives a 25 per cent conversion, in place of 6 per cent at 200 atmospheres.

BUCHER PROCESS. This process was discovered in 1846 by Lewis Thomson (Bucher, *Am. Inst. Chem. Eng.*, Vol. 9, p. 335, 1916) and is represented by the following reaction:

$$Na_2CO_3 + 5C + N_2 = 2NaCN + 3CO$$

which requires metallic iron as catalyzer. The temperature is between 900 and 1050 deg cent. A plant was built at Saltville, Va., to make cyanide for war requirements. The furnaces were 8-in. iron tubes heated externally by hot gases. The reacting mixture is finely ground, briquetted hot with water, dried, and then treated with nitrogen. This plant was never put in operation at full capacity. See Ferguson and Manning, *J. Ind. and Eng. Chem.*, Vol. 11, p. 946, 1919; Posnjak and Merwin, *J. Washington Acad. Sci.*, Vol. 9, p. 28, 1919.

SERPEK PROCESS. In this process aluminum nitride is made by heating aluminum oxide, carbon, and nitrogen together. On heating the aluminum nitride with water, ammonia and aluminum hydrate are formed. The product obtained from the furnace is said to contain 20 to 24 per cent of nitrogen, and the power required per unit of nitrogen is said to be only one-half of that used in the calcium-carbide method. This process never got beyond the experimental stage. (*Bull. de la Soc. ind. de Mulhouse*, Vol. 79, p. 39, 1909. U. S. Pat. 996,032, 1911.)

ELECTRIC RESISTANCE HEATING

By Frank Thornton, Jr.

20. GENERAL PRINCIPLES

There are a few general-purpose types of electric heating units but to secure most satisfactory results it has usually been necessary to design the heating elements as part of the complete appliance or apparatus. Electric heat can be released in exactly the right amount and in exactly the right place. Because of the difference in hearing characteristics, certain fundamentals of heat behavior require greater attention when applying electricity for heating than when using fuels. A brief review of these fundamentals is necessary before taking up the various applications.

The first thing that must be known is how much heat is necessary and at what rate it must be delivered. A careful study must be made of the entire process. Often, a process as conducted when using a fuel as the source of heat may not be the best process. Electricity may make it possible to improve the results greatly by changing the heating cycle. Therefore, it is important to study the fundamental requirements of each new application.

Heat is used to (*a*) raise temperature, (*b*) fuse, (*c*) evaporate, or (*d*) cause chemical change.

The weight of the material to be heated must always be known. In addition, the following facts must be known before calculation can be made of the heat required for any of the four functions mentioned above.

(a) **Raise Temperature.** The specific heat of the material must be determined at the temperature involved. It should be pointed out that this is not a constant value but may change with the temperature. For accurate computations of heat requirements at high temperature a careful check of the specific heat is important.

(b) **Fusion.** Melting point and latent heat of fusion must be known.

(c) **Evaporation.** Boiling point and latent heat of evaporation must be known for the pressure at which it is to take place.

(d) **Chemical Change.** Heating applications for the purpose of causing chemical change require special knowledge of the reactions involved. Some chemical reactions require the addition of heat; others give off heat; and still others require heat to start them and then give off heat.

After the amount of heat and the time cycle involved in the process are known it is possible to proceed with a calculation of the heating device or apparatus.

The selection of the proper length, cross-section, and surface area of resistor is governed by many different considerations which will be discussed later in connection with the various applications.

21. RESISTANCE MATERIALS

Metallic resistance materials are usually used for temperatures below 2000 deg fahr. For exceptionally high temperature furnaces a molded refractory resistance material has been successfully used.

Nickel-chromium alloys are the most generally used resistance materials for heating purposes. They have high specific resistance, reasonably low temperature coefficient, and high resistance to oxidation.

Nickel-copper alloys, such as Advance, Copel, and Monel, have some uses for lower temperatures.

Data on these alloys are given in Tables I and II. See Section 2, Art. 6 and Manufacturers' Catalogs for additional resistance data.

Table I. Temperature Limits for Resistance Materials

Material	Chemical Composition (approximate) per cent	Specific Resistance, ohms per cir mil fact. 68° F	Temperature Coefficient per deg fahr (average)	Maximum Working Temperature, deg fahr
Copper-nickel	Cu—60, Ni—40	294	0	800
Nickel-iron-chromium	Ni—60, Fe—25, Cr—15	675	0.00008	1400
Nickel-chrome	Ni—80, Cr—20	650	0.00007	2100

	.00200	169.	162
	.00175	220.	212.
	.00150	300.	289.

Although the temperature coefficient of nickel-chrome materials is not high, yet it should be considered in making calculations. In the production of these materials manufacturers find it impossible to duplicate the temperature coefficient exactly in succeeding batches. Table III gives average coefficients and variations from the average.

Table III. Change in Temperature Coefficient of Heater Wires

(These values are average. The excess over 100 per cent may vary plus or minus 20 per cent from these figures.)

Temperature		Resistance in per cent		Temperature		Resistance in per cent	
Deg fahr	Deg cent	Nickel-iron-chromium	Nickel-chromium	Deg fahr	Deg cent	Nickel-iron-chromium	Nickel-chromium

1000	539	107.4	104.0	2000	1094	....	104.8

22. ELECTRICAL INSULATION

The choice of electrical insulating material depends a great deal upon the temperature, size, and type of device being designed. Mica is very commonly used for the smaller devices such as flat-irons, toasters, waffle-irons, etc. There is a wide variety of mica both in mechanical and thermal characteristics. When it is clamped tightly in place, built-up mica may be used, the volatile bond being baked out after assembly if necessary. All mica has a definite temperature of dehydration at which the crystals give up the water of crystallization. This happens in some grades at as low as 800 deg fahr; in others it does not happen below 1200 deg fahr. The element must be so designed that the dehydration temperature will not be reached because, when that occurs, there is a rapid

deterioration of the nickel-chrome resistance material which may be in contact with the mica.

Porcelain for use in these applications not only must have sufficient electrical insulation at the working temperature, but also must resist cracking and spalling due to the changes in temperatures.

For larger apparatus, furnaces, melting pots, etc., appropriate grades of fireclay, silica, magnesia, zirconia, lava, alundum, and other materials are selected to suit the various needs.

23. INDUSTRIAL HEATING APPLIANCES

Small Appliances

Electrically heated appliances have been developed for a very large number of uses. The following list contains only a few of the more common devices.

Tailors' pressing irons.	Hatters' irons.	Hot tables.
Solder pots.	Velouring stoves.	Press blocks.
Soldering irons.	Glue pots.	Chocolate warmers.
Branding irons.	Sealing-wax heaters.	

Usually the cost of the energy to operate such devices is immaterial in view of the great advantage gained in speed, convenience, safety, and uniformity of operation.

Small solder pots of 10 to 50 lb capacity are particularly convenient because they may be located anywhere on a work bench since it is not necessary to provide for the escape of the fumes and burnt gases.

Larger solder and babbitt pots of lead, capacities up to 2000 lb, are in use. A typical example would be a 750-lb pot, rated at 13.5 kw, with automatic temperature control. Such a pot has been known to melt 4500 lb of 50–50 solder, operating at 800 deg fahr, in 9 hours with a total energy consumption of 150 kwhr.

Automatic temperature control is very desirable. A number of thermostats, such as the disk type and others, are available on the market. They are usually built into the heating appliance in such a manner as to be very responsive to changes in temperature.

24. INDUSTRIAL APPLICATION UNITS

These are small heater units, complete in themselves with supports and terminals which have been designed to meet a wide variety of applications of heat to machines and appliances to which heated surfaces or spaces are essential to their successful operation. Usually the application involves only minor changes in the construction of the machine to accommodate the electric units. Terminals are provided for readily connecting up the units.

Such units are usually provided in standard voltages of 110 and 220 volts, although the larger units for ovens are suitable for operation in series up to 550 volts. Some of the types and applications of these units are described in the following paragraphs.

CARTRIDGE HEATERS. A tubular unit having terminals at one or both ends and designed to be inserted in holes drilled in castings which require heating, such as embossing presses, hot molding presses, shoe machinery irons, hat machine irons, etc., is called a cartridge heater. Nickel-chrome resistance material is used for the heater and is wound on a central core of porcelain or lava and insulated from the outer tube of brass by cement or mica. Cartridge heaters may be used in applications up to 300 deg cent. Manufacturers' catalogs should be consulted for sizes and ratings.

STEEL-CLAD HEATERS. This is a flat type of element consisting of a mica form on which a resistance element is wound, insulated with flat plates of mica, and enclosed in a casing of sheet steel pressed flat on the element. Terminals are usually located at one end.

This unit is made in a wide variety of sizes and is suitable for hot-press heating, hot tables, heating rolls, small ovens, etc., in which the uniform distribution of heat is desired. A wide variety of sizes and ratings are available, and manufacturers' catalogs should be consulted for exact information and recommendations as to applications.

METAL-MELTING HEATERS. Special shapes of cast-in-heaters are available for immersion in lead pots, babbitt pots, type-metal pots, etc. Wattage, voltage, and shape must be designed to suit the particular application.

SPACE HEATERS. These have one terminal located at each end and run from 12 in. to 43 in. long and 220 to 1250 watts input. The 24-in. length is a standard size and is suitable for a wide variety of applications, of which the following is a partial list.

The unit is 1 $1/2$ in. wide, $3/16$ in. thick, and is supplied in two designs, one for 110 volts and the other for 220 volts, the rating being 500 watts in either case.

Small Industrial ovens.	Watchmen's houses.
Blueprint dryers.	Elevator cabs.
Hoist cabs.	Laundry dryers.
Ticket booths.	

INDUSTRIAL OVEN HEATERS. These heaters are designed for the larger sizes of industrial ovens. They are of nickel-chromium ribbon wound over porcelain bushings and assembled into a metal frame. Exposed heating ribbon is used to give free radiation into the oven space. The heating is done partly by radiation and partly by convection. Terminals are provided at the ends of connections. Units are usually made up for 110-volt and 220-volt service. Two 220-volt units may be connected in series for 440 volts. Complete sets of suitable connection straps and insulators are provided to accompany the heaters.

25. INDUSTRIAL OVENS

Electric heat has been applied to ovens for japanning, lithographing, paint drying, lacquer drying, core baking, armature baking, and many other purposes requiring temperatures up to 800 deg. fahr. The absence of fumes and gases, reduction in fire hazard, ease of control, and increased production have in many cases justified even increased costs of heat. Ovens are of the usual kiln type, the semi-continuous type, or the continuous type.

A Kiln Type Oven is usually rectangular in shape with a door at one end into which the material to be baked is loaded. When the oven has been loaded, the door is closed and current turned on. When the baking has been completed, the current is turned off, door opened, and work removed.

A Semi-continuous Oven has doors at both ends, and a new load is pushed in at one end while the finished load is removed from the other end.

In a Continuous Oven the work is carried through the oven on a continuous conveyor loading at one end and discharging at the other at a uniform speed.

Heaters are installed along the side walls or on the floor. A space of 8 to 10 in. from the wall or floor should be provided. Over the heaters a screen of expanded metal or wire mesh can be installed to prevent work dropping on the heaters and connections.

Control is usually by magnetic switches. Door switches are sometimes provided so that when the doors are opened the main switches also open. A thermostat is generally used to regulate the temperature by turning the current on or off as may be needed. This thermostat operates through a relay to control the main magnetic switches.

Either 110, 220, or 440 volts, of any frequency, and either single phase, two phase, or three phase, can be used. Direct current up to 550 volts can be used also.

HEAT REQUIRED FOR INDUSTRIAL OVEN. In calculating the heat requirements, the following losses and uses of the heat must be carefully determined.

Heat to Raise the Temperature of the Work, Including Trucks. The total weight of the material to be baked, the initial and final temperatures, and the specific heat must be known. Dividing the heat required by the time gives the heat per hour needed. The japan or paint can be ignored. The heat required to heat the trucks or hangers is calculated in the same way for each load.

Heat to Raise the Temperature of Oven Walls. The insulating material in an oven wall absorbs heat in the period of heating up even though it may be fairly good heat insulator. The usual method is to average the temperatures of the inner and outer surfaces, and subtract the initial temperature to obtain the average temperature rise. This is multiplied by the weight and specific heat to obtain the total heat required. Dividing this by the time allowed for the heating operation gives the rate at which heat must be supplied.

The interior framework and oven lining of metal are heated on the average to the same temperature as the work in the oven, and can be calculated in the same way.

In a kiln-type oven the interior cools down somewhat during the period when the doors are open for emptying and reloading. For this reason a portion of the heat must be replaced with each charge. This may be from one-quarter to one-half of that required on the first bake.

Radiation Losses from the Oven. This depends upon the wall and door construction. It is of prime importance that the amount of metal extending through the oven walls from the inner to the outer surfaces be reduced to a minimum. Average radiation loss from a metal oven with 2 in. of insulation (air-cell asbestos or magnesia) and door at one end only will be approximately 50 watts per square foot of total outside surface of oven,

with an inside temperature of 400 deg fahr. Exact figures for radiation loss cannot be given, as it is controlled to such a great extent by the design of doors, corners, vents, etc., as well as by the thickness and character of the insulation.

Ventilation. The amount of ventilation required depends upon the product to be baked. Ovens for japanning, paint drying, core baking, and all other operations that give off gases or vapors require ventilation. Where a paint or japan is used that contains a volatile solvent of combustible nature, good ventilation is necessary to reduce the danger of fire or explosion. This danger is much more remote with an electrical oven than with a gas or other fuel-heated oven because of the uniform temperature regulation obtained with an electric oven. Ventilation also removes the gases given off during baking and improves the surface obtained.

For japanning ovens from ten to twenty changes of air per hour are usually allowed. To calculate the heat required the volume of the oven is multiplied by the weight of a cubic foot of air at the oven temperature, by the temperature rise, by the specific heat of air, by the number of changes per hour.

Totals. Adding together the heats required for each of the above throughout the time allowed will give the total heat. Dividing by the number of hours gives the rate the heat will be required. If the heat is calculated in Btu, divide this rate by 3415 to get the power input in kilowatts.

It is impracticable to give average figures of inputs for various oven sizes and applications. As an example, however, it may be stated that for japanning ovens at 400 deg fahr, 2-hour baking period, the input would be around 100 watts per cubic foot of volume of the oven.

26. INDUSTRIAL RESISTANCE FURNACES

The electric furnace is much like the fuel-fired furnace in appearance and construction. More attention is usually paid to the elimination of heat losses from the electric furnace because of the higher cost of the heat units. Electric furnaces have many advantages that often more than offset the increased heat unit cost. The cost of heat may often be a very small part of the total cost of a process. It is important, therefore, to examine carefully all the factors that enter into production costs when planning the heating equipment for a process. Repair and replacement of linings, loss of material rejected on inspection after treatment, cost of handling material through the furnaces, space requirements, failures in service because of lack of uniformity—these are all elements of the total cost of a heat-treating process.

Electric furnaces may be built to meet almost any requirement as to size, shape, temperature cycle, or process. Table IV indicates roughly the classes of furnaces and some of their uses:

Table IV. Classification of Resistance Furnaces

Class	Temperature	Typical Uses
I	Low-temperature furnaces 300 to 1200° F	Temper drawing Nitriding Low-temperature annealing of steel, brass, glass, etc.
II-A	Medium-temperature furnaces 1200 to 2000° F	Hardening Vitreous enameling Carburizing Normalizing High-temperature annealing of steel
II-B	Pot-type furnaces 600 to 1650° F	Lead furnaces Cyanide furnaces Other salt furnaces
III	High-temperature furnaces 2000 to 2500° F	Forging High-speed steel hardening Ceramic firing

CONSTRUCTION. Since there is no combustion, the electric furnace requires no grates, ashpit, air or fuel inlets, or smokestack. It is usually built as a solid steel box. The outer shell is of heavy sheet steel $^3/_{16}$ or $^1/_4$ in. thick, supported and reinforced with steel angles or channels as needed. Inside this shell are several inches of heat-insulating material in the form of blocks, or wool, or powder. Next comes a wall or layer of semi-refractory slabs or bricks having good heat-insulating qualities and able to withstand the

higher temperatures of this zone. Finally, there is the inner lining of firebrick in the zone of highest temperature.

The electric heating elements are installed on this inner lining. They may be attached to the sides, roof, or bottom, as desired. In some furnaces they have even been mounted on the inside of the doors. Heaters are located as needed to give the proper distribution of heat inside the furnace. Ordinarily, location on the bottom and sides is sufficient.

In locating heaters, it is necessary to take into account the work going through the furnace and also the doors and other structural features that may conduct heat through the walls.

Heating elements for the low- and medium-temperature classes are of the best grade of nickel-chromium wire, rod, or ribbon, and are bent or formed before assembly into the furnace. They may be assembled into frames complete with insulators, or the insulators may be built into the refractory lining of the furnace and the zigzag heater mounted during the construction of the furnace.

Provision is usually made in the design for easy replacement and repair of the heating elements.

Terminals of the heaters are usually brought out through the walls and connections made outside the furnace. Terminals are usually of the same material as the resistor but of larger cross-section to reduce heating effect. They are usually welded to the resistance material.

Metal parts that may be required inside the furnace are generally of cast nickel-chromium. This is used for guards in front of side-wall heaters, cover plates over bottom heaters, rails, bumpers, conveyor parts, hanger hooks, melting crucibles, and many other purposes. Ordinary cast or wrought iron or steel is not suitable for this service because of the rapid oxidation and corrosion at these high temperatures.

For the high-temperature class of furnaces which are to operate between 2000 and 2500 deg fahr a molded resistance material is generally used in the form of rods. These units extend through the furnace walls so that terminal connections may be made on the ends. Water cooling of the terminals is often desirable. Units are available in a variety of sizes varying in length by 2-in. steps from 6 to 48 in. and in various appropriate diameters. This type of material is available under the trade names of Globar and Silit. Recent developments indicate that there may be some metallic resistance alloys capable of withstanding these higher temperatures.

Table V gives a few typical sizes of Globar units:

Table V. Typical Globar Units

Length, in.	Diameter, in.	Volts	Amperes	Watts	Length, in.	Diameter, in.	Volts	Amperes	Watts
5	5/16	30	14	420	16	1	65	85	5525
6	5/16	40	15	600	24	1 1/4	85	110	9350
8	3/8	55	20	1100	36	1 3/4	110	185	20,350
12	1/2	75	29	2175	48	1 3/4	150	200	30,000

Furnaces may be of almost any size and shape to suit the needs of the process. The following brief review will suggest the adaptability of electric furnaces.

BOX FURNACES. These are rectangular in shape with a door in the end or side. The smaller sizes are usually charged by hand, but the larger sizes are often equipped with power-operated charging apparatus. Table VI covers only some of the standard sizes. Much larger furnaces of this type are often built for special purposes. (Fig. 1.)

Table VI. Typical Box Furnaces

Type No.	Maximum Power, kw	Dimensions (inches)						Insulation, in.	Shipping Weight, lb
		Inside			Outside (overall)				
		Width	Depth	Height	Width	Depth	Height

ROTARY-HEARTH FURNACES. These are cylindrical in shape with a hearth that rotates. The work is loaded on this hearth through the door and travels around through the furnace one or more revolutions and is then unloaded. Loading and unloading may be automatic if desired. Different temperature zones may be arranged to provide the proper heating cycle. Sizes vary, although hearth diameters of 5 and 7 ft have been common.

PUSHER FURNACES. These are similar to large box furnaces with automatic charging apparatus for feeding in the work and pushing it through and out the other end. The work may be pushed straight out the other end or dropped down a chute into a quenching bath. Time cycle and temperature being automatically controlled, accurate duplication of results is obtained on a mass production basis.

PIT FURNACES. These are open-top furnaces used for heat-treating large charges of small parts or large parts that can be most conveniently handled from a crane. Covers are lifted off by crane.

BELL TYPE FURNACE. The body of this type of furnace is arranged so that it can be lifted off the bottom by a crane or hoist and easily transferred to a different bottom. Several bottoms may be used so that the loads may be arranged in advance and the furnace moved from one to another, thus obtaining the full heating capacity of the furnace. The bottoms may be equipped with wheels for ease in transportation about the shop.

The furnace body or bell may be made gas tight by welding all seams and by properly sealing all terminals in case it is desired to use non-oxidizing atmosphere inside during the heating cycle. The seal, being at the bottom of the furnace, is less subject to atmosphere leakage that when at the top as in a pit furnace.

ELEVATOR-TYPE FURNACE. This is similar to the bell type in principle except that the body is fixed in a position high enough above the floor to clear the loads that may be piled on the bottom. An elevator is provided beneath this furnace which hoists the bottom up into position under the furnace.

CAR FURNACE. These are very large box-type furnaces for handling large quantities of material on cars. Rails are run inside the furnace. A specially designed car is piled full of material and pushed in through the open door. These furnaces sometimes assume very large dimensions.

CONVEYOR FURNACES. These are furnaces built around a conveyor system. They are quite generally used for vitreous enameling, which is a process involving comparatively light materials but one in which accurate conrtol of heating cycle and temperature is very important. Also the product is easily damaged in handling and by foreign particles, such as dust, falling on the surfaces. Some of these furnaces are well over 100 ft long and handle very large amounts of material per day.

PERFORMANCE. The performance of a furnace is usually stated in terms of pounds of product per kilowatthour for a certain set of conditions as to time and temperature cycle, total hours per day operated, size of charge, etc. Average economies to be expected are given in Table IX for general information only, and are not to be used as exact figures for any specific problem.

Table IX. Production per Kilowatthour

Operation	Approximate Temperature, °F	Average Pounds per Kilowatthour
Hardening carbon steel	1550	8 to 11
Tempering " "	600	20 " 25

" steel forgings	1600	10 " 12

TEMPERATURE REGULATION AND CONTROL. Electric furnaces can be automatically controlled to a high degree of exactness. The type of control apparatus depends upon the requirements of the application.

Thermostats and pyrometers are available for all temperatures, and it is best to consult the manufacturer for definite recommendations. These thermostats have maximum and minimum contact points which are connected through relays to the main control panel. In some cases the entire current is turned on and off by the thermostat as required to maintain temperature. In others, only a portion of the heater circuit may be under automatic control. Sometimes it is desired that different parts of the furnace be kept at different temperatures, as in a long tunnel furnace where one portion is for preheating at low temperature and another part at high temperature to complete the process.

A temperature-limiting fuse is often a very desirable feature in a furnace to protect against overheating and possible damage to the furnace and to the work in it.

ELECTRICAL PRECIPITATION OF SUSPENDED PARTICLES

By N. W. Sultzer

The removal and collection of finely divided solid or liquid particles carried in suspension in air or other gases may be accomplished by the application of a high-potential unidirectional electrical current to such gases. The Cottrell electrical precipitation processes embodying this principle have been applied with successful results in a large number of installations throughout the world.

28. PRINCIPLES

The essential elements of an electrical precipitator are two sets of electrodes. One set, known as the discharge electrodes, are of such form as to facilitate an electric discharge from their surface, as for instance a wire or a light chain, or a strip of metal having relatively sharp edges; the other set, known as collecting electrodes, are of such shape as to prevent as far as possible any discharge from their surface, as for instance, a flat plate or a pipe with a smooth interior surface. These electrodes are so arranged in the precipitator that the different types oppose each other, and between them a silent or glow discharge is maintained by supplying to the discharge electrode electrical energy of a unidirectional character and at a high voltage.

In practice, the collecting electrodes are grounded for reasons of convenience and safety. A simple form of precipitator, for example, consists of a grounded pipe along the central axis of which is placed a wire connected to a source of unidirectional high-voltage current.

The air or other gas carrying suspended liquid or solid particles which are to be removed is passed between the discharge and collecting electrodes. During passage the particles of suspended matter are charged and are driven away from the discharge electrodes and over to the collecting electrodes upon which they are deposited. The air or other gases pass on and out of the precipitating chamber.

It has been found that the most effective precipitating action is obtained when the potential difference between the electrode is sufficient to produce a glow known as the corona on the discharge electrodes (see Corona), and when the discharge electrodes are charged negatively rather than positively.

The voltage employed in a precipitator depends upon the size and type of discharge electrode used, the gap distance between the discharge and collecting electrodes, and the temperature and other characteristics of the gas being treated. There is a definite relation between the velocity of the gases through the precipitator and the length of the path between the electrodes. In other words, the particles must be under the influence of the electric field for a suitable period of time in order to secure satisfactory removal of these particles from the gases. The length of this period depends to a considerable extent upon the character of the particles to be precipitated. If the particles are fluffy in character, light, dry, and very finely divided, a longer time will be required than if they are relatively heavy or coarse or of a liquid or sticky nature.

29. EQUIPMENT

In electrical precipitation, the two essential groups of equipment are: the electrical equipment to generate the high-potential unidrectional current required; and the precipitator proper, in which the gases are cleaned or treated.

ELECTRICAL EQUIPMENT. To generate the high-voltage unidirectional current, electrical equipment of a more or less special type is used, developed or adapted from standard equipment. Where the source of power is a 220- or 440-volt, two- or three-phase, 25- or 60-cycle, a-c supply, a synchronous induction motor is used to drive a direct-connected mechanical rectifier, rectifying the secondary current from a special transformer energized from this same supply. Where direct current—usually at 250 volts—must be used, a motor-generator unit provides a low-voltage alternating current for the transformer and rectifier just mentioned. In this case, the rectifier is direct-connected to the alternator, which must be a four-pole machine.

Electronic tube rectifiers for precipitation work are now being designed.

SWITCHBOARD. A control panel carries all necessary switches and controls for the low-tension circuit. An a-c board has a motor starting switch with two clips for throwing the motor on the line, first through the starting resistance and then directly. In addition there are an overload circuit breaker with low-voltage trip; a single-pole, five-throw transformer switch; a double-pole, double-throw switch in the main transformer circuit for getting proper polarity on the discharge electrodes; an ammeter and voltmeter; a plug switch for connecting the voltmeter to read potential on either side of the primary resistance or rheostat in the primary circuit used to regulate the potential to the transformer and to minimize the effect of surges caused in the high-voltage circuit and reflected back into the primary circuit.

In an installation operating from a d-c supply the panel board carries, in addition to the apparatus just listed, a motor starting box with no-load release, and an alternator field rheostat. Protective fuses are also used, where required.

SYNCHRONOUS MOTOR-RECTIFIER. In this, the motor element is of the induction type with standard squirrel-cage stator for starting purposes. It is so built, however, that it has the four poles of the synchronous motor minus the windings, the magnetism being induced in the poles by a stator current. The frame is about the size of that of a 3-hp motor; and the motor may be for 220 or 440 volts, two or three phase, 25 or 60 cycles. A starting resistance is also provided.

The rectifier element is, in effect, a synchronously driven switch. Four bronze shoes, spaced 90 deg apart on a circle, are mounted on fixed insulating arms of Bakelite. The top shoe is connected to the precipitator; the bottom shoe is grounded; and each side shoe to one secondary terminal of the transformer. Rotating within these shoes, with a clearance of $^1/_8$ to $^1/_4$ in., is a rotor with four tips at 90-deg intervals, mounted on Bakelite arms or a Bakelized disk. The two adjacent tips are electrically connected, but the two pairs of tips are not connected.

TRANSFORMER. The transformer used is from 5- to 25-kv-a capacity, according to the requirements of the precipitator installation. Standard design calls for a single-phase, 25- or 60-cycle, 200-, 400-, or 500-volt primary, 50- to 85-kv secondary, with a number of primary taps (usually five) to afford a range of secondary voltages. The coils are immersed in oil and specially insulated. Choke coils and, usually, resistance rods are provided in each leg of the secondary to reduce surges. Radio interference correctors are also installed, if necessary, to prevent "static" interference with radio reception.

THE PRECIPITATOR. The type of precipitator used in any particular installation is determined largely by the nature of the operation and such factors as the kind of gas to be treated, the character of the material to be removed or recovered, and the space available for the equipment. The size of the precipitator depends primarily upon the volume of gas to be treated in unit time and upon the degree of cleaning required.

Pipe Type. This type of precipitator is used primarily in the precipitation of liquids from gas or air, and for dust and fume removal where a particularly high degree of gas cleanliness is required. It consists of a group of vertical pipes 6 to 8 in. in diameter and 9 to 12 ft long. These are nested in a shell, with connections such that the gas passes up through the pipes and emerges from the shell through a connection at the top. Within each pipe a wire is axially suspended from an insulated framework above, and weighted below. The material precipitated from the gas, in passing through the pipes, collects on the interior walls and settles into a lower header from which it is removed through drains or hoppers.

The size of a pipe precipitator is limited by mechanical and structural considerations, and for large volumes of gas, several units may be required. The material used in the construction is determined by the character of the gas treated and of the suspended matter removed, non-corroding materials being used where the nature of the treatment requires.

Plate Type. The plate type of precipitator is intended primarily for removing solids from air or gas. Here a series of parallel plates in a casing or shell form the channels through which the gas flows, and between these plates a series of wires is suspended from an insulated framework.

The material used in the construction of the plates varies with the particular conditions of each problem. In some cases they are of steel or alloys; in others, they are in the form of a concrete slab with embedded conductors at the center. Rod curtains are sometimes substituted for steel plates, offering certain structural advantages. The dust, after collecting on these plate electrodes, settles into a lower header or hopper from which it is removed and disposed of.

A TYPICAL INSTALLATION. The electrical equipment is located reasonably close to the precipitator. A single conductor carries the unidirectional current, through the bushing provided on the electrical substation, to the precipitator. Where several precipi-

tator units are provided, disconnect switches are installed on each so that any one or several may be disconnected electrically without interference with the operation of the other unit.

30. OPERATING CHARACTERISTICS

Electrical precipitation may be employed for the removal or recovery of practically any type of suspended matter from any kind of gas, with a temperature range from atmospheric to approximately 1300 deg fahr. This upper limit is determined by the ability to secure structural materials that will stand up under extreme heat.

The precipitator sets up practically no resistance to the flow of air or gas. Its introduction in a gas system, therefore, raises no added problems in draft maintenance or suitable gas flow.

The electrical power consumption is nominal. The current flow is so small as to be measured in milliamperes. Speaking in general terms, the power consumption is 5 to 8 kwhr per million cubic feet of gas cleaned.

The labor required is almost negligible. Practically no attention is needed when a liquid material is being precipitated, as in such cases the precipitator is self-cleaning. When precipitating dust, the collecting plates must be rapped and cleaned at intervals. Where labor is at a premium, mechanical and automatic contrivances are supplied to perform these functions.

RECOVERIES AND EFFICIENCIES. The phenomena of electrical precipitation are such that the degree of removal of suspended matter is a function of the time during which the suspended matter is within the electrical field. This permits the design of equipment to give practically any degree of gas cleanliness required. In certain cases, a 90 per cent removal is all that is needed. In other instances, where the demand is for practically a complete removal or recovery of suspended matter, this demand can be met, removing more than 99.99 per cent of the suspended matter.

An installation is usually made up of two or more precipitator units, which permits continuous gas treatment even when one unit is temporarily removed from service to permit cleaning—and this with but a slightly reduced efficiency of recovery or removal.

31. TYPICAL INSTALLATIONS

Electrical precipitation has been widely applied to miscellaneous gas cleaning in industrial operations where the gas after cleaning is discharged to atmosphere or utilized in subsequent operations or distributed for subsequent use. In some cases the material removed from the gas is a dry dust or fume; in others, a liquid—such as acid, tar, etc. In some cases the material collected has a value; in others, its removal simply results in abatement of a nuisance or improvement in subsequent operations. In some cases the gas is cleaned at atmospheric temperature; in others, at temperatures ranging up to 1200 deg fahr. The following are some of the more typical installations.

REMOVAL OF FLY ASH FROM PULVERIZED COAL FIRED BOILER GASES. In June, 1931, Cottrell electrical precipitation equipment was in use or under construction in thirteen different power stations. The individual installations ranged in size from one handling 50,000 cu ft per min of gas to one treating 1,500,000 cu ft per min.

DETARRING GAS. In June, 1931, electrical precipitation was in use or under construction at about seventy different gas plants, such as carburetted water gas, by-product coke oven, etc. It removes tar and oil from the gas ahead of purifiers, saturators, light oil towers, etc. The individual installations range in size from 1,000,000 to 70,000,000 cu ft per day.

COLLECTION OF METALLIC FUMES. Numerous plants in the non-ferrous metallurgical industry are using electrical precipitation for the collection of metallic compounds, such as tin, lead, zinc, etc., from gases coming from reverberatory furnaces, blast furnaces, kilns, and other smelting and refining operations. Much precious metal is also recovered.

COLLECTION OF CEMENT KILN DUST. Many of the portland cement plants are using electrical precipitation for the collection of dust from gases coming from rotary kilns producing cement clinker.

ROASTER GAS CLEANING. Where zinc or pyrites ore is roasted, electrical precipitation is used for the recovery of the dust and fume carried over in the gases, particularly where the gas is utilized in the subsequent production of sulfuric acid.

ACID MIST COLLECTION. Electrical precipitation is in use in many plants for the collection of sulfuric acid mist from exit gases coming from acid concentrators and for the purification of gas, i.e., removal of acid mist and other suspended materials, in contact sulfuric acid plants.

CLEANING IRON BLAST FURNACE GAS. Electrical precipitation is in use in several steel plants for primary cleaning of the hot gas and for secondary gas cleaning of the cooled gas directly following primary gas washers.

In addition there are numerous other applications in various industries.

ELECTRIC WELDING

By H. M. Hobart

33. GENERAL CONSIDERATIONS AND DEFINITIONS

Among the various processes of joining metals by welding, several employ electrical energy as the source of the heat. Some one or other of these electrical methods is appropriate for almost any welding requirement.

It is proper, however, to state that in many instances there are excellent non-electrical alternative methods. Thermit welding and autogenous gas welding are notable examples. For extensive classes of work, it is generally found that electrical methods are particularly economical, rapid, and effective, probably usually much the most rapid, and, in the majority of cases, at least as effective in securing joints of high quality. Indeed, the rapidity inherent to electrical methods of welding is an important factor in obtaining high quality, since the influence of the oxygen and nitrogen of the air, at the high temperatures required,* presents one of the principal harmful factors; therefore, the more rapidly the

* In various alloys and in materials refined by heat treatment, the liability to unfavorable changes due to migration of particles of important constituents is a serious consideration.

weld is completed, the better in general will be its quality, since there is less time during which the oxygen and nitrogen are in contact with the very hot metal. High speed, of course, also contributes to low outlay for both labor and capital charges.

The great advances made in recent years in the art of welding have not only brought about its extensive use as an alternative to riveting but now permit of making joints of kinds and for conditions not heretofore possible, particularly as regards tightness, and ability to withstand extremely severe mechanical stresses.

STANDARDS AND DEFINITIONS. The American Institute of Electrical Engineers has developed *Standards* for electric welding apparatus. These Standards relate respectively to resistance welding apparatus and electric arc welding apparatus. For many years these standards contained the following definition:

"**Weld.** A solid union of metallic parts formed by either heating to a plastic or fluid state the surfaces of the parts to be joined and allowing the metals to flow together (with or without additional molten metal being supplied) without any pressure being supplied; or by uniting or consolidating by hammering or compressing, with or without previous softening by heat."

In the 1934 revision * this is replaced by the following:

"**Weld.** A localized consolidation of metals."

The writer considers this too brief to convey a useful understanding of the term. Mr. F. T. Llewellyn may be quoted (Outline of welding and allied processes, *Metal Progress*, December, 1930, and January, 1931) as follows:

"Welding may be briefly defined as a localized consolidation of metals by means of heat. While it is true that, as a laboratory experiment, the surfaces of certain metals can be united without heat, and that the several welding processes involve other factors in addition to heat, yet the importance of heat in all practical welding operations warrants its inclusion as a common factor in any useful definition."

The several processes of electric welding may be placed in three groups:

I. Resistance welding.
II. Arc welding.
III. Other welding methods having electrical features.

34. RESISTANCE WELDING

The art of welding metal parts by passing a low-voltage current (practically always an alternating current) across the surface of contact of the metal parts to be joined, was invented and also made a commercial success by Professor Elihu Thomson in the 1880's. This process, which is known as resistance welding, has been used widely for many years in a great number of manufacturing industries. In each successive year, however, new applications continue to be made, and there is as yet in sight no limit to the extent of the usefulness of resistance welding for joining metals. On the contrary, particularly during the last few years, the rate of increase in its use has been enormous.

THE PRINCIPAL ENGINEERING PROBLEMS IN RESISTANCE WELDING. For any given application of resistance welding, the engineering problems usually chiefly relate to (1) the design of machines for holding the parts; (2) bringing them into suitable juxtaposition; (3) regulating the mechanical pressure and rate of pressing together of the parts to be joined, at various stages of the process of heating the metal at the surfaces of contact; (4) arresting the process at the proper instant; (5) the regulation of the current to the most suitable amount at all stages of the process; and (6) the provision of means for cooling various parts (usually by water circulation) of the transformer, the electrodes, and the other parts carrying current. Careful consideration must also be given to the sizes, shapes, and condition of the two surfaces of the parts to be welded which are brought together and of the thermal conductivity and the proportions of the parts in the neighborhood of these surfaces.

KINDS OF JOINTS. Before further describing the resistance welding process, it is desirable to explain that the kinds of joints made by that process may be grouped in three main categories: (1) butt welded, (2) seam (or line) welded, (3) spot welded. Thus it may be said that resistance welding comprises three main varieties, and these may be defined as follows:

Butt Welding. When, in the resistance process, the parts to be welded to one another are "butted" together, the current passing through the entire section of metal at the weld, the term butt welding is often employed.

Seam Welding. When, in resistance welding, the point of introducing and carrying away the current moves along a line so as to make a continuous weld along that line, the

* See A.I.E.E. Standards Nos. 38 (arc) and 39 (resistance), January, 1934, revision.

term seam welding or line welding is employed. Seam or line welding is sometimes accomplished by making a series of spot welds adjacent to one another, in fact, most seam welding is actually a series of spot welds. (Sometimes in using this means of making a seam weld between thin sheets, the successive spot welds overlap one another.)

Spot Welding. When, in resistance welding, the current is passed transversely across two plates which it is desired to join at many places (or spots) the term spot welding is employed. In the early days spot welding was limited to relatively thin plates of metal. It is now also applied to the welding together of materials of considerable thickness.

Pressure Welding and Flash Welding

Resistance welding may be subdivided also according to two different procedures with respect to the mechanical pressure. These two varieties may be respectively designated as (1) pressure welding and (2) flash welding.

PRESSURE WELDING. In pressure welding the procedure consists in first bringing together the surfaces to be welded, then sending current across the contact between them until the material reaches the proper temperature and finally, effecting the weld by forcing the surfaces of the plastic metal into one another a short distance. The current may be cut off either before or after the last stage of the process. Pressure welding (if employed for butt welds) usually produces a somewhat enlarged cross-section at the weld, due to the upsetting of the metal. The enlargement, if objectionable in the product, is sometimes removed while hot and sometimes ground down. Great mechanical pressure is required in butt or spot welds of parts of large cross-section. As a rough indication, it may be stated that the requirements for electrical power and mechanical compression, with medium-rolled steel, are (per square inch of area to be united) respectively from 30 kv-a to 200 kv-a for 10 sec (these quantities varying with the shape, size, and thickness and grade of the material) and not less than 5000 lb nor more than 8000 lb. If the process is carried out more slowly, the electrical input required per square inch is less. But the best results usually correspond to short time and great power.

FLASH WELDING. In flash welding (as applied to butt joints), instead of immediately pressing the parts together, the current supply circuit breaker is first closed The surfaces are then brought approximately together but with little or no pressure between them. Current now flows across this poor surface of contact and arcing ensues. By continuing these conditions and this procedure for a sufficient time, the surfaces to be welded become gradually better fitted to one another. When the right temperature condition has been reached sufficiently uniformly over these surfaces, the two parts are abruptly pressed into one another. Sometimes the current supply circuit is interrupted prior to this concluding phase of the process, but in other cases, a very heavy current flows (since the resistance has greatly decreased as the result of pressing the surfaces together), and, sufficient heat for the weld having now been provided, the current is cut off. In the flash process, dirt, impurities, and oxides are ejected from the joint in molten form, or consumed, whereas with the pressure process, such impurities are unable to escape from the joint and may impair its quality.

For butt welds, particularly for high grades of steel or for very large or complicated cross-sections, flash welding often gives the best results. Flash welding may, however, also be applied to small parts. Indeed, the choice between (1) pressure welding and (2) flash welding is governed by many highly technical considerations and is based on the results of accumulated experience.

In the January, 1934, revision of A.I.E.E. Standard No. 39, entitled Standards for Resistance Welding Apparatus, there is given the following definition for flash welding:

"**Flash Welding.** A resistance butt welding process wherein the welding heat is developed by the passage of current in the form of an arc across a short gap between the surfaces to be welded, these surfaces being kept slightly separated until they have flashed off to parallelism and have reached the desired temperature. The electrical circuit is then opened and the upsetting movement takes place. The operation of the machine may be manual, semi-automatic or fully automatic. The name 'flash' arises from the fact that during the heating period, oxidizing metal is thrown off in a shower of sparks."

With the flash method, a less depth of material has to be brought to the ultimate temperature. But whereas, in the pressure method, the material is brought up only to the plastic condition, in the flash method it is heated up almost to the molten condition and thus permits the impurities to be squeezed out with the resultant improvement of the joint. The flash method is more of a surface process and occasions less change in the quality of the neighboring material. Consequently, for butt joints in steel of high quality, the flash method is sometimes the most satisfactory. The flash method is unsuitable, however, for some alloys such as stainless steel. For these it is all-important to prevent

access of air to the heated spot, and also to heat as small a mass as possible and in so short a time as to prevent any migration of carbon from the heated material. It would be very difficult for even the most experienced metallurgical and welding specialists to state any generalization as to the respective merits and fields of application for these two resistance-welding alternatives (pressure welding and flash welding). The broad term resistance welding is used below to cover both varieties.

Fields for Resistance Welding

The flash process is confined to butt welds and is usually incompatible with the conditions required in seam welding and spot welding. (However, since in some designs it is hard to decide whether the joints should be designated butt or spot, and since pressure welding shades off into flash welding, it is extremely difficult to set up rigorous distinctions to which there shall be no exceptions.) The kind of metal affects the choice. Usually the pressure process must be employed for non-ferrous metals and for most alloys and metals whose qualities are dependent on cold working or heat treatment. For such materials the pressure process with thyratron timing control (described below) is proving very effective and is coming into extensive use.

With an automatic welding machine, many hundreds (and, in some instances, even thousands) of small welds are made per hour and with relatively small * current and mechanical pressure. In one known application, the machine makes 9000 spot welds per hour.

In striking contrast to these small welds may be cited welds between enormous parts (many tens of square inches of cross-section) which may require many tens of thousands of amperes and many tens of tons of pressure.

Butt welds of iron parts of 15 sq in. cross-section can be made by the flash welding process at the rate of a few minutes per weld with an energy consumption of the general order of some 20 kwhr and with the labor of only one man and a helper. It has been pointed out that, for such a weld, there was formerly required by forge welding the labor of three or four men for a matter of half a day, and the making of such joints was an art acquired only after long training. Moreover, while, by the forge process, only low-carbon material could be joined, the flash process welds high-grade steels and various other materials which were not susceptible of welding by the forge process. The ability to weld these high-grade steels permits of their employment in machines and structures and permits of effecting great reductions in their weight in the many cases where strength is the desideratum as distinguished from mass.

METALS TO WHICH RESISTANCE WELDING IS APPLICABLE. Most metals in reasonable states of purity can be joined to one another by the resistance process. Resistance welds can also be made between many alloys. Practically all grades of steel are readily welded. Different metals can also, in many instances, be welded to one another. The current for resistance welding usually is supplied from the low-voltage secondary of an a-c transformer, but direct current can be used to advantage under certain circumstances, and recently has been employed for welding the longitudinal seams of steel tubing, the direct current being provided from an acyclic generator supplying 2.5 volts and up to 20,000 amp. (See p. 60 of the April 24, 1930, issue of the *Iron Trade Review*.)

SPOT WELDING OF THICK PLATES. Spot welding of thick plates is an alternative to the long-established process of riveting, but is as yet not extensively employed where the plate thickness is greater than $^1/_8$ or $^3/_{16}$ in. During the World War a number of experimental heavy-capacity spot welders were built, and by their use it was demonstrated that two steel plates, each 1 in. in thickness, could be successfully spot welded together. Such large resistance welders are inherently quite expensive, and the concurrent and rapid development of arc welding (considered in the next article), combined with its broader field of application, has perhaps unduly retarded the commercial development of heavy spot welding. Only a few of these heavy welders with deep jaws have been built, but since they admirably illustrate the principles involved in resistance welding (indeed better than the complicated machines used in mass-production applications of resistance welding) Figs. 1 and 2 from the preceding edition of this handbook are again included.

STATIONARY DUPLEX SPOT WELDER (Fig. 1). The construction of commercial spot welders for use in ship fabrication may in general appearance be similar to so-called bull-riveters. A large spot welder which was built for such a purpose had a 6-ft gap and was for operation from a 60-cycle circuit. This outfit was a stationary machine, in the frame of which two transformers were incorporated. The steel plates and shapes

* To avoid misconception, it is desirable to point out that even in joining such thin materials as two strips of 40-mil stainless steel, the "relatively small current" is of the order of 20,000 amp when making a spot weld. But it flows for only some 0.03 sec.

were brought to the welder. Bulkheads, frames, floors, and other parts were constructed with it, and were then transported by cranes to their places in the ship. This 6-ft-gap machine had the capacity to weld together two $^3/_4$-in.-thick steel plates. It provided a pneumatic pressure of 60,000 lb and a current of 50,000 amp. It was called a duplex welder, and it welded simultaneously two spots, each of some 1.5-in. diameter, in about 30 sec.

The arrangement is shown diagrammatically in Fig. 1. The outfit comprised two transformers, one located on each side of the plates to be welded. The current crossed the plates in one direction between two opposed electrodes and then back again between two other opposed electrodes. Thus the two secondaries and the two joints constituted four elements connected in series. *AA* represent the two primaries. *BB* represent the two secondaries (which, in the actual construction, had only one turn each). *CC* and *DD* represent water-cooled copper electrodes. *EE* represent the two steel plates to be joined.

The above-described duplex feature was introduced in this spot welder to decrease the inductance of the long loop of conductor which otherwise would have been necessary

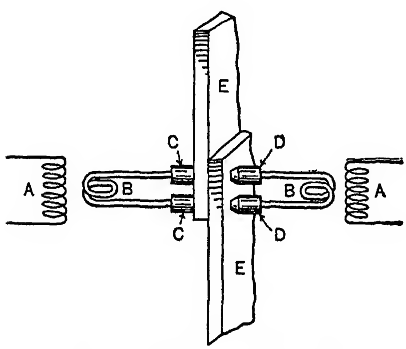

Fig. 1. Duplex Spot Welder

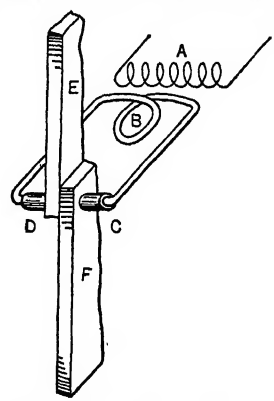

Fig. 2. Simplex Spot Welder

and which would have involved proportioning the transformer secondary for a higher voltage to overcome the inductive drop. The duplex construction thus improves the power factor.

SERIES WELDING. This method which has proved best in certain cases may be explained by referring to Fig. 1 and conceiving that everything at the left of the plates *EE* is replaced by a thick copper plate pressed against the back of the upper plate *E*. In this application, the electrodes *DD* are actually located considerably farther apart from one another than is indicated in Fig. 1. The current passing from the electrodes *DD* into the steel plates *EE* passes through these plates to the thick copper plate at the back, there completing the secondary circuit. This method usually is employed for welding thinner material than is indicated by the plates *EE* in Fig. 1.

PORTABLE SPOT WELDER. Fig. 2 is a diagram of the circuits of an ordinary (simplex) spot welder which welds only one spot at a time. In this figure: *A* represents the primary of the transformer. *B* represents its secondary. *C* and *D* represent water-cooled copper electrodes. *E* and *F* represent the two plates to be welded.

A typical 60-cycle portable welder of this kind, having a 27-in. gap, weighed only 2800 lb, including the transformer (which was embodied in the structure), and welded together steel plates of a thickness of half an inch with a current of about 30,000 amp. The pressure required for such work was some 25,000 lb.

In experimental work, currents exceeding 100,000 amp have been employed in improvised spot welding machines, and pairs of 1-in.-thick steel plates have been welded therewith.

SPOT WELDING VS. RIVETING. Spot welding has decided advantages over riveting for a great variety of important work now usually done by riveting. By employing spot welding, great savings are effected through eliminating the laying out and punching of the rivet holes, and the subsequent reaming when the holes do not match up.*

* In some naval vessels it is required that the rivet holes be drilled, thus involving still greater cost as compared with welding.

Furthermore there is avoided the reduction in cross-section and strength occasioned by the necessity for the rivet holes and thus the removal of material otherwise available for strength. With spot welding there is a great saving in material through the reduction in overlap made practicable as compared with provision for the two or three rows of rivets which are often required. Tests show that greater strength can be obtained with a single row of spot welds than with the best triple riveting.

Experience with and confidence in arc welding have so increased in recent years that proposals are now being made to *butt* weld the hull plates of ships, thus completely eliminating overlap, further reducing the weight of the hull, and providing a surface with decreased frictional resistance.

PROJECTION WELDING. The term "projection welding" is used to denote a slight modification of ordinary spot welding and is defined by Llewellyn as "a method of spot welding wherein small ridges, or other projections, are pre-formed (by rolling or otherwise), on one or both of the pieces to be joined; the projections serving to localize the current." Two examples of projection welds are shown in Fig. 3.

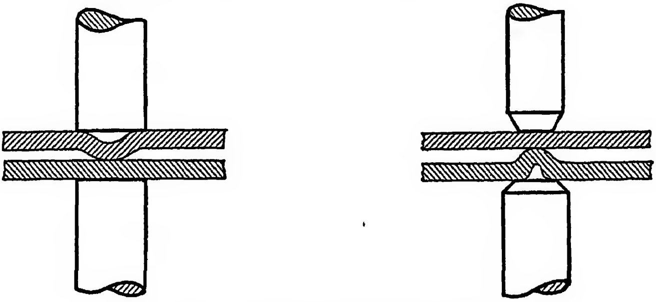

FIG. 3. Two Forms of Projection Weld

APPARATUS FOR RESISTANCE WELDING. Since resistance welding is a single-phase load of poor power factor and is usually characterized by extremely great, rapidly recurring peaks of short duration, there is particular need for careful provision that these severe characteristics shall not harmfully affect the interests of other people obtaining power from the same circuit. A single-phase load which cannot be distributed fairly equally between the phases of a polyphase system is always relatively objectionable to the power company, and it is far more objectionable when it is extremely variable in amount and when the peaks constitute a large percentage of the total load on the circuit, and particularly when the power factor is low. Unfortunately, the power factor is usually considerably lower the larger the rating of the welding machine and is as low as 0.6 in very large machines. However, with the present-day large-scale distribution systems provided in many industrial areas, the usual resistance welding load, even when large, is a smaller percentage of the total load on the distribution system than it would have been even fifteen years ago. Furthermore, it often should be quite practicable to distribute several single-phase welding transformers fairly uniformly on a polyphase system. To obtain the full advantage there would be required some interlocking plan to insure equality in the number of welding machines on each phase which would be carrying the welding current at any instant. In view of these facts, it is sometimes desirable, with particularly large resistance welding loads, to interpose, between the distribution system and the welding transformer, a motor-generator set consisting of a polyphase motor and a single-phase generator. This precludes any unbalancing between the phases of the supply system and eliminates from the distribution system all bad consequences of the poor power factor of the welding load. It does not, however, level out the peaks in the load. This can in some cases be done to a considerable extent by providing the motor-generator set with appropriate flywheel capacity, if the motor is of the induction type and designed for suitable slip. On the other hand, if the advantages of smoothing out the load are foregone, usually it will be preferable to employ a synchronous motor and operate it with overexcitation. This will be of advantage to the supply company through improving the power factor of the system and decreasing the voltage drop, and will tend to compensate for the increased cost of service occasioned by the poor load factor.

The single-phase generator of the motor-generator set is an expensive machine, much larger than a polyphase generator of the same rating, has lower efficiency, and is more prone to noise and vibration. So if the resistance welding load can be divided into two

these two kinds of electric welding should be employed. Resistance welding is applicable to joining almost all kinds of metals; electric arc welding is at present most widely applied to the welding of mild steel. However, rapid progress is being made in extending its use to the welding of high-grade steels and various other metals and ferrous and non-ferrous alloys. Indeed, the claim is made by reliable welding authorities that arc welding is already being applied with complete success to "a great variety of alloy steels, cast iron, copper, aluminum, nickel, Monel metal, bronze and a vast variety of other types of material." It is the opinion of the author of this article, however, that much remains to be accomplished in the case of many materials of these categories with respect to the uniform reliability, durability and high mechanical quality of the weld, and with respect to the speed of welding, the cost of the processes, and the general availability of artisans capable of producing such results. As already stated in this article, it is the welding of mild steel which, at present, constitutes the overwhelming preponderance of all arc welding. In the arc welding of mild steel not only are welds of uniformly unimpeachable quality readily made but also they are made cheaply and with rapidity and certainty by workmen possessed of ordinary training and ability. For most materials other than mild steel, the writer believes that, although arc welding is making rapid progress, resistance welding methods are at present farther ahead.

Before entering upon the consideration of electric arc welding, it should be pointed out that it is one of the two main subdivisions of an art which is often termed **autogenous** welding, but which will here be designated **fusion** welding.

FUSION WELDING. The term fusion welding is employed to comprise **gas welding** and **electric arc welding.** Gas welding does not come within the scope of this article, and it must suffice to state that the gas fusion process in its simplest form usually consists in simultaneously fusing (ordinarily with an oxyacetylene flame) (1) the material at and near the surfaces which it is desired to join, and (2) some material (which may or may not be similar in composition according to the object to be accomplished) in the form of a rod (termed the filler rod), the tip of which is subjected to the heat of the flame. The oxyacetylene (or other) flame is directed with one hand and the welding rod is manipulated with the other.

Kinds of Electric Arc Welding

Electric arc welding may be subdivided into several classes. One classification comprises: (*a*) carbon arc welding, and (*b*) metal arc welding.

CARBON ARC WELDING. In carbon arc welding, an arc (usually several tenths of an inch in length) is established between a carbon or graphite electrode (usually a carbon electrode) and the two pieces of metal which it is desired to join. This carbon electrode is manipulated with one hand, and material from a welding (or "filler") rod is fed into the weld by manipulating the filler rod with the other hand. The manual activities in carbon arc welding are seen to be similar to those in gas welding. In neither process is it necessary for the material of the welding rod (i.e., the filler rod) to traverse the arc.

These considerations inspired the development of a carbon arc welding method exploited under the name of the **electronic tornado system.** Its sponsors stress the less opportunity for impairment of the quality of the weld by oxygen and nitrogen inclusions when metal is not transferred *through the arc* from an electrode to the weld. In the electronic tornado system, an electromagnetic field is provided to direct and stabilize the arc and to focus the arc stream directly beneath the carbon. The system is employed in automatic welding machines, and an "autogenizer" is fed into the arc for the purpose of surrounding the hot metal with a neutral gas, thus shielding it from the oxygen and nitrogen of the surrounding air. When added metal is required, it may be fed to the weld automatically or it may be laid along the line of weld. The system is carefully described by E. W. P. Smith at p. 18 of the September, 1933, issue of the *J. Am. Welding Soc.* in an article entitled Use of shielded carbon arc in Class I welding. The electronic tornado system is employed in the automatic welding of boilers, tanks, pressure vessels, large water pipes, rear axle housings, some types of automobile frames, etc. Its use is not limited to any particular types of joints.

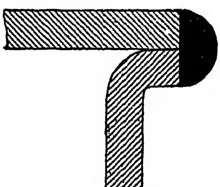

FIG. 4. Type of Arc Weld Not Requiring Additional Electrode Material

KINDS OF WORK NOT REQUIRING WELDING ROD. In carbon arc welding, the edges of the parts to be joined sometimes may be so designed as to obviate the need for any additional material; in other words, no welding rod is necessary. In Fig. 4 is shown a case where it is not necessary to use a welding rod, since it suffices simply to melt together the adjacent flanges with an arc.

METAL ARC WELDING. Metal arc welding is fundamentally different from carbon arc welding. Thus in metal arc welding of mild steel, instead of having a carbon electrode for one terminal of the circuit, the arc is established between a steel welding rod (or welding electrode) and the steel parts to be joined. The shortest practicable distance is maintained between the end of the welding rod and the work. This distance is bridged by an electric arc. It is important that the arc be maintained as short as practicable so that a minimum of oxygen and nitrogen from the surrounding air may gain access to the hot metal. Where the arc is protected (as in welding in a neutral gas or with a suitable flux-covered electrode), the length of the arc is less important and, with some heavily fluxed types of electrode, relatively long arcs have been found advantageous.

Welding Machinery

The voltage at the arc with the metal arc process in the open air is usually only from 12 to 35 volts, the lower values being used with bare electrodes and the higher with heavily coated electrodes; consequently, if a circuit of standard distribution voltage, such as 125 or 250, were employed as the power supply for the arc, with a suitable resistor in series with the arc, a great deal of power would be wasted in the resistor. For most arc welding today, however, motor-generator sets are employed to deliver direct current at considerably lower than standard distribution voltages. Two different systems of power supply from motor-generator sets are commonly employed, one known as the **multiple-operator system,** and the other as the **single-operator system.**

MULTIPLE-OPERATOR SYSTEM. In this system a motor-generator set is employed, which has a generator of a capacity sufficient for supplying several welding arcs. The generator is usually designed to operate at 50 to 75 volts and is flat compounded so as to deliver approximately constant voltage regardless of load. Then each welder employs a current-regulating resistor, and frequently an arc-stabilizing reactor, in his indiviual welding circuit. It is obvious that with this arrangement the power losses in the resistor will be very greatly reduced below what they would be if the open-circuit voltage were 125 or 250.

SINGLE-OPERATOR SYSTEM. In this system, power for each welding circuit is supplied by an individual generator which may be motor, belt, or engine driven. The generator is designed with special characteristics such that the open-circuit voltage may be from 50 to 100 volts; when the arc is struck and current drawn from the generator, the output voltage drops to the arc voltage. No resistor is ordinarily used in series with the arc, and the welding current is adjusted by various means, such as changing the shunt field rheostat, changing taps on the series field, or shifting brushes, depending on the design of the individual generator. A certain amount of reactance in the circuit is desirable in order to stabilize the arc, and this may be embodied in the design of the generator itself, or else a separate reactor may be employed.

Each of several manufacturers has placed on the market types of welding apparatus comprising single-operator d-c generators with characteristics for which various advantages are claimed and realized. Even very brief descriptions of the principal varieties of these machines would occupy too much space for this article.

MULTIPLE VS. SINGLE OPERATOR SYSTEM. Which system of power supply should be employed for any given welding operation depends upon individual conditions. If a number of welders are working in a comparatively small area continuously, the multiple-operator system may prove to be the most efficient from the standpoint of power cost. If the welding operations are scattered, or if portability is a factor, then the single-operator set should be chosen. Each installation must be studied and a decision arrived at based on the merits of the case. This subject is discussed at considerable length, introducing further important considerations, in an article in the September, 1934, issue of the *Welding Engineer*, entitled Multiple-operator welding sets or single-operator sets, which? by J. L. Jones of the Bureau of Construction and Repair of the Navy Department.

KIND OF CURRENT EMPLOYED. Direct current is most generally employed for arc welding. The generators of the motor-generator sets to which reference was made in the preceding paragraphs are d-c generators. It has been the usual conclusion in America that a d-c arc is more readily established, maintained, and manipulated, and that it permits of obtaining better welds, than an a-c arc. With direct current, a good bare-wire electrode is usually reasonably satisfactory for ordinary welding of mild steel, whereas with alternating current it has been the usual experience that a flux-covered electrode is preferable and often necessary for securing a steady arc and ready manipulation. There is, however, a disturbing influence peculiar to direct current, namely, the effect of the magnetic field to deflect the arc. This becomes quite serious when

welding with very great currents such as are often employed with automatic arc welding. This erratic behavior with direct current may be mitigated by suitable compensating arrangements, and is by no means serious with the moderate amount of current usually employed with manual welding. There has already been described the use, in the electronic tornado system, of a magnetic field imposed on the arc to increase the stability by "focusing" the arc stream.

With alternating current, especially when the current is small, there is a tendency for the arc to be extinguished every time it passes through zero when reversing. But with the greater amount of heat in a heavy current arc, this tendency is much less in evidence, particularly if a high periodicity is employed and if the current is considerably out of phase with the voltage so that, at the instant when the current is passing through zero, there is a considerable voltage to help maintain or re-establish the arc when the current is reversed. The material surrounding a covered electrode may also be of such composition and construction as to constitute a means of preventing cooling and extinction of the arc while the current is reversing. As already indicated, d-c welding is at present by far the most widely used in America; however, the development of low-cost, heavily covered electrodes suitable for use with the a-c arc has offered considerable impetus to the adoption of alternating current. It seems especially suitable for automatic welding on a large scale with very heavy currents. But in pointing out its especial suitability for automatic welding with very heavy currents, there is no intention of suggesting any limitation to the use of alternating current for manual welding. Such use has been made of it, especially in England, since the earliest days of the arc welding industry.

The choice of kind of current is not confined to direct current versus alternating current but involves the relative merits of single phase and polyphase * and of low periodicity and high periodicity. It might be supposed that the fact that the use of 60 cycles is so general would eliminate any question of periodicity. But there are all sorts of ways of transforming the periodicity, and, furthermore, the inevitable accentuation of the present enormously rapid expansion of the welding industry and the commercial importance of making the very best welds with all sorts of metals and by the most rapid and economical processes sooner or later will insure the thorough consideration and examination of all alternatives, irrespective of existing traditions, prejudices, and standards.

Several electrical manufacturers are now offering a-c welding equipments consisting inherently of high reactance transformers with suitable means of varying the reactance, and thereby the welding current. These units are usually designed to give an open-circuit or "striking" voltage of 70 to 100 volts, and with sufficient reactance so that when the welding current is flowing, the voltage drops to that required for the arc. With the heavily covered electrodes usually employed this will range from 25 to 40 volts.

Kinds of Electrodes

It will be impossible, in this brief article, to do more than mention the general situation as regards electrodes. They may be placed in two chief classes, **bare** and **covered.**

Up to a few years ago, most welding people would have agreed that bare electrodes were usually regarded in America as the most suitable for ordinary kinds of welding, particularly for welding low-carbon-steel rolled sections and plates. Bare electrodes of special compositions are also manufactured for various difficult kinds of welding, including non-ferrous metals and alloys and high-grade steels. On the whole, it has been more convenient, in automatic welding at high speeds, to employ bare welding wire automatically fed to the arc from reels. Mention has already been made of the method of automatically feeding an "autogenizer" to the arc to shield it. However, several interesting means have also been developed for the more satisfactory use of covered wire for automatic welding, when, as often is the case, it gives more adequate results.

For most work, the bare electrode is of low-carbon steel manufactured with great care and often especially treated in various ways. For work where it is more suitable, the bare electrode is of high-carbon steel, manganese steel, phosphor bronze, or sometimes of other alloys. All sorts of ingredients have been tried, sometimes with very important results on the quality of the weld.

In covered electrodes even greater diversity is found in the brands on the market. The variations are not confined to the covering but extend to the metal electrode within the covering. Some electrode purveyors standardize the enclosed electrode and confine the variations to the covering; others standardize the covering and accomplish the respective purposes by variations in the composition of the enclosed electrode; still others vary both. Metal constituents (deoxidizing or for alloying purposes) are often embodied in

---

* Bethenod's polyphase current arc-welding system has been employed considerably in France. It is described in *Bull. Tech. de la Suisse Romande,* Jan. 14, 1928, p. 7.

the essentially non-metallic covering. In other cases, deoxidizing and alloying ingredients are embodied in the metal core of the electrode.

Sometimes the covering is so constituted that, when melting at the working end of the electrode, it gives off a copious supply of protecting or deoxidizing or denitrogenating gases which displace or neutralize the oxygen and nitrogen in the surrounding air as well as the gases which the heat of the arc expels from the metal being welded.

Until comparatively recently the first cost of heavily covered electrodes was so high that they were but little used. Within the past few years, however, developments in this field have been very rapid, and today such electrodes are available at reasonable cost, and the quality of the weld obtained is such that the covered electrode is rapidly displacing the bare electrode where welds of really high quality are required. This is especially true in the welding of pressure vessels and in cases where welds must have good ducility.

Gaseous Protection

There is a group of welding processes that provide for making the weld in the midst of a gaseous medium which protects the weld from the oxygen and nitrogen in the surrounding air and which may also reduce the oxygen given off from the parts being welded or from the electrode metal, or both. Again it would be impossible to describe all the methods that have been employed. As typical may be mentioned the process in which a continuous stream of hydrogen or other suitable gas is supplied around the arc. In the case of hydrogen, the arc drop is some 60 volts as against some 20 volts in air. Consequently, for the same current some three times as much heat is developed at the arc. This gives much better efficiency if the welding is done from a constant voltage supply, since it is no longer necessary, in regulating the current, to waste in the control rheostat so large a percentage of the energy supplied from the circuit. However, there are some difficulties in the way of applying this process successfully, and the welds obtainable from it have not shown sufficient superiority to justify its commercial acceptance.

Solid Protection (other than an electrode covering)

F. T. Llewellyn, in an article entitled Outline of welding and allied processes which appeared in the December, 1930, and January, 1931, issues of *Metal Progress*, describes an example of solid protection of the weld (during welding), as follows:

" In another recent process a bare metal electrode plows with oscillating motion through a thick mass of powdered fluxing material which serves both as a shield for the arc and as a blanket to permit the metal already deposited to cool slowly."

Reduction of Stresses

ANNEALING. The process above described by Mr. Llewellyn combines the advantages of affording protection while welding, and annealing the weld after it is made, and should sometimes permit of avoiding the expense of again heating the product in an annealing oven to release locked-up stresses and otherwise improve its quality. In general, when practicable, it would be of advantage to cover up promptly the welded product with some material of poor thermal conductivity before it has cooled, thus annealing it by retarding the rate of cooling. When the welded product is small, made in large quantities and quickly, it should sometimes be practicable to have each piece, while still hot from just having been welded, automatically ejected to some suitable place and then automatically covered with hot sand. Usually, with large objects, the weld has cooled at one part before other parts are welded and, if the locked-up stresses must be relieved, it is usually done in an annealing oven as a subsequent process. In the use of some electrodes with a heavy flux covering, this flux forms a thick crust on the weld when it " freezes " and serves to retard the cooling and thus anneal the deposited metal. Sometimes it is justifiable to deposit an outer bead of metal to effect a partial annealing of the lower layers, the outer bead later being machined off.

PEENING. Another way of releasing locked-up stresses, and in other respects improving the quality of the metal right after the weld has been completed and while it is very hot, is by peening (for example, with a pneumatic hammer). This is well known to be a valuable and often very economical means of reducing residual stresses. But although it has been urged repeatedly that a scientific technique should be developed by careful research tests at various temperatures and with various kinds and amounts of peening (such as the severity and periodicity of the blows), it is not known to the author that this has been done yet in an adequate manner, studying the quality and the relative freedom from internally stressed conditions after different peening techniques have been employed. At p. 33 of the March, 1934, issue of *Metal Progress*, in describing the welding of the gates for the Boulder Dam penstocks, Mr. C. H. Jennings says: " All layers of deposited weld

metal were peened with a blunt-nosed peening tool in a light chipping hammer, to reduce residual stresses and to clean the weld. The peening operation was carried out immediately after the deposition of each 6 to 8 inches of deposited metal before it and the adjoining metal became cold."

LOCKED-UP STRESSES and the **IMPORTANCE OF DUCTILITY.** By employing suitable welding technique it is often possible to avoid the creation of "locked-up stresses." Furthermore, even when they are not avoided, their amount sometimes can be controlled within permissible limits so that the product shall have the necessary strength. There is still a great deal of research work which ought to be done to increase the available knowledge in this field. Locked-up stresses will be less if the materials to be welded and the electrode material and the welding technique are all such as to provide ductility in the weld, for even when the weld will not be subjected in service to any bending stresses, its ductility will permit of internal adjustments of minute dimensions which distribute the total tensile (or shear or torsion) stress more uniformly over the entire cross-section provided to withstand the stress. This would appear to be the most scientific method of securing the best result. But there are those who contend that, unless the weld will be subjected to bending stresses, there is no virtue in striving for ductility, but rather there should be provided a maximum of rigidity, and they sometimes insure this rigidity by enlarging the cross-section at the weld sufficiently to be adequate even when locked-up stresses prevent the internal readjustments necessary to secure uniform distribution of the stress over the entire cross-section.

Recent and important additions to our knowledge of the stress concentrations and their relation to static and dynamic loading are well described by Thurm & Bantz in *Stahl u. Eisen*, Sept. 26, 1935, p. 1025.

Miscellaneous Processes

The **ARCOGEN PROCESS.** This process was developed by the Griesheimer Autogen Gesellschaft and has been described in an article entitled Das kombinierte autogen-elektrische Schweissverfahren Arcogen, by Dr. H. Munter, in Nos. 22 and 23 of *Autogene Metallbearbeitung* for 1930. The arcogen process consists basically of the use of the oxyacetylene torch held by the operator in his right hand and a flux-covered metal electrode maintaining an electric arc at its tip, the operator manipulating this electrode with his left hand. The electrode is generally of a larger diameter than would be employed for a given application with the oxyacetylene process or with the arc process. About half of the heat is provided by the oxyacetylene flame and the other half by the electric arc. The electric arc is supplied by alternating current of commercial frequency from a transformer which is smaller than would be needed for ordinary arc welding (because only half the heat is supplied electrically) and which has a higher power factor than the ordinary arc welding transformer. A somewhat higher voltage is employed for the arc, namely, some 33 volts as against 20 volts. Under these conditions, the power factor of the transformer is of the order of about 0.40 and the efficiency is about 0.75. In the arcogen process the electrode is not touched to the work in order to start the arc. It is simply necessary to bring the end of the electrode up to the cone of the oxyacetylene flame, whereupon the arc establishes itself, the no-load voltage being 80, falling to about 33 volts when the current flows. The author of the paper to which reference has been made states that, with the arcogen process, the flame (1) preheats the work, (2) brings it to the point of melting, (3) does its share in melting the welding wire, and (4) provides for the ionization of the gaseous path by burning the ionizing flux covering of the electrode. Then the arc (1) melts the electrode and (2) maintains the molten pool in fluid condition and increases the penetration. It is claimed that shrinkage stresses, as compared with those with gas welding, are less because of the less width of the seam and the higher speed of welding.

The **ATOMIC HYDROGEN PROCESS.** In this process the welding is not accomplished *directly* by means of the heat of the electric arc. The arc is established between the tips of two tungsten wires. The current is alternating and is usually supplied from a single-phase transformer connected to any ordinary distribution system. The arc is located in the path of a stream of hydrogen gas. The heat of the arc breaks up the hydrogen molecules into free atoms. When the hydrogen in the atomic form has traveled a short distance beyond the arc it has cooled sufficiently to recombine into the molecular form, and the energy thus released constitutes the heat actually employed for welding. Thus the weld is made in a predominatingly hydrogen atmosphere and is much more free from oxides and nitrides than when made in air. Secondly, the tungsten electrodes also last longer than they would with an arc in air. And this system of welding provides a third good feature which is, in the author's opinion, even more important than the first

two features: namely, it permits the operator to manipulate his " torch " in whatever manner is preferable for each particular job. If it is desirable to thoroughly " puddle " the material being welded, the " torch " can be used to do so. For some other kinds of jobs it will be better so to manipulate the torch as to bring the two surfaces to be joined just up to the " sweating " temperature and then deposit metal from the filler rod. Moreover, there can be used filler rods of whatever material is most suitable for the particular job without reference to the behavior of such material when it forms one end of an electric arc. It will be seen readily that these various features render the atomic hydrogen system of welding not only very flexible but also suitable for many kinds of jobs for which ordinary arc welding could not be used, or if used, would be less satisfactory. The process has been applied with particularly excellent results to the welding of thin sheets and for welding various ferrous and non-ferrous alloys.

ATOMIC HYDROGEN WELDING OF ALLOYS. The process may be employed for steels with any carbon content up to 1.25 per cent. In an article entitled Progress in atomic hydrogen welding, by Samuel Martin, Jr., at p. 537 of the *Iron Age* for March 3, 1932, many applications of the atomic hydrogen process are described and illustrated. In several of these applications no filler rod is required. It is stated in the article that chrome steels, including those having a chromium content up to 40 per cent, have been welded, and that if the chromium content is less than 20 per cent, the resultant welds are not particularly brittle. The article furthermore states that heat treatment after welding relieves any tendency to brittleness, giving a strong, ductile weld. Thus ascoloy (a chrome steel which has a chromium content between 12 and 16 per cent) can be welded by this system, and welds made on super-ascoloy (which has 17 to 20 per cent of chromium and 7 to 10 per cent of nickel) are strong and ductile without heat treatment. Ka–2, enduro, and Allegheny metal are further examples of ferrous alloys which may be welded by the atomic hydrogen process.

Among the non-ferrous alloys mentioned by Martin as being satisfactorily welded by the atomic hydrogen process are calorite (15 to 20 per cent chromium and 80 to 85 per cent nickel), which can be welded whether in the worked form or in the form of castings; brass (of certain compositions); and Monel metal (75 per cent nickel and 25 per cent copper). Martin mentions another successful application of the atomic hydrogen process, namely the application to drills, dies, and other equipment requiring high wear-resisting surfaces of various hard surfacing materials such as stellite, stoodite, cristite, borod, blackor, and tungsten carbide. In giving these illustrations, it is not intended to imply that it is with the atomic hydrogen method alone that these things could have been accomplished, but rather to indicate the particular adequacy of the process to several admittedly difficult welding tasks.

ATOMIC HYDROGEN PROCESS APPLIED TO AUTOMATIC WELDING. The atomic hydrogen system has also been applied to automatic welding and sometimes to the joining of thicker plates. In atomic hydrogen welding, the voltage required to start the arc is much higher than for ordinary metallic arc welding. After the arc is established, the voltage decreases to about 80 volts. It should again be emphasized that the atomic hydrogen process, the arcogen process, and the carbon arc process share in common the feature of permitting of preheating, to any desired extent, suitable portions of the materials to be welded together. The absence of this feature is a limitation (though for much work, such as welding mild steel, possibly not an important limitation) of ordinary metallic arc welding.

WELDING NICKEL AND MONEL METAL. Nickel is difficult to weld because of its property, when molten, of absorbing great quantities of gases, especially oxygen. At p. 15 of the January, 1932, issue of *Zeitschrift für Metallkunde*, will be found an article by Canzler entitled Die Nickelschweissung, which describes many methods of welding nickel and also Monel metal. It is stated in the article that, for such work, the atomic hydrogen method has been employed with success in obtaining good non-porous welds owing to the considerable prevention of oxidation by the surrounding hydrogen atmosphere which also serves as a reducing medium for such oxygen as penetrates from the surrounding atmosphere. The filling rod, stated in the article as being employed, is of Monel metal.

ARC WELDING WITH SINGLE-PHASE ALTERNATING CURRENT. It has already been pointed out that direct current has been most generally used for arc welding and that the use of a-c metallic arc welding is rapidly increasing. One difficulty with a-c welding has related to the tendency of the arc to be extinguished when the current passes through zero in reversing. At the zero instant, no heat is being supplied and the temperature tends to decrease. If the voltage is in phase with the current, the instability is increased. But if the voltage is greatly out of phase, although the stability of the arc will be greater, the low power factor may render the load objectionable to the power supply

company, unless some corrective means is adopted. Furthermore, the transformer costs more, is heavier, and is less efficient. Therefore it is important to provide additional means for stabilizing the arc. Flux coverings help a great deal.

STABILIZING THE A-C ARC BY SUPERIMPOSED HIGH FREQUENCY. In describing the arcogen process it has already been stated that the arc is established and maintained by means of the oxyacetylene flame and hence does not need to be "struck" in the ordinary way. Another way of starting and maintaining the arc, which has been employed in Europe for several years, consists in superimposing, on the welding circuit, high-frequency oscillations which maintain the ionization of the arc path and thus stabilize the arc. This means is also employed in a system now in use in America. It is described in a paper entitled *An Improved Alternating Current Arc Welder*, by A. M. Candy, presented in January, 1932, at a convention of the American Institute of Electrical Engineers.* The oscillator circuit (seen in Fig. 5 to consist of a condenser A, an air core

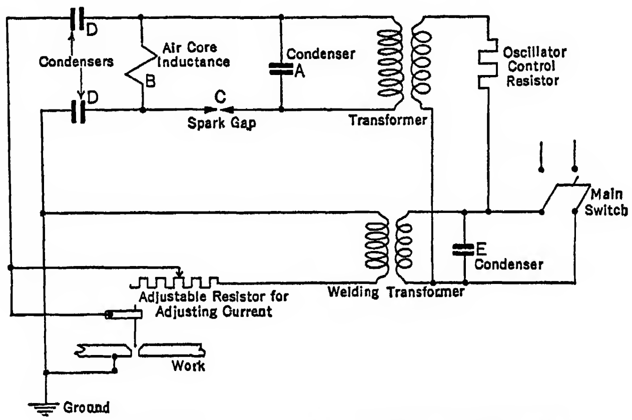

FIG. 5. Circuit Connections for an a-c Arc Welder, 100 Amperes

inductance B and a spark gap C) occasions sparks to cross the gap, reducing its resistance and enabling the low-frequency supply to establish and maintain a welding arc. The frequency in the oscillator circuit is stated to be so high as to "preclude the possibility of any annoying or injurious physiological effects upon the person using the apparatus." By providing two blocking condensers, D, placed in the circuit between the oscillator and the welding electrodes, the welding circuit is prevented from supplying any energy to the oscillator inductance, B. These blocking condensers constitute barriers to the low-frequency welding current, but they offer no impediment to the high-frequency discharge. In order that the oscillator shall not feed into the power circuit (which would be likely to cause interference with neighboring radio sets), a condenser, E, is connected across the input terminals. It is stated that a 100-amp set has an efficiency of 30 to 35 per cent (varying with the load) and a power factor above 90 per cent. Regulation of the welding current is effected by a series resistor. The open-circuit secondary voltage is only 73 volts, thus minimizing danger from shock. Successful welding is permitted by the system down to very small currents (such as are necessary for joining thin material), because the oscillator relieves the low-frequency welding arc from the duty of being self-maintaining. It is stated that, with this process, the weld has less penetration than one made with the same number of d-c amperes, and that this is a distinct advantage in welding thin plates. It is further stated that if, on heavier work, more penetration is wanted, a larger current and larger electrode can be used and the speed of welding correspondingly increases.

Welding of Various Metals and Alloys

Distributed through the preceding paragraphs are allusions to the application of various electric welding processes to the joining of specifically mentioned materials such as mild steel, high-carbon steel, various ferrous alloys, and various non-ferrous metals and

* See also Alternating Current Arc Welding Transformer and Circuit Characteristics, A. M. Candy, *J. Am. Welding Soc.*, Sept., 1934, p. 23; and at p. 405 of Feb. 27, 1932, issue of the *Elec. World*, an article by J. B. Gibbs entitled Oscillator Stabilizes a-c Welding Arc.

alloys. It has been indicated that, the greater the affinity of the metals for gases, particularly for oxygen and nitrogen, the more the need for special features to obtain good welds. Also a high percentage of carbon in steel was emphasized as requiring special features in the welding procedure employed. Brittle materials are particularly subject to acquiring internal strains, the avoidance or subsequent relief of which presents special problems. Tendencies toward porosity, which are of different degree in different metals and with different processes, must be carefully considered. In recent years the welding of stainless steels and of aluminum and its alloys (notable among which is duralumin) has been the subject of much study.

Within the limits of this article it would be futile to attempt to consider in detail these important problems, and we can do no more than suggest to the reader that, during the last few years, there have been published in the columns of the *J. Am. Welding Soc.* a good many papers and articles and informative discussions of these subjects.

WELDING AS A FOUNDRY TOOL. The Allgemeine Elektricitäts Gessellschaft's book entitled Elektrisches Schweissen, at the close of a chapter dealing with the arc welding of cast iron, states: "The foundry engineer may, by the proper application of 'hot' welding, construct iron castings of shapes and sizes which would be difficult if made in a single casting, by joining together several simple component castings." That paragraph is the only reference of which the author has knowledge, suggesting the applicability in the construction of iron castings, of the procedure of joining together two or several simple castings. Until the application of arc welding to cast iron has advanced considerably beyond present knowledge and practice, such a plan would be considerably limited because of the difficulties and slowness and consequent cost attending cast iron welding in general and because of the mediocrity of the resultant product unless slow and expensive procedures are employed.

JOINING MILD STEEL CASTINGS BY WELDING. For use in *steel* foundries, however, great economies and a better piece of work will often result if two or several small and simple mild-steel castings are joined by electric welding (arc or resistance) to form the larger and often much more complicated casting which otherwise would need to be made in a single casting. Often the cost should be much decreased, and the weight as well, and furthermore the quality should be superior to that which could be secured in a single large casting. Ever since it became widely recognized that the arc process is an especially satisfactory and economical method of welding mild steel in particular, it has been rapidly adopted in all sorts of manufacturing undertakings. But, with negligible exceptions, the designs have been worked out for using rolled material. This has tended to decrease the demand for steel castings to a serious extent, from the standpoint of the foundry's interest. For some years there occurred isolated instances of the joining of two or several steel castings to one another (or to rolled steel) by welding, and yet the great possibilities and advantages in this direction were almost completely ignored, though it is hard to see why they were not very obvious. More recently these possibilities and advantages have been pointed out, and the steel foundry industry has only itself to blame for not employing welding as a very effective tool in the steel foundry and as a means of making better, cheaper, and lighter steel castings.

The following articles dealing with this important subject should be consulted for a more complete description of the proposal:

Welding combined with foundry practice, by W. H. Namack and H. M. Hobart. *Gen. Elec. Rev.*, Dec., 1930, pp. 674–676.

The use of steel castings in welded structures, by J. G. Ritter. *J. Am. Welding Soc.*, March, 1932, pp. 27–30.

Welding's relation to steel castings, by T. S. Quinn. *Ind. and Welding*, August, 1932, p. 3.

36. MANUAL VS. AUTOMATIC WELDING

Much the greater portion of all electric resistance welding is done on automatic machines. For arc welding, manual operation was at first very usual. In many applications, notably shipbuilding, steel building, and bridge construction, much manual arc welding is at present necessary, but in the construction of trusses and girders in the shop the welds will doubtless more and more often be made automatically, the manual welding being reserved for the erection-in-place welds. For a very great many applications arc welding is done with automatic machinery, and new applications are constantly being developed where the welding is automatic.

Although the initial installation of automatic machinery is relatively expensive, the saving in time and the superior character of the welds generally justify the method in mass production. There are many alternative types of machinery. Essentially, the elec-

trode material is fed automatically to the arc, and the arc is fed along the seam to be welded. The mechanism for feeding the electrode is embodied in a part designated the "welding head." Sometimes two or more welding heads follow one another in welding a seam. The current employed may be much greater than for manual welding, and the speed of welding is also far greater. An automatic machine holds steadily an arc which is shorter than is usually attainable manually, and thus decreases the access, to the hot metal, of oxygen from the surrounding air. The machine does not need periods of rest from the effort and strain, which are very considerable for the manual arc welding operator. The machine has no eyes to smart or muscles to ache, and it is never nervous or worried. It is not subject to occasional lapses into carelessness or indifference. Often one man can run continuously more than one automatic machine. Altogether it is reasonable to expect that inventive ingenuity will gradually largely eliminate manual arc welding.

37. APPLICATIONS OF ELECTRIC WELDING

Space limitations will not permit of much more than listing some among the many very important fields in which electric welding is being applied.

USING WELDED ROLLED STEEL SECTIONS AND PLATES INSTEAD OF GRAY IRON CASTINGS. This application is placed first as being one of the largest as well as one of the earliest to be taken up.

STEEL BUILDINGS. Among the kinds of buildings which have been constructed by joining rolled sections and plates by the electric arc method of welding (instead of joining them by rivets) may be mentioned (1) hospitals and hotel buildings and buildings in their vicinity (where it is particularly desirable to avoid the noise of riveting); (2) factory buildings, including machine shops, laboratories and warehouses; (3) office buildings (one recently erected being 19 stories high). Spraragen states that several experimental steel frame dwelling houses have been erected at a cost which compares favorably with that of wooden structures. He states that general adoption would provide an outlet for more than a million tons of steel annually. Welding is already permitted by the building codes of a great many municipalities in America, and special permits are readily obtainable in many other cities. In one of the Engineering Foundation's research narratives entitled Welding Steel Structures, Spraragen mentions a very heavy welded truss made for the Forest Lawn Memorial Park Mausoleum. It weighs 60 tons and has a span of 96 ft and a height of 18 ft. In substituting welding for riveting in building construction, there is usually a material saving in weight. This saving, though rather small in welded beams and columns, may, it is stated by Spraragen, amount to as much as 36 per cent in ordinary roof trusses, and similar savings are obtained in plate girder construction.

The Report of the Structural Steel Welding Committee of the American Bureau of Welding, published in September, 1931, by the American Welding Society, describes and analyzes the results of an elaborate series of tests made for the important purpose of providing reliable data for the design of steel structures employing electric arc and gas welding. The report (comprising more than 200 pages) covers investigations which have involved the fabrication and testing of several thousand specimens welded by 61 welders at 39 shops and tested at 24 laboratories, including college and commercial institutions and the U. S. Bureau of Standards. Spraragen states that: "Tests on 2495 specimens indicated that joints commercially welded by qualified welders may be expected to possess strength within 12 per cent of general average results."

STEEL SHIPS. During the War, strenuous efforts were made in this country and in Great Britain to induce those in authority to design and build ships with the hull plates joined by welding instead of by riveting. During and immediately after the War, a completely arc-welded, cross-channel barge was built by the British Admiralty and a coasting vessel by Cammell Laird, but the inertia of the shipbuilding interests, both merchant and naval, has in all countries, until very recently, prevented much progress in joining the hull plates by welding, although welding has been used very extensively in the interiors of most ships. However, Germany has made wide use of welding (including the hull plates) on several important warships, and most countries with shipping interests are now alive to the great advantages of welding methods. Welding is now widely employed in the hull construction of barges, tankers, ferryboats, naval targets, dredgers, motor ships, lifeboats, and many other varieties of small and medium-sized craft. Recently, in the navies of Germany, Japan, America, and France, riveting is being gradually superseded by welding for the hull construction of important vessels of all classes. The very general use of welding in place of riveting for hull construction is inevitable and cannot long be delayed even by indifference and inertia.

Among the recent articles on the subject of welded ships are:

Description of all-welded auxiliary vessels being built at the U. S. Navy Yard, Mare Island, California, by Lieut. H. A. Schade. *J. Am. Welding Soc.*, May, 1931, p. 23.

The future of welded ship construction, by J. Kjekstad. *J. Am. Welding Soc.*, September, 1931, p. 13. Discussion, December, 1931, p. 12.

M. S. Shean, ferryboat *Suwa Maru*, and steam tug *Hakutaka Maru* are described in articles in *Elec. Welding* (London), for October, 1931.

Electric welding in ship construction. *Elec. Welding* (London), February, 1932, p. 19, and April, 1932, p. 13.

Welding on *U.S.S. New Orleans*, by Captain J. O. Gawne. *J. Am. Welding Soc.*, April, 1932, p. 9. Discussion, July, 1932, p. 5.

All-Welded Steel Barges, by R. B. Reid, *J. Am. Welding Soc.*, March, 1934, p. 25.

New System of Welded Ship Construction, *J. Am. Welding Soc.*, October, 1935, p. 11.

Motor Ship *Joseph Medill*. *Elec. Welding*, London, August, 1935, p. 202.

OTHER APPLICATIONS. Electric welding (resistance or arc) is being increasingly used in the construction of (1) bridges, piers, roof trusses; (2) pipe lines (for oil, gas, and steam, and for very high pressures); (3) pressure vessels, fired and unfired; (4) large storage tanks for gas and oil; (5) electric generators, motors, transformers, and switches; (6) automobiles; (7) machine tools; (8) engines; (9) locomotives; (10) other railway rolling stock; (11) rail joints; (12) all kinds of tanks and containers; (13) gears; (14) refrigerators; (15) aircraft; (16) concrete reinforcement; (17) hard facing; (18) steel mill machinery; (19) mining machinery; (20) tunnel linings; (21) towers for transmission lines, windmills, elevated water tanks; (22) in fact, in nearly all instances where metals require to be joined. This last statement (22) is possibly premature. It is already a fair statement for structures of low-carbon steel, but for many other metals and for most alloys, though developments are rapid, much remains to be done in developing techniques which will insure thoroughly satisfactory results not only as regards quality but also as regards speed and cost. A particularly important example is aircraft which, to some extent, awaits development of methods for welding light alloys.

38. BIBLIOGRAPHY

There are listed below some recent books on electric welding. Unfortunately, arc welding is stressed out of all proportion to its relative importance (in the author's estimation) as compared with resistance welding.

The art of welding is undergoing such extraordinarily rapid development that, in many respects, books on the subject are obsolete before they are published. The best sources of up-to-date information are, consequently, technical periodicals. At present, the "house" journals of large corporations are on the whole (in the author's opinion) the most useful and up-to-date sources. Amongst these and professional journals the following will be found valuable as sources of current welding information:

J. Am. Welding Soc.; Die Elektroschweissung (Journal of the Deutsche Gesellschaft für Elektroschweissung); *The Welding Engineer* (Chicago); *Ind. and Welding* (The Industrial Publishing Co., Cleveland); *Elec. Welding* (published by the Quasi-Arc Co. of London); *The Welder* (published by Murex Welding Processes, Ltd., of London); *V.D.I. Zeitschrift; Stahl und Eisen; Autogene Metallbearbeitung; Zeitschrift für Metallkunde; Krupp'sche Mitteilungen; A.E.G. Mitteilungen; Siemens Zeitschrift; Gen. Elec. Rev.; Elec. J.; Engineer; Engineering; Journal of the Ateliers de Constructions Électriques de Charleroi; The Brown Boveri Review; Bulletin Oerlikon; J. Iron and Steel Institute* (London); *Metropolitan Vickers Gazette; Association Suisse des Électriciens Bulletin.*

Welding Societies. American Welding Society; Deutsche Gesellschaft für Elektroschweissung (Braunschweig); Institution of Welding Engineers (London); The Iron and Steel Institute (London) is very active in fostering the art of welding.

Welding (whether by electric or other means) involves so many departments of science and engineering that articles of value relating to welding are published in great numbers by practically all the scientific and engineering societies. In America, the relatively successful effort is made to utilize the American Welding Society to keep track of and guide developments in this enormous field. The columns of its *Journal* should consequently be consulted; they will be found to contain not only articles and reports of importance, but also references to material appearing in other publications in America and elsewhere.

Some publications which are issued by the American Welding Society or sponsored in part or wholly by that Society, and which may be obtained through its headquarters (29 West 39th Street, New York City, Miss M. M. Kelly, Secretary), are as follows:

Arc Welding Instruction Manual.
Resistance Welding Instruction Manual.
Code for Fusion Welding and Gas Cutting in Building Construction.
Structural Steel Report.
Final Report of Committee on Welded Rail Joints.
Specifications for Fusion Welding of Pressure Vessels.
Filler Metal Specifications.
Tentative Code for Fusion Welding Pressure Piping.
Part D—Rules for the Fusion Welding of Hulls and Hull Parts of Marine Code for Fusion Welding and Gas Cutting.
Rules for Fusion Welding of Gravity Tanks, Tank Towers and Risers.
Report on Welding and Cutting, Nomenclature, Definitions and Symbols.

Research always has played an important part in the activities of the American Welding Society. Up to recently, this work was done by the American Bureau of Welding, a board functioning under the joint auspices of the A. W. S. and the National Research Council. In this way, probably more research work was done in the welding field than by any corresponding similar technical organization. The published reports have formed the basis for continued advancement of welding in all branches. These reports have been accepted throughout the world as authoritative sources of information free from commercial bias. In 1935, the A. W. S. took over the A. B. of W. and now operates it under the title of Bureau of Welding Research. The B. of W. R. continues to maintain close cooperation with other leading technical and scientific bodies. At the present time (1936), the Bureau of Welding Research has two important committees—the Fundamental Research Committee and the Structural Steel Committee. The B. of W. R. is arranging to embark upon further research activities and collaboration for this purpose is now being developed between A. W. S. and Engineering Foundation. The Fundamental Research Committee has some sixty investigations under way in the various universities in this country. Each year its reports form the outstanding papers presented at the Fall Meeting of the Society. The headquarters of the F. R. C. are at 29 West 39th Street, New York City.

ELECTRICITY ON THE FARM

By Lee C. Prickett

1. POWER SUPPLY

SYSTEM. The farming regions of the United States are being rapidly covered with distribution lines reaching to the farms. Both overhead and underground distribution are used and, at the present time (1936) the designs are in a state of transition with no standardization in sight. However, underground supply as yet is little used.

The usual distribution is three phase with grounded neutral 2300/4000 volts, 60 cycles, but by far the greater number of farms are supplied by single-phase current.

RURAL LOAD CHARACTERISTICS. It is practical to carry a farm connected load of from eight to ten times the rated size of the transformer, especially with proper fusing and good general protection of motors and devices. In a typical test community, the average of the individual load factors for five farms with an average demand and monthly energy consumption of 13 kw and 207.8 kwhr, respectively, was 12.1 per cent, 14.1 per cent in summer and 10 per cent in winter. The time of maximum demand for these farms is also typical: in the evening when the load was largely lighting and household appliances; between 11 A.M. and 1 P.M. after a sizable range load was added to the line; and between 6 A.M. and 7 A.M. when the load had been still further increased by the addition of milking machines and water heaters.

For a group of farm lines the demand factor can be safely taken as 15 per cent or less of the total connected load, and well-developed farm lines should have load factors of 30 per cent or more. If special care is used to see that suitable equipment is installed, it is reasonable to expect a monthly energy consumption of 15 or even 20 kwhr for each kilowatt of connected load.

2. DAIRY FARMING

BOTTLE WASHERS. The electric power drive connection for bottle washers may be of either the direct or belt type. The consensus is that a speed of 900 rpm is more satisfactory than direct drive (1800 rpm). Screen door springs have been successfully used as (non-slipping) belts, and garden hose for direct couplings. A supply of hot water is necessary for satisfactory bottle washing.

See also Sterilizers and Water Heaters.

A $^1/_6$-hp motor is large enough for a single-brush bottle washer. For the double-brush type a $^1/_4$-hp motor is generally satisfactory. The energy consumption per 1000 bottles washed varies from 0.25 kwhr to around 0.6 kwhr respectively for single- and three-brush units.

Automatic bottle and can washers are available for use in creameries or large dairies.

BUTTERMILK WARMER. An insulated cabinet automatically keeps the air temperature around three cans of freshly skimmed warm milk at 70 deg fahr with an energy consumption of about 1 kwhr per day, a 1500-watt heating element being used. The resulting non-wheying buttermilk nets the producers as much as sweet milk.

CHURNING. A small rotating dasher type of churn, with a capacity of 12 gal of cream and operated by a $^1/_4$-hp motor, uses less than 1 kwhr per 100 lb of butter churned, the average churning and working time being 52.4 min and 17 min, respectively. A typical 6-gal barrel churn operated by a $^1/_4$-hp portable motor uses $^1/_6$ kwhr per churning, and in another case the energy consumption is about 1.85 kwhr per 100 lb of butter.

COTTAGE-CHEESE MACHINE. A typical cottage-cheese machine has a capacity of 50 gal of skim milk and is heated by a 50-gal water bath, the inner vat being made of tinned copper and the outer being insulated with 1 $^1/_2$ in. of good heat-insulating material. The water bath is kept at 70 deg for 12 hr by a thermostatically controlled 1000-watt element; the curd is then cut and the temperature immediately raised and kept at 140 deg fahr by a thermostatically controlled 2000-watt element for about $^1/_2$ hr or until the right solidity is obtained. Each vat has a thermometer attached, and the outer one a water gage.

CREAM SEPARATORS. The uniform speed of electrically driven separators results in cream of rather uniform quality and prevents heavy cream losses due to the speed dropping below the dead line. This is especially important during the winter since few separators will skim efficiently when the milk temperature is below 90 deg fahr, particularly if operated at speeds below that for which they were designed. No machine should leave more than 0.03 per cent of butterfat in the skim milk, but a survey in a typical area shows 45 per cent of the machines falling below this standard, resulting in an average annual loss of $18.74. A dirty separator enormously increases the bacterial count of milk and cream and by restricting the cream holes forces considerable cream into the skim milk. Similar losses occur when the cream opening and spout are not properly lined up.

The average farm separator requires $^1/_8$ hp (up to 1000 lb per hr) to $^1/_4$ hp (up to 1400 lb per hr), depending on machine design. The energy consumption per 1000 lb of milk separated varies widely, data showing 0.16 to 1.10 kwhr, depending particularly upon the quantity separated per operation. The average per month for each 10 cows from which all the milk is separated is not far from 2 to 2.5 kwhr.

Drip cups should furnish three or four drops of oil per minute, and the oil case should be drained about every six months (depending on amount of use), washed with kerosene, and refilled.

MILKING MACHINES. A milking machine pays its way in a herd of 15 cows where the equipment is cared for by the brush method, and in a herd of only 10 cows when the equipment is cared for by backwashing or suction washing, the brush method taking about as much time as milking four or five additional cows, and suction washing as milking one additional cow.

The average milking machine results in a labor saving of around 50 per cent in herds of 20 to 25 cows, and a reduction of 25 per cent in the total cost of milk production, the task of milking representing 41 per cent of the total labor. In fact, in herds where as many as 50 cows are milked a machine will take the place of one full-time man, an average of 20 cows (13 to 28 a typical range for various herds) being milked per man-hour. Combine and rotary combine milkers save about 70 and 95 per cent respectively of the total milking time or labor.

Power and Energy Requirements. For portable, double-unit milking machines the $^1/_6$-hp motor is practically standard, and for pipe line machines the average power requirements per cow milked range from $^1/_8$ to $^1/_2$ hp for various equipments. The energy requirements per month per 10 cows milked, for portable and pipe line machines, should not exceed 30 and 15 kwhr respectively, the consumption for the drive rod type being only a little higher than for portables. Some well-designed more recent equipment of both general types has much lower requirements.

Types of Milking Machines. Milking machines operate by either applying suction intermittently to the teats (as in less-expensive types) or a combination of suction and pressure (imitating the calf) applied to the teats.

There are six types of milking machines:

1. Pipe line. The vacuum pumps are either reciprocating or rotary, and the pulsations are either of the automatic or controlled type.
2. Drive rod. The pumps are portable and stanchion rows must be straight.
3. Portable. Less expensive and less dependable than pipe line type.
4. Relay. Usually three or four milking stalls and milk goes direct to milk room in sanitary piping.
5. Combine. Modified relay in which the milk first goes into a glass receptacle suspended from a scale where it can also be mixed by an air jet and a sample taken before it goes to the milk room to be cooled or pasteurized, or both. The milk could be bottled or canned without being touched by human hands. Manipulating the cow's udder until very little milk is seen to enter the receptacle eliminates hand stripping. However, other tests show no losses in average yearly production where no stripping is ever done.
6. Rotary combine or Rotolactor. A specially designed continuous milking plant, a rotating platform with a capacity of 50 cows, platform operated by $^3/_4$-hp motor, every rotation 12 $^1/_2$ min. Two men operate the milkers which are automatically sterilized after each milking, but 8 or 10 additional men are required to wash, dry, and care for the cows.

Milker Considerations. Vacuum pumps should have reserve capacity to take care of leaks that invariably develop from time to time.

Improper care of a milking machine results in low-quality milk, increases danger of infecting cows with mammitis or other udder disturbances, and causes a rapid deterioration of rubber parts. (See Fig. 1.)

In a typical case it took 20 min per day to wash two double units (double units seldom used), but suction or backwashing gives at least as good results. Immediately after each milking the machine is thoroughly rinsed, first with cold water and then with 1 $^1/_2$ gal per

unit, of hot water at 165 deg fahr (dousing so as to give an air brush, temperature must be no lower). The teat cups and long milk tubes are then placed on a rack and filled with disinfecting solution, preferably a 0.3 to 0.5 per cent solution of lye. In some cases they are placed in dry cold storage at 50 deg fahr instead. The teat cups, etc., are taken apart only frequently enough to inspect and renew leaking teat cup liners, etc. If the equipment is allowed to stand, this system of washing is not satisfactory until after the machine is brush washed. While not at all necessary, in some cases the milker heads are brushed when the rinsing is done, and some dairymen at milking time again rinse but this time first with hot (165 deg fahr) and then with cold water.

MILK PASTEURIZATION. An all-electric pasteurizer with a demand of 50 kw and a capacity of about 600 gal of milk at 40 deg fahr per hr (12 gal per kwhr, the pasteurized milk preheating the incoming milk) occupies only one-fourth the space required by comparable steam pasteurizers. The electricity flows through the milk and the rate of milk flow determines the pasteurizing temperature, which is 160 deg fahr. Pathogenic bacteria are killed without the usual alteration of flavor and cream line. In most types of

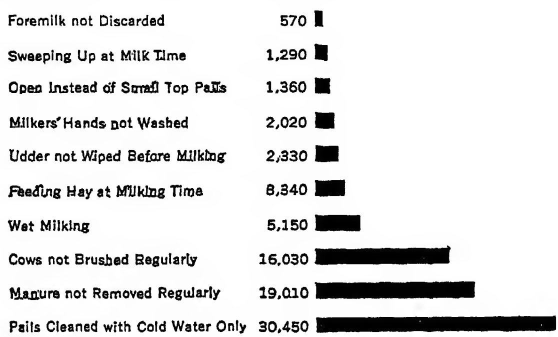

Fig. 1. Relative Contamination of Milk by Various Careless Operations, or Omissions, Showing Necessity of Clean Milking Machines

pasteurizers electricity is used only to operate the agitating equipment (batch type units). Recently (1935) electric pasteurizers with some major improvements have become available.

Milk is being pasteurized experimentally with supersonic waves, sound vibrations of around 100,000 cycles per second.

REFRIGERATION. Dairy. If fresh, good-quality milk is kept at 50 deg fahr or less, it can be stored for at least 24 hr without any marked increase in bacterial count (see Fig. 1); the critical temperature for cream is 40 deg fahr. Quality milk which is being shipped should leave the farm at a temperature of not above 40 deg fahr. On many farms, coffee-grade cream is left to accumulate for a week or even longer, and in such cases the cream should be cooled to at least 36 deg fahr in 3 hr or less by either wet storage in cans of not over 5-gal capacity, or by a tubular cooler or its equivalent, and then stored at 33 deg fahr. Fresh cream should never be mixed with old cream until completely cooled.

Methods of Cooling Milk. Milk and cream are cooled and stored by either the wet or dry methods, water being 21 times as efficient for cooling as air at the same temperature. Precooling is not necessary where the wet storage has ample cooling water at 35 to 40 deg fahr (water to milk ratios for night and morning cooling of 3 to 1 and 4 1/2 to 5 to 1 respectively), or where the dry storage has forced air circulation at around 33 deg fahr and small cans (5 gal) are used. Butter is best stored at 0 to 5 deg fahr. At this temperature and 80% humidity, butter will keep for 6–8 months. In the wet-type storage the cooling water should extend up the neck of the can at least as far as the milk.

Tubular coolers should be of the two-way type, cooling water in the upper half materially reducing energy requirements. For cooling less than 200, and from 200 to 400 gal of milk per day, 1/2- and 3/4-in. brine centrifugals respectively are satisfactory, both operated by 1/4-hp motors.

Types of Milk Boxes or Tanks and Cooling Units. Dry storage meets the needs of retail dairymen particularly and can also be used for the storage of vegetables, food, etc. For each 10-gal can stored a floor space 15 by 15 in. should be allowed, and for each quart bottle case a space 16 by 20 by 12 in. should be provided. Dry storages are cooled either by the brine system or by direct expansion, the former requiring 1 1/2 to 2 gal of

brine per gallon of milk cooled, and the latter, because of a lack of storage, having a lower capacity per horsepower.

Wet storage is favored by wholesale dairymen, the milk being cooled in the cans in which it is shipped. With forced circulation a higher water temperature can be used. (See above.)

Power Requirements and Energy Consumption. In tanks the average annual energy consumption for cooling 100 lb of milk below 50 deg fahr is 1 kwhr, and in a typical case for cooling and storing 10 gal of wholesale milk, 5 kwhr. For dry storage 60 kwhr per month per 100 qt of retail milk cooled and stored daily is typical. According to more specific averages, milk cooled and stored in 10-gal cans, by the brine system, requires about 0.12 kwhr per gal; milk cooled and stored in bottles by the brine system, 0.17 kwhr per gal; milk cooled and not stored by the brine system, 0.09 kwhr per gal; and milk when either cooled and stored, or cooled and not stored, by the direct expansion system, about 0.05 kwhr per gallon.

A $^1/_2$-hp water-cooled or $^3/_4$-hp air-cooled unit will take care of 50 to 100 gal of milk cooling and storing, or 75 to 125 gal of cooling alone, both with brine system, or 50 to 75 gal of milk cooling and storing, or storing alone, by the direct expansion method. Comparable figures for 1 hp water-cooled and 1 $^1/_2$-hp air-cooled units are 150–200 gal, 200–250 gal, and 100–150 gal respectively, and for 2-hp water-cooled and 3-hp air-cooled units, 275–350 gal, 325–400 gal, and 200–250 gal respectively. (See also Table I.)

Table I. Refrigeration Required in Retail Dairies in Southeast *

To cool 1 gal of milk from 95 to 40° F	3.5 lb of refrigeration †
To cool bottles or cans for 1 gal of milk from 85° to 40° F	1.5 " " " †
Two pounds of ice to crack over milk en route to market	3.2 " " " †
To provide cold storage and allow for losses, drinking water, etc.	2.0 " " " †
Total refrigeration needed per gallon of milk	10.2 " " " †

* Alabama Power Company averages.
† One pound of refrigeration is equivalent to the heat absorbed by the melting of 1 lb of ice.

Cost of Dairy Refrigeration. Estimating electric power at 2 cents per kwhr, and depreciation, interest, and upkeep at 10, 7, and 3 per cent respectively, a milk cooling plant will cost from $^1/_2$ to 1 cent per gallon cooled, depending on size, method of handling milk, etc. It is less expensive to cool milk in tanks with mechanical refrigeration than with ice, when electricity and ice costs are 3 cents per kwhr and $^1/_2$ cent per lb respectively. Total costs for ice refrigeration run from 45 to 156 per cent higher than for electric refrigeration, according to data from New Hampshire.

General-purpose. General-purpose boxes most frequently have a storage capacity of around 50 cu ft and will take care of ordinary food, freezing of ice cubes, and water cooling, also storing of a 5-gal can of cream, or a hog carcass, or other large piece of meat. Frequently a unit operated by a $^1/_4$-hp motor is sufficient, and nothing larger than $^1/_2$ hp should ever be required.

STERILIZERS AND WATER HEATERS. Utensils can be sterilized by exposure to: (1) dry hot air at not less than 230 deg fahr for 30 min; (2) humidified hot air at 205 deg fahr for 30 min; (3) steam or vapor at 170 deg fahr for at least 15 min; (4) steam or vapor at 200 deg fahr for not less than 5 min; (5) live steam for at least 1 min; (6) a chlorine solution of proper strength for 2 or more min, or (7) immersion in water at 170 deg fahr for not less than 2 min. However, utensils must be thoroughly washed (hot water very essential) if effective sterilization is to be assured, results with chemical solutions and live steam probably being the least and most affected, respectively, by any lack of cleanliness.

Sterilizers should be equipped with sanitary heat insulation, especially small units in cold climates or drafty locations. They should use a minimum of water with no dead compartment spaces (water level best maintained automatically so as to avoid danger of burning out heating elements), and the heat should be automatically turned off at the proper time by time switch or thermostat. Air or water circulation is essential to rapid heating, in the former case baffles and shields being required unless forced circulation (more desirable, especially for larger units) is available. It is suggested that in order to avoid the heat the fan blades be mounted on an extension shaft inside and the motor mounted outside. Temperatures much above 300 deg fahr will injure solder on pails, cans, etc. Sterilizers should be large enough to take the largest pieces of equipment such as a small 18 by 36 in. surface cooler. Probably the most popular size holds four 10-gal cans and other accessory equipment.

The heating elements for 4-can steam and dry or humidified hot air sterilizers, plus other

equipment, should be about 5 and 2 kw respectively, a 3-kw unit being ample for 7-can units of the latter type. In some areas a combination water heater and steam sterilizer with a small heating unit (low energy rate due to 100 per cent load factor) is proving satisfactory even though about one-third more energy is required than for other types.

The wash water can be heated with less energy and the water kept noticeably more sanitary through the use of a separate heater. However, the first cost of equipment is higher than where a combination type is used.

The energy consumption for sterilizing the equipment for a herd of up to 40 cows will average about 7.5 kwhr per day—for hot air types perhaps 6 kwhr. For herds of around 20 and 10 cows, the daily consumption will usually average a little under 7-kwhr and (very roughly) 3.5 to 4 kwhr (often only one batch) respectively. In somewhat typical cases for consecutive sterilizations 2.5 kwhr were required for 80 lb of metal and 3.65 kwhr for 125 lb of glass (4 cases).

About the same amount of electricity is required to heat wash water as to sterilize. From 7 to 10 gal of water at 140 deg fahr is ordinarily needed per day per 10 cows, this requiring around 25 kwhr per 100 gal heated, or 50 to 75 kwhr per 10 cows per month.

3. GRAIN AND FEED

CORN HUSKING AND SHREDDING. Shredding destroys corn borers, and the resulting stover is better than timothy hay or straw for milk cows, and better than straw for horses. The shredded stover likewise is better than straw and far superior to long unshredded stover for bedding, also much easier to feed.

The average man-hours required by hand methods and with a corn husker and shredder are 19 and 13, respectively. However, only 8 hr of man-labor are required to husk from the stalk where the stover is left in the field and the corn yields about 40 bu per acre.

Purdue data show that a 2-roll husker can be operated by a 5-hp motor, also that a 4-roll machine can be handled by a 7 $^1/_2$-hp motor by keeping the husker below full capacity. The energy consumption per 100 bu husked varies from 20 to 40 kwhr, the latter, as it happens, relating to a 2-roll machine.

CORN SHELLING. A $^1/_4$-hp motor will operate the average hand sheller with ease, almost doubling its capacity and saving the time of one man. Often the belt can be placed on the flywheel, the ordinary $^1/_4$-hp 1800-rpm motor and pulley giving about the right speed.

In a typical case a 2-hole sheller operated by a $^1/_2$-hp motor at 246 rpm had a capacity of 1536 lb per hr, using 0.02 kwhr per bu of shelled corn or 0.35 kwhr per cwt of shelled corn. The energy requirements with corn having a moisture content of 22 per cent were 12 per cent lower than with corn having a moisture content of 30.5 per cent. Shelling data for a hand sheller show 0.08 kwhr per bu of shelled flint corn.

DRYING. See Art. 9.

ELEVATING GRAIN AND SHAVINGS. Elevators are great labor savers; for example, they enabled one man to bin the grain from a thresher and reduce the cost of storage (making higher buildings practicable). The energy consumption per 1000 bu. elevated for vertical cup, tubular portable, portable drag, and chainless bucket (endless rubber belt equipped with buckets) elevators runs from a little over 1 kwhr (oats) for the vertical cup to a little more than 8 kwhr (ear corn) for the portable drag. Typical data on the energy consumption per 1000 bu per ft of lift for portable drag and vertical cup elevators show averages of 0.41 (0.28 to 0.59) and 0.13 kwhr respectively.

Ensilage cutters and fan elevators on hammer mills, as well as regular pneumatic equipment, are also used for elevating, the energy consumption running from about 10 (oats) to 33 (barley) kwhr per 1000 bu elevated. Ordinary 5-hp hammer mills will elevate 250 to 500 bu per hr to heights of 15 to 38 ft, ordinary 12-in. fans running at 2500 rpm elevating to heights of 38 ft but a maximum of 1200 to 1600 rpm, for elevations of 15 or 20 ft, is recommended if hulling or cracking of the grain is to be avoided. Horizontal runs of more than 8 or 10 ft are made by running the pipe high enough so that it has a downward slope of at least 30 deg.

Dry and wet shavings used for bedding were elevated 35 ft into a mow with a 45-in. fan 8 $^3/_4$ in. wide operated at 960 rpm by a 10-hp motor, at the respective rates of 8 and 2 tons per hour, with demands of about 10 and 5 hp respectively, and ton energy requirements of something over 1 and 2 kwhr respectively.

ENSILAGE CUTTING. See Silo Filling.

FEED AND ROUGHAGE GRINDING AND CHOPPING. **Grain.** The hard coats of ordinary grains and seeds must be broken or softened if they are to be fed efficiently, grinding being three or four times as effective as soaking. (See also under Soybean Cook-

ing.) Grinding medium fine and in some cases coarse is more profitable than finer grinding. (See Table II.) When corn is 50 cents per bushel, wheat is worth around 53 1/2 cents for sheep and poultry, and 56 cents for hogs and beef cattle.

Table II. Efficiency of Feed Utilization for Dairy Cows *

Whole corn...........	30–35% undigested
Whole oats............	20–25% "
Crushed corn..........	5–10% "
Crushed oats..........	1–2 % "
Medium corn..........	1–2 % "
Medium oats..........	0.001–1 % "
Pulverized grain.......	No findings

* Data from Purdue University; in general applies to other livestock as well.

Grinding Costs. The total cost of grinding with properly selected equipment is usually from 3 to 5 cents per 100 lb, and it is not generally profitable to own a mill unless at least 300 bu of oats or 150 bu of shelled corn (or their equivalents) are ground per year, the installation being assumed to operate without an attendant.

Grinding Considerations. 1. Grinding oats for hogs pays only when fed in amounts not to exceed one-fifth of the ration. Do not grind too fine (medium fineness preferred from the standpoint of economy), although finely ground oats are more palatable for hogs. Grinding grain for steers (cattle) and sheep frequently does not pay. Grinding grain for milk cows is usually good practice, medium fine grinding bringing the highest net returns. It is commonly thought that mash for chickens should be ground fine, but recent data favor coarser grinding because of greater palatability.

2. Hammer mills appear to be somewhat more efficient for fine and medium grinding, and burr mills for coarse work; also roller mills are ideal for cracking or coarse grinding. It is the peripheral speed of the hammers and not the rpm which is effective in hammer mill grinding.

3. Small hammer and burr mills may be successfully operated with motors of from 1 or less to 5 or more horsepower. Hammer mills are higher in first cost but are more easily adapted to semi or full automatic operation than are burr mills (less danger of injury to equipment).

4. Operation without an attendant is the main basis for the greater economy of the small-capacity mill, and therefore a feed supply and means for meal removal are essential to economical operation. The equipment overhead for a small mill is also materially lower, this being much the largest factor in determining grinding costs for fair-sized equipment unless an unusual amount of grinding is done. Burr mills operated without attention should be safeguarded against intrusion of foreign material and against running empty.

A small mill operated by a 1/2 hp motor will easily do the grinding for a herd of 40 cows or 2000 chickens with a wide margin of safety (even during the heavy grinding season), having a capacity of 30 to 200 lb per hr, depending on mill and degree of fineness. (In a few cases 1/4 hp motors have been successfully used in connection with small burr mills.) Such small mills are not adapted to grinding ear corn or any other type of roughage or semi-roughage. On a basis of 1/10 bu of ground feed per day per cow a ton of dairy feed will last a herd of 10 to 15 cows about a month.

Where grains are ground in unequal proportions, reducers or nozzles must be provided for the grain chutes, one nozzle for each rate of feed. Governor regulation can also be provided but is usually rather expensive. If the feed is fed on the same floor on which it is ground, an overhead bin should be used for storing it. A bucket type or any other suitable elevator can be used to carry the ground feed from the mill to the overhead bin. A fan elevator can be purchased as an integral part of most hammer mills, and with it feed can be lifted greater distances than with other types of elevators: 35 to 40 ft vertically but ordinarily not over 8 or 10 ft horizontally unless the pipe runs high enough so that it slopes down to the feed bin at an angle of not less than 30 deg. The use of such a fan increases the fineness of grinding, the mill capacity, and the power and energy requirements. The fan may also be used to elevate grain by removing the gooseneck (goosenecks with square or rectangular cross-sections at the hopper bottom of the mill and with smooth curves are materially more efficient than the common stovepipe type), and adding a special hopper (grain going into the fan directly), or by removing the screen and running the grain through the mill. A fan elevator should have a concentric housing with a clearance of about 1/8 in. and ample air inlets, screen opening alone being insufficient.

It is advisable to use a dust collector with most ground feed elevators; in fact, some method of dust control is almost essential with hammer mills. A variety of dust collectors are on the market, and the Agricultural Engineering Department at the University of Wisconsin has plans available for homemade dust collectors. Some farmers have found it satisfactory merely to close with sacking an otherwise airtight bin which is open at the top, or, less preferably, where the opening is a window as far as possible out of line with the delivery pipe opening.

5. Burr mills in general operate most efficiently at slower speeds, 200–500 rpm. Hammer mills are most efficient at their rated high speeds such as 2000, 3600, and 4500 rpm depending somewhat on type, etc.

6. The energy consumption for feed grinding, which does not vary materially with the type of mill, is generally 10 to 15 kwhr per ton (20 kwhr for chicken mash) including ground or cracked scratch and mash. Fine grinding consumes energy entirely out of proportion to the increase in fineness. As the moisture content of grain increases, the power required to grind increases.

In practice the energy consumption per 100 lb for medium grinding of dry shelled corn, barley, and oats is around 0.5, 1.0, and 1.5 kwhr respectively. It takes about two and one-half times as much energy to grind ear corn as to shell and then grind the same amount of shelled corn, but where bulk is needed, for example in the South where roughage is expensive, and where, as for sheep, the available concentrates would otherwise be too heavy, such grinding is fully justified.

7. By a new system of high-pressure grinding that is as yet only done locally, the grain is formed into dustless flakes resembling breakfast food. The product is very popular among rabbit feeders.

8. See also under Feed Mixing.

Roughage. Forage grinding or chopping increases gains but is profitable only when roughage is high in price or labor and power are cheap. Data from Idaho are typical, and with long, chopped, and ground hay show daily rates of gain, with steers, of 1.56, 1.82, and 1.87 lb respectively and hay losses of 10.3 per cent, 4.6 per cent, and none respectively, similar hay losses for sheep being 30.1, 13.8, and 1.8 per cent respectively. According to Kansas data, nothing is gained unless the roughage contains grain (cane fodder, Kafir fodder, etc.), most of the benefit coming from the cracking of the grain. Hay losses from tramping at the feeding racks have been reduced in California as much as 10 to 20 per cent, and refuse from low-grade hays or other roughage, for example, corn stover, coarse soybean hay, or poor alfalfa, by 15 per cent or more. It is likely that decreasing the refuse of poor quality roughages is poor economy, especially with cows. Chopped or ground hay, though dustier, is easier to feed and occupies only one-third to one-half the space required for comparable quantities of long hay. Taking account of time required to mow away, it takes about the same amount of man and horse labor to store cut as long hay. Artificially dried hay can now be compressed while still warm, into dustless and palatable briquettes. Refuse, such as cornstalks, is commonly used for bedding, and the resulting manure is much more easily handled than when the roughage is whole.

Cost of Grinding. The total cost of grinding roughage including labor, power, and equipment overhead, was found, in Kansas tests, to range from $0.99 to $1.39 per ton, depending considerably upon the number of tons ground per year and to a lesser extent on fineness of grinding. In Texas, grinding costs, exclusive of labor, of such forages as snapped corn, hegari, etc., averaged $1.75 per ton with 40-hp outfits, and $1.18 per ton with 5- to 7 $^1/_2$-hp equipment.

The average energy consumption required for grinding is around 10 kwhr per ton, and for chaffing or chopping probably 3 $^1/_2$ kwhr or less per ton, although in some cases it amounts to as much as 5 kwhr per ton. It takes about 5 kwhr to shred a ton of corn stover, very little more energy being required to husk corn at the same time. Where hay is rather finely ground, as for baby chicks, as much as 30 kwhr may be required per ton.

Size of Machine Required. It is possible rather than practical to grind or chaff roughage with a 5-hp motor, but 7 $^1/_2$-hp motors with certain types of carefully operated mills are in some cases proving fairly satisfactory. It is next to impossible to get sufficient feed into the restricted openings of some small mills, for example, 10-in. burrs being preferred to 8-in. burrs. However, a large proportion of the present installations are operated by 25-hp motors.

Type of Machine, Operation, and Fineness of Grinding. Hammer mills are especially adapted to fine grinding and plate mills to coarse grinding, the former, however, being available in a larger range of capacities and sizes than the latter. The combination mill, containing cutter head which can also be used without the mill proper, is suitable for a wider range of grinding than the other types.

An ensilage cutter can be and often is used for chaffing hay. In a typical case a 5-hp motor operating a cutter used 3 to 4 kwhr per ton of hay cut into $^1/_4$-in. lengths, hay being chopped at the rate of 1 $^1/_2$ tons per hour. *Most farmers find hay of this length fine enough for all purposes.*

Hammer mills should be operated with a peripheral speed of 14,000 to 15,000 ft per min (due to excessive bearing friction small diameter mills are sometimes best operated at lower velocities), rpm being of only incidental importance, and a burr mill should run at

600 to 850 rpm. The economical speed for ensilage cutters at most does not exceed 500 to 600 rpm, according to Kansas findings.

Keeping Qualities of Ground Roughage. Dry roughage when ground will keep longer, but is dusty and disagreeable to grind and is probably less palatable to stock than feed containing 25 per cent or more moisture. Ordinary ground corn or Kafir forage cannot be stored for more than 36 hr without heating.

FEED MIXING. Feed mixers are about as frequently found a part of a feed-grinding installation as separate equipment. The grinders together with their elevators and overhead bins are used for this purpose; the batch of material is moved back and forth as required, three moves usually being sufficient. Sometimes the concentrates and grain are mixed as ground by placing alternate layers of the required materials in the bin or container from which the mill is fed.

When used for mixing, the rotor pulley of hammer mills should preferably be disconnected or at least the gooseneck should be removed and a special hopper emptying directly into the fan should be used. Some hammer mills have a tendency to clog with ground feed.

One size of a vertical auger mixer, which carries the feed upward through the center of an upright container, the elevated feed then rolling toward the outside from the top, thoroughly mixes 600 lb of feed in 8 min (5 min actual mixing and 3 min of agitating to facilitate bagging) with an energy consumption of 0.5 kwhr per batch, with a 5-hp motor. Deducting grinding power, some data for a 5-hp hammer mill show 0.67 hp and 560 lb of ground feed elevated per hour at 3550 rpm and 1.85 hp and 2530 lb of ground feed elevated per hour at 3950 rpm. At these higher speeds, feed can be elevated vertically 35 or 40 ft, but not over 8 or 10 ft horizontally unless the pipe is high enough so that it slopes down to the storage bin at an angle of not less than 30 deg.

GRAIN AND SEED CLEANING AND GRADING. An electric motor on the fanning mill saves the time of a man or boy as operator. In addition, it makes the use of a sacker practicable, the sacker alone reducing the total cleaning time by about one-half. The unvarying speed makes for greater effectiveness; such equipment removes weed seed, trash, and undersized grain, and eliminates danger of mixing varieties in elevator cleaning. It is particularly valuable in the cleaning of vegetable and other small seeds. One-half horsepower or less, $^1/_4$ hp ordinarily, will operate most fanning mills, and the cleaning of 100 bu of grain or 20 to 30 bu of small seeds requires around 1.7 kwhr, larger and more efficient units operated by 1-hp motors apparently cleaning 1000 bu with a consumption of only 4 kwhr. With similar screens capacity is not materially influenced by weight, it being largely a matter of volume.

GREEN FEED AND STRAW CUTTING, AND ROOT SHREDDING. Apparently typical kale cutting tests show 5.6 times as much man-labor and 2.8 times longer cutting time (same amount of cutting) for hand operation as for the use of a motor on the same machine, representing a saving of $3.65 per ton of kale cut: 30 cents per hour for labor and 3 cents per kwhr for power. Energy consumption usually runs from 0.07 to 0.13 kwhr per 100 lb of kale cut, or from 0.17 to 0.51 kwhr per 100 birds per month with kale serving as the green stuff. It is recommended that from 8 to 10 lb of young kale—roots sometimes used—or 5 lb of more mature kale be fed daily per 100 layers. Unless the kale is cut, $^1/_2$-in. lengths, the midrib is left and up to 50 per cent is refuse; if cut, only up to 20 per cent becomes refuse.

For root shredding the average energy consumption is about 0.07 kwhr per 100 lb of roots—around 0.09 kwhr per month per 100 birds. In two instances with larger equipment the consumption was $^1/_3$ and 6 kwhr per ton respectively, with a 1-hp unit.

For chopping green alfalfa into $^1/_2$-in. lengths (practically one-half is lost as refuse unless cut) the average energy consumption is around 0.1 kwhr per 100 lb—about 0.15 kwhr per 100 birds per month.

Cutting straw into 2-in. lengths for baby chick litter, etc., takes around 0.11 kwhr per 100 lb cut.

Cutters with throats up to 10 in. may be operated with a $^1/_2$- or $^3/_4$-hp motor, some small machines requiring only $^1/_4$ hp. The top speed recommended is around 350 rpm, a very satisfactory speed for the larger hand machines being 200 to 250 rpm.

HAY BALING. Most balers can be satisfactorily operated by 5- or 7 $^1/_2$-hp motors, but the larger machines may require up to 25 hp. Presses should turn out from 3 to 5 tons per hp per 10-hr day and should not require, even under unfavorable circumstances, over 0.2 to 0.3 kwhr per 120-lb bale or, say, 2 to 5 kwhr per ton, in one typical case an average of 1.62 kwhr per ton being required for 75-lb bales.

HAY HOISTING. A motor on a suitable hay hoist shortens the total unloading time and saves the time of a driver for the team, a properly designed hoist being operated from a load. A motor is usually slower in elevating than horses, but this time is more than

made up in returning the fork or slings, the latter task with horses requiring about three-fourths of the total time.

Hay hoisting being an intermittent job, the motor can safely be made to carry almost 200 per cent normal load and, instead of 7 1/2 or even 10 hp, 5 hp is ample, 3 hp being used occasionally, and even 2 hp (rope speed 120 ft per min in a typical case) giving satisfaction. Slings require no more power than a fork.

The energy consumption per ton hoisted varies with the hoist, height of track, etc., ranging from 0.1 to 0.65 kwhr or an average of 0.35 kwhr—a total of about 10 kwhr per season on the average farm. Some owners of hoists cut down their overhead by using the equipment for other tasks such as hoisting sacks of feed, fertilizer, etc., lifting the dirt from a well being dug (in a typical case using an average of 1 kwhr per cu yd to hoist an average of 18 ft), and in at least one case such equipment was satisfactorily used with a grabhook to load manure.

MILLS, GRIST. It takes about 1 kwhr to grind a bushel of cornmeal.

OAT SPROUTING. A 25-watt heater will take care of a sprouter large enough to supply the average farm flock if located in a protected place, such as a cellar. A well-insulated sprouter furnishing a bushel of oats daily (enough for 1000 hens, 1 to 2 cu in. each) should not have a maximum demand of more than 125 watts or an energy consumption above 75 kwhr per month.

SEED CLEANING AND GRADING. See Grain and Seed Cleaning, etc.

SEED CORN TESTING. Operating data for a well-insulated homemade two-compartment 3 by 8 by 3 ft 1600-ear or 8000-kernal electrically heated germinator, in a protected outbuilding, are typical. The temperature was kept at 80 deg fahr, and the humidity was maintained between 95 and 98 per cent by placing a pan of water over the 400 watts of heat. The trays were staggered so that there was positive circulation of the warm air over the top of each of the four trays in each compartment. The corn kernels were placed on muslin which in turn was placed on wet-down sawdust. The energy consumption for the 7-day germinating period was around 34 kwhr, close to 1/2 bu (48 ears) being tested with 1 kwhr. Energy consumption for large germinators amounts to about 3 kwhr per bu.

SILO FILLING. There are two types of ensilage cutters: (1) cylinder, the corn being cut by a cutting head which, though an integral part of the machine, is separate from the elevating fan; (2) flywheel, the knives, varying in number from two to three or even four or more, attached to the elevating fan.

Silos have been filled with 3-hp motors and in many cases are being filled with 5-hp and to all practical heights, but in practice, especially where much help is hired, 7 1/2-hp is more satisfactory. The success of filling silos with small-horsepower motors depends more upon the use of minimum operating speeds than upon anything else. (See Table III.) Likewise there should not be over 1/8-in. clearance between the fan tips and

Table III. Minimum Speeds for Various Sized Ensilage Cutter Fans to Elevate Corn into Silos of Different Heights*

Diameter of Cutter Fan, in. (wing tip to wing tip)	Height of Silo, ft								
	25	30	35	40	45	50	55	60	75
	Revolutions per Minute of Cutter Fan

42	355	380	410	435	465	490	515	535	595
44	340	360	390	415	440	470	490	510	570
46	325	345	375	400	425	450	470	490	545
48	310	330	360	380	405	430	450	470	520

* These speeds are based upon carefully conducted tests with a reasonable allowance to insure uninterrupted elevation and represent operating efficiencies of about 30 per cent. Good cutters will successfully operate at these speeds according to the formula; $\text{rpm} = \frac{250\,H}{\sqrt{HD}}$, where H is height of silo and D, diameter of cutter fan in feet. Experience in Oklahoma indicates that for cane or Johnson grass, or a combination of both, speeds will have to be increased at least 10 per cent. On the other hand, in Minnesota they are successfully operating cutters at lower speeds, with corn, suggesting that these data may be 5 to 15 per cent higher than necessary with their type of corn and conditions.

housing and a reasonably close fit at the sides; the pipe should be rather straight (vertical), and the cutter well anchored; the knives should be sharpened every half day (where cutter is kept reasonably busy), and the machine should be evenly fed, generally lapping the bundles about one-third and good judgment being used where a bundle is unreasonably large. The silage is usually cut into $^1/_2$-in. lengths. The cutter may be and often is fed by the wagon drivers. The normal rate of filling under these conditions is around 8 tons per hour.

THRESHING. The unvarying speed of electric motors is ideal for threshing, but in most communities portable transformers are necessary. In a typical set-up a 21 by 36 in. thresher was operated by three motors: 7 $^1/_2$-hp (could be detached from a portable truck during the threshing season) on the cylinder; 3-hp variable speed driving the racks, grain pan, shoe, tailings elevator, grain auger, and grain weigher; and 2-hp on the stacker. The operating costs were about the same as for a tractor.

Energy Consumption. Typical energy consumption data from Minnesota vary from 0.078 kwhr per bu for succotash (oats and wheat) or 0.242 kwhr per cwt, to 0.265 kwhr per bu or 0.441 kwhr per cwt for wheat. Dry and wet barley required 0.167 and 0.427 kwhr per 100 lb threshed, respectively, and poor crops full of weeds about 0.5 kwhr per 100 lb. Succotash, barley, oats, wheat, flax and wheat, timothy, and clover have energy requirements per hundred weight in the order named, ranging from 0.242 to 11.2 kwhr. The average for grain is 0.335 kwhr per 100 lb. From 5 to 8.7 bu of barley were threshed per kwhr, and an average of 7 bu of barley, oats, wheat and oats, and flax per kwhr.

Electrical equipment reduced average stack losses from 1 to 0.15 per cent; reduced dockage from 3 to 1.2 per cent; decreased the operating force from 3 to 2 men; reduced the total crew to 6 men and 5 wagons, a short haul but 900 bu of barley being threshed per day; and reduced the set-up time by 1 hr. However, the equipment had to be moved by horses or tractor from job to job.

The average demand of 13.4 kw for the thresher mentioned above was reduced about 11 per cent by roller bearing. In an older model the running light was about two-thirds the operating demand, 86 per cent on the blower motor, 96 per cent on the grain shoe and shaker, and 50 per cent on the 10-hp motor on the cylinder. However, the losses were about the same for the newer equipment.

Starting is made easier by high belt speeds, around 3400 ft per min being satisfactory in a typical case.

With a 22 by 38-in. thresher only 4 or 5 hp are required to do the actual threshing, operating speeds being too high, belts being too tight and crossed, new machines requiring almost double normal power until " run in," and in many machines the wind stacker pipe, being too large.

A small thresher in Alabama operated by a 7 $^1/_2$ hp motor had an energy consumption of 26 kw hr per 100 bu threshed, mostly oats.

4. LIVE STOCK

ANIMAL GROOMER. According to Cornell data, groomers shorten the grooming time per cow to 2 min per animal as compared to 5 or 10 min by hand methods. Not all types (knapsack, truck, etc.) are equally effective, owing to suction variations. Loose hair, dirt, and scurf constitute one of the greatest sources of milk contamination.

BARN VENTILATION. A well-ventilated barn should meet the following standards:

1. The temperature of the stable should be from 45 to 50 deg fahr with an allowable variation of 10 deg fahr for extremes in weather conditions. According to most authorities, 35 deg fahr is considered the minimum. Satisfactory temperature maintenance requires keeping the barn properly filled with animals and the use of more than a single layer of siding, or equivalent.

2. The relative humidity should be maintained at about 75 per cent and never exceed 85 per cent. (Owing to important savings in cost of insulation, etc., many do not object to some condensation during the most extreme weather if other conditions are satisfactory.)

3. The air flow through the stable may vary from 40 to 60 cu ft per cow per minute (a minimum of around one to two complete dilutions or changes per hour with fans running restricted).

4. There should be complete mixing of incoming air with stable air to insure a uniform quality of air throughout the stable. It is ordinarily assumed that this means several properly spaced and located inlets.

5. The convection currents in the stable should be constantly in operation to insure complete mixing of fresh air and stable air and to assist in the diffusing of the fresh air.

6. Intakes should be so constructed that the velocity of the incoming air is reduced, as

it enters the stable, to such a degree that no objectionable drafts can possibly result; an objectionable draft is a stream of air which is of lower temperature than the surrounding air and which blows directly onto an animal or attendant.

The forced-draft system of barn ventilation has several advantages as compared to the natural-draft system:

(*a*) Lower overall first cost ($350 as compared to $900 in a typical case in Minnesota). The operating cost of the fans is often lower than the interest and depreciation on the extra investment in a gravity system.

(*b*) Although exhaust fans should always be installed on the side of the barn away from the prevailing winds, they are largely independent of wind and wind direction.

(*c*) Operation is automatic, the fan regulating within a range of 2 or 3 deg fahr. The air outlet is restricted as the stable temperature drops; and should it drop too low, the fan stops until the temperature again rises.

Table IV. Data for Forced-draft Barn Ventilation *

State	Kwhr per Year	Kwhr per Season per 100 Head of Stock
Iowa............	2.6 †	1000
Minnesota.......	300.0	1000
Minnesota.......	36.0	144
New York.......	810.0 ‡	1250 ‡

* Data are so variable that none are really typical. Material from Iowa is more recent and probably indicative of monthly requirements during the ventilating season, preferably a period of 8 months' continuous and 4 months' intermittent operation, according to Cornell University investigation.

† Per month per cow.

‡ Many think these figures too high but they may actually be too low.

CLIPPERS, HORSE AND COW. Clippers are available in stand, suspended, and hand portable types, one being operated by the vacuum from a milking machine. One electric design operates on the vibrator principle and is very compact.

DROPPING-BOARD CLEANING. In New Jersey a flexible dropping board, similar to the canvas on binders or the apron on some manure spreaders, is operated by a motor, a stationary knife bearing against the under side at the end scraping the droppings into the box used to carry them away. The cleaning time is reduced from an hour or so to a few minutes.

In another type of installation which works fairly well, even when the boards are very dirty or the droppings frozen fast, consists of a motor-driven scraper made by attaching angle irons to common chains moving at the rate of 40 ft per min, motor and pump jack for speed reduction being mounted on a shelf above. The droppings fall into a screw conveyor which carries them outside through a hole in the back of the house, making it possible to eliminate all hand work up to unloading. This particular dropping board is only 30 ft long but of course could be made indefinitely longer if adequate power were available.

ELECTRIC HEAT FOR YOUNG PIGS AND LAMBS. In cold climates a reflecting heater sitting on a shelf so that its warmth is directed among the young animals during their first few days, if the weather is unseasonable, materially reduces cold-weather losses from chilling. In a typical instance a Minnesota hog breeder increased his income for the year by $600 ($3 per pig).

FOX-FARMING EQUIPMENT. On the fox farm, electricity lights the yards, protects against robbery, preserves and grinds the fresh meat, and in some cases cooks the rations, etc.

OX-GRUB REMOVAL WITH A VACUUM CLEANER. A special high-suction cleaner designed by the U. S. Department of Agriculture is very efficient in removing grubs from the backs of cattle.

SHEEP SHEARING. Tests with hand shears, a 10-tooth Steward hand power machine, and a 13-tooth Steward power clipper operated by a $^1/_2$-hp motor, show an average of 8 min required to shear a sheep by hand, two-thirds as long as with the hand-operated machine, and only a little more than half as long with the motor-driven machine. About 2.4 kwhr were required to shear 100 sheep with the motor-operated machine.

Water Heating for Stock Tank. Warm water as compared to cold resulted in an added average gain per steer of 8 lb during January and February, in Idaho, shelter during the same period adding another 7 lb of gain per steer. Under similar conditions the gains for lambs were not increased. The average daily midwinter energy consumption in Caldwell, Idaho, in 1930–31, for a 52-gal cylindrical tank insulated with 3 in. of granulated cork was 5.2 kwhr, about 1.8 kwhr per 100 gal (water kept at 55 deg fahr by thermostat with a 10-deg fahr range) or less than 0.25 kwhr per cow per day. The 22 cows drank an average of about 13 gal of water per day. The energy consumption for an uninsulated tank, also at Caldwell, where the water was merely kept from freezing (manually controlled—on in daytime only) was 0.15 kwhr per steer per day.

5. POULTRY—GAME—EGGS

BROODING. Brooder technique is rapidly advancing, the designs shown being indicative of general methods of heating but not necessarily representing equipment still being sold—at least in large volume. In Fig. 2–*A* is a blackheat brooder (representing

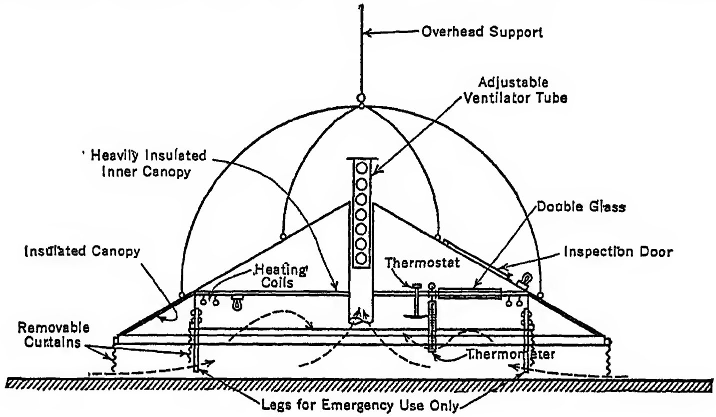

Fig. 2-A

the hover type most commonly used) the outstanding features of which are: a curtained inner compartment two-thirds of the diameter of the curtained outer compartment; heavy insulation of canopy and ceiling; and a 3-in. adjustable ventilating tube. The heat control is automatic. There are a pilot light, an attraction light on a separate circuit, an inspection door in the canopy through which the thermometer, etc., can be inspected, a glass window through which the chickens can be observed under the hover, and a suspending rope, pulleys, and counterweight for adjusting the height of the brooder and for convenience in cleaning. No brooder should be without this last feature.

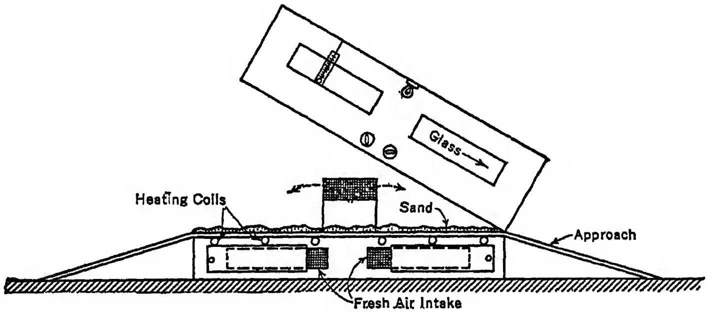

Fig. 2-B

B is an underheat brooder. Locating the heating elements beneath the false floor assures dryness, also good ventilation while some of the heating elements are on. In other fundamental respects the brooder resembles *A*.

C is an underheat brooder similar to *B* but with the heated air entering from the back. A layer of sand (1 $^1/_2$ to 2 in. thick) on the brooder floor, above the heating elements, stores a substantial amount of heat which is valuable in case of power interruption. The heating elements are controlled by three manually operated switches (Pacific Northwest), but the changeable weather of most sections of the country makes automatic control essential. Heating cable, presumably lead covered, buried in that part of the conrete brooder house floor adjacent to and directly beneath the hover of the ordinary blackheat type has been successful in keeping the litter dry.

D is a locally popular type of blackheat brooder (for example, with type *A* making up

practically all the brooder sales in certain areas of Oregon) which is insulated with 2 in. of sawdust; it is sold with slatted platform of lumber with wire netting between slats, and has an inside diameter of 28 $^{1}/_{2}$ in. and any length required to take care of the chicks to be brooded, 5.2 sq in. per chick being allowed by the manufacturer's plans.

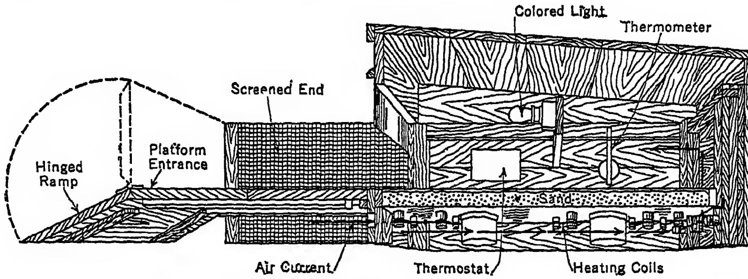

FIG. 2-C

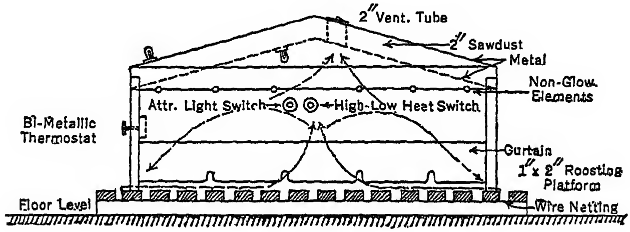

FIG. 2-D

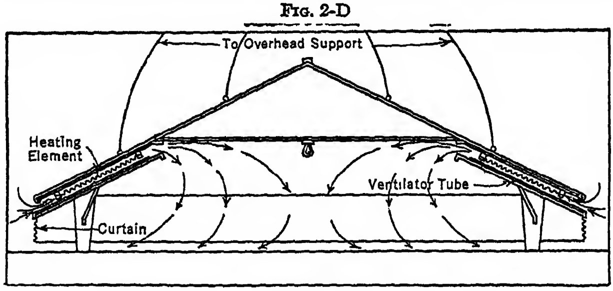

FIG. 2-E

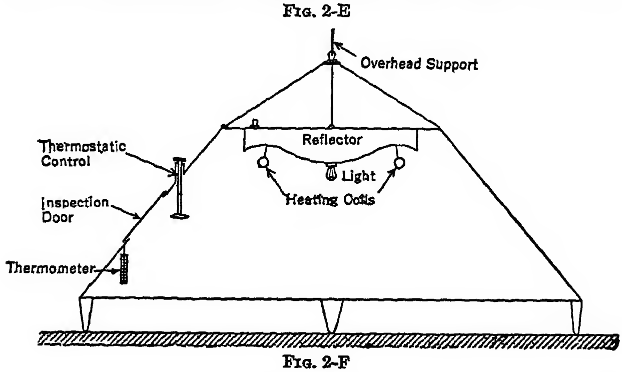

FIG. 2-F

E is a blackheat brooder with supplementing convection tubes, two tubes being used only in large units. The heating elements (glowing radiant) in the ventilating tubes are

on continually. The regular heating elements are located on porcelain knobs attached to the hover ceiling.

F is a glowing radiant-type brooder; the four elements operate at red heat. No curtains are used and there are no ventilation problems, but the energy consumption is high. Insullation on the canopy would help to lower this consumption. This general type is widely used in mild climates.

Wattage and Energy Requirements. The proper heating capacity for glowing radiant brooders varies from around 2 watts per chick in mild climates to 2.5 to 3 watts per chick where freezing temperatures are experienced, and for blackheat brooders from 1.3 to 2 watts per chick. The brooder should be able to maintain a temperature of 100 deg fahr (90 deg fahr for underheat types) with the thermometer bulb 2 1/2 to 3 in. above the brooder floor during the coldest brooding weather and before the chickens are put under the hover.

Energy consumption for the radiant type varies widely but averages between 1.2 and 1.5 kwhr per chick-season (California Bulletin No. 441); for the blackheat type the range is from less than 0.2 to 2 or more kwhr per chick-season but should not average above 0.5 kwhr per chick-season with good equipment and good operating conditions when the brooder-house temperature does not drop below 0 deg fahr. Some power companies in the Middle West and East assume an average of 1 kwhr per chick-season. The range for the underheat brooder is between 0.5 and 2 kwhr per chick-season, and for other types the averages are usually between those for the radiant and blackheat types.

The energy consumption figures for turkey brooding from Texas and Oregon show an average of a little over 1 kwhr per poult-season, poults requiring much more space (at least 12 sq in. per head recommended) than chickens but the season generally is later.

The area per chick under the hover is one of the important factors in determining the unit energy consumption. For instance, it will take only about half as much energy where 3.5 sq in. are allowed per chick as compared to 7 or 7.5 sq in., the latter being considered as the minimum for the production of husky chicks unless crowding is avoided by removing some of the chicks as they become larger. Ducks, goslings, and poults require about 14 sq in. each.

Much more space per chick is required with battery brooders. One southern (Texas) poultryman operating a heated room type of battery brooder recommends the following:

Age	Sq in. per Chick
Start	14
2 weeks	20
4 weeks	35
6—8 weeks	50

(Less space is required per chick in unheated rooms.)

One cubic foot of fresh air per minute per pound of chicks.

The use of good insulation on the brooder will materially lower the consumption when the area per chick is taken into consideration. If fibrous materials are used they must be protected or the chickens will eat them. (See Fig. 2*E*.)

The temperature in the brooder house will also materially affect the energy consumption. No data are available, but it appears that the consumption of a well-insulated brooder would be doubled by a drop from 70 deg to 0 deg fahr in the brooder house, assuming 1/2 in. of fiber insulation or its equivalent for the hover. Some tests at Manhattan, Kans., with an uninsulated brooder show the consumption doubling with a 20-deg fahr drop in temperature.

It is the opinion of at least one Petaluma, Calif., poultryman that automatic temperature control would reduce his energy consumption, as compared to manual control, by 15 to 20 per cent. The actual length of time that heat is required usually varies from 4 to 8 weeks, depending on weather conditions. At this point it is interesting to note that E. C. Easter assumes for Alabama conditions an average wattage per brooder of 500, and an average energy consumption of 60 kwhr per 100 chicks per year.

In a late season test at Schenectady, N. Y., it was found that approximately 50 per cent of the energy for brooding was consumed during the first week, and around 80 per cent during the first two weeks of operation, that is, with thermostatic control and temperature reductions as the chicks became older. However, with low outside temperatures, a somewhat larger percentage of the energy would be used later in the season.

Expense of Brooding. According to data from Oregon, electric brooding is cheaper than oil or coal brooding with kerosene at 18 cents per gallon, briquettes at $17 per ton, and electricity at 3 cents per kwhr.

CHICKEN SCALDING. An insulated scalder in rather general use on the Pacific Coast is 39 in. long, 24 in. wide, and 19 in. deep, and is divided into two compartments one

of which is twice as large as the other. Each compartment has a false floor to catch loose feathers, and is heated by a 750-watt thermostatically controlled immersion-type element, the temperatures being 190 and 140 deg fahr, respectively, in the small and large compartments. The operating costs are reported as 31 per cent of those with coal. A single-compartment insulated scalder used in the New England States is heated by a 2-kw immersion element, thermostatically controlled within $^1/_5$ deg fahr of the setting; it is used almost entirely for semi-scalding. Depending on age and type of bird, optimum semi-scalding temperatures range from 125 to 130 deg fahr and optimum immersion from $^1/_4$ minute to 1 minute.

COLD STORAGE. Egg storages should maintain a humidity of 82 to 85 percent and are usually kept at between 28 and 30 deg fahr, variations of more than 1 or 2 deg fahr resulting in watery eggs. A typical 800-case Texas plant, insulated all around with 8 in. of cork and having cottonseed hulls packed between the studs and to a depth of 6 in. over the ceiling, cost $2000. Eggs are frequently stored loose in cases until shipped, as they cool quicker, and a case holds 55 dozen loose eggs as compared to 30 dozen when packed. The average energy consumption for the 5 months' storage period of a 500-case Texas plant and an 800-case Texas plant (both plants rated in loose eggs) was 1.7 and 2.2 kwhr per case, the larger plant also serving as a domestic refrigerator.

GAME-BIRD-FARM EQUIPMENT. Electricity is used for incubation and brooding, materially reducing labor costs and disease losses. The uninsulated 100- to 150-watt 20-pheasant chick brooders on a farm at Saratoga, Calif., use during the average brooding period of 28 days (season extends from April 25 to September 25) an average of about 0.8 kwhr per chick raised.

INCUBATION. Well-designed electric incubators generally produce more and sturdier chicks, furnish no fire hazard, and have much lower operating labor requirements than types with other forms of heat.

Essentials of Incubation. While the actual proper incubating temperature (varying somewhat with type of poultry) is undoubtedly always the same, the thermometer reading varies from around 99 deg fahr (forced ventilation cabinet type) to 103 deg fahr (natural

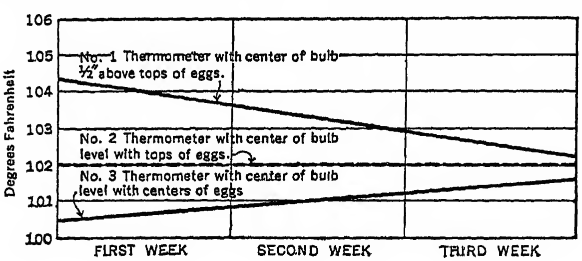

FIG. 3

ventilation flat-top type) with the thermometer location specified by the manufacturer. The center of the thermometer bulb should be just at the top of the eggs. (See Fig. 3.)

An **incubator cellar** had best be held at a temperature between 55 and 65 deg fahr, as providing proper ventilation at 85 deg fahr or above is very difficult and temperatures below 55 deg fahr greatly increase the energy requirements and with some machines lower the incubator temperature.

Emergency Heating is seldom provided (gas engine operated generators giving satisfaction), in cabinet types (forced ventilation) resulting in spotty heating. An alarm system should be provided, a combination which furnishes warning of no-voltage and high and low temperature, being best. The thermostats should keep total temperature variations below 0.5 deg fahr, some large machines having several separately controlled units in parallel. Mercury-type switches are most frequently recommended. California data indicate increasing likelihood of losses, (in case of power interruption), as the stage of incubation advances, proper temperature being particularly necessary while the chicks are hatching and are still wet; likewise the damage is usually less for 12-hr and 18-hr than for 6-hr interruptions, losses resulting from 24-hr interruptions usually exceeding those for 6-hr intervals.

After temperature, proper **humidity** is probably the most important factor in successful hatching; most machines with bad hatching records make a good showing when humidity is kept up. Higher humidity than required (can be reduced by increasing ventilation) does not lower the hatching percentage but may damage the glue and varnish of the

machine. Humidity can be increased by sprinkling the incubator cellar floor; by sprinkling the eggs; by the use of wet cloths, wet sponges, pans of water or wet sand (latter is more effective owing to greater surface) below the trays or, best of all, by regular humidifying systems now available at moderate cost. Machines should never be opened after the nineteenth day, a few beads of moisture on the glass observation door indicating proper moisture conditions. Under proper operating conditions the air cell of hens' eggs should be equivalent to a little less than one-third the size of the egg ($^{23}/_{32}$ in. deep) on the eighth day; one-third the size of the egg ($^{25}/_{32}$ to $^{13}/_{16}$ in. deep) on the fourteenth day; and two-fifths the size of the egg ($^{15}/_{16}$ to $^{31}/_{32}$ in. deep) on the nineteenth day. A more accurate way of checking up on the humidity is to weigh a tray of eggs from time to time. No egg should lose more than 0.33 oz by the nineteenth day. (See Table V)

Table V. The Normal Loss in Weight of 100 Ordinary Hen Eggs During the First Nineteen Days of Incubation

Day	Ounces	Day	Ounces	Day	Ounces	Day	Ounces
1	1.65	6	10.00	11	18.60	16	27.44
2	3.31	7	11.72	12	20.33	17	29.21
3	4.96	8	13.44	13	22.10	18	30.99
4	6.62	9	15.16	14	23.88	19	32.77
5	8.28	10	16.88	15	25.66		

Incubating chicks *breathe* through the egg pores, particularly at the air cells, and air containing more than 150 parts of carbon dioxide per 10,000 results in high mortality, actual fresh air requirements ranging from 1 to 10 cu ft per hr per 100 eggs. Little ventilation is required during the first two days, but after that, in a properly designed machine, the ventilators are gradually opened up to and including hatching so as to maintain proper humidity as the incubation period advances.

Flat-top machines are more adaptable than the cabinet type, and for farmers and small hatcherymen are less costly to operate since only as many units as are required need be used; also the full capacity of the machines set (instead of one-third as in the cabinet type) can be hatched at one time, saving growers considerable trouble in brooding. These small machines should have individual capacities of 1 $^1/_2$ to 2 cases of eggs. They can be stacked in compact tiers without legs or with very short ones. Many hatcherymen, for sanitary reasons, do no hatching in their cabinet-type machines, placing the eggs in "hatchers," or incubators made for that purpose, on the nineteenth day.

Practical units are available for converting oil-heated incubators to electric heat.

Energy Consumption, Wattage, and Cost of Incubation. The average energy consumption per 1000 eggs set of all-electric incubators ranges from 200 kwhr for small flat-top incubators to 25 kwhr for large cabinet or mammoth types. A well-insulated 200-egg machine has a consumption of 78 kwhr per 1000 eggs set as compared to the average of 134 kwhr for the same size of machine. A well-insulated 36-egg machine has a demand of about 130 watts. The average (say 600 egg) for all types is $^1/_2$ watt per egg (more for small and less for large machines). A drop of 20 deg fahr in the incubator cellar temperature apparently will almost double the energy consumption of poorly insulated machines. (See above under Incubator Cellar.) To obtain the wattage and energy requirements for turkey eggs, on account of their greater size and the extra week of incubation, the comparable data for hen's eggs must be multiplied by 1.67 (wattage) and 2.22 respectively. Kerosene-heated electrically ventilated incubators show averages per 1000 eggs set of 17.4 gal of oil, 17.0 kwhr for 2000-egg machines, and 4.3 gal of oil, 9.4 kwhr for 12,000-egg machines. California averages per hatch per 1000-egg capacity for 150- and 540-egg electric and 150- and 540-egg kerosene incubators are 250 and 200 kwhr, respectively, and 26.0 and 12.0 gallons of oil respectively.

Lighting. See Art. 7.

Water Heating. Nothing is gained by feeding chickens unless water is available, and it is apt to take several weeks to get them back into production after the slump which frequently follows any serious variation in regular routine such as a lack of water on cold days. Providing warm water instead of allowing ice to form results in an increase of about 20 per cent in water consumption, but three-fourths of this gain is due to keeping the ice melted and the other one-fourth to keeping the water temperature from falling below 40 deg fahr, higher temperatures being of little value.

Poultry water heaters are of the immersion or clamp-on or stove types. The former is more efficient than the non-immersion type, but in most cases will burn out if left turned on while not immersed in water; a 30-watt, flexible, rubber pad type now available is not so affected. Stove-type heaters generally have three available heats; some of this type

have a tendency to short to the metal after a few months' service. Homemade heaters include cylinders of sand, containing a light bulb, for immersion; box heating, etc.

For 14-ft uninsulated buckets, and possibly for even 4-gal vessels, 30-watt, 50-watt, and 75-watt immersion will prevent freezing in mild, ordinary, and severe climates respectively; for stove-type heaters, up to 100 or 125 watts would be required. In the latitude of Richmond, Va., 25 watts in a box surrounding the base of the drinking vessel are generally adequate for 3-gal vessels. Reducing the quantity of water in the vessel raises the operating temperature. Insulation consisting in the first instance of 1-in. dry boards, and in the second of 2 in. of dry shavings, reduces energy requirements by about 25 and 40 per cent respectively, 50 watts with an insulated vessel apparently being about equal to 75 watts with an uninsulated vessel.

The convenience outlets should be on a circuit separate from the lighting. Sometimes two vessels can be heated from each outlet. During cold weather the units should be left on continuously.

6. FRUIT

APPLE-BUTTER MAKING. Apple-butter stirrers are readily operated by electric motors. A Missouri farmer reports the saving of one full-time seasonal hand (12 hours a day), the $^1/_2$-hp motor consuming 6.5 kwhr per 20-gal batch of apple butter (0.3 kwhr per gal). It takes three girls 4 hr to pare and cut into eighths the 12 bus of apples usually required per batch.

DRYING. See Art. 9.

FRUIT WASHERS. Merely wiping off the visible spray residue is not sufficient, and excessive washing destroys keeping qualities. Washing in a $^1/_3$ to 2 per cent solution of hydrochloric acid reduces the arsenic (calculated as A_2O_3) to the required 0.01 grain per pound of fruit, an effective water temperature of 90 to 105 deg fahr being required for waxy or oily varieties. A typical electrically heated commercial washer has a capacity of 250 boxes per hour and a practically continuous demand of 29 kw for heating the 300 gal of washing solution. For tanks, copper, copper alloy, and lead corrode, but Monel metal and waxed wood seem to be satisfactory. Some consider rotating submergers necessary for washing and spray nozzles close to the apples as essential to proper rinsing.

GOOSEBERRY GRADING AND CLEANING. A typical gooseberry grader consists of an inclined table 6 ft long by 2 ft wide with a screened opening through which an air blast from a 4-in. fan operated by a $^1/_2$-hp motor is directed, the strength of the air blast being regulated by a sliding door on the table. The considerable amount of leaves and trash gathered with the berries in the process of stripping from the bushes, together with the wormy fruit, is blown away and the small berries are blown to one side on to a shelf directly above the inclined table. The average energy consumption is about 1 kwhr per 6900 lb of gooseberries cleaned.

GRADING. See Art. 11.

WAXING LEMONS. A typical lemon waxer has 15 kw of heating in the polishing chamber, 2 kw of heating in immersion elements serving the wax melting and atomizing unit, and 1 kw of heat for the air used by the atomizing fan.

7. FARM LIGHTING (INCLUDING ULTRA-VIOLET LIGHT)

ADVANTAGES. Chores usually can be done with electric lights in about two-thirds the time required with a lantern.

Where the ceiling and walls are dark in color the use of reflectors will increase the useful light from a given wattage lamp by as much as 100 per cent under extreme conditions. In the usual low-ceilinged barn the lights should be mounted as high as possible so as to lessen the chances of lamp breakage by livestock, etc. Workbenches and other working areas should have their own light outlets. Toggle-type wall switches are preferred, and the lighting in a large building should be divided into suitable sections with separate switch control. Only vacuum lamps should be used in granaries and other dusty locations.

Sheep feeders have increased the capacity of their feeding barns 20 per cent by keeping the lights over the feeding racks on during the night. A light spacing of 20 ft seems satisfactory.

In feed-storage barns a small floodlight with a 150-watt lamp can be mounted as high as practicable in the mows at the ends of the barn. The lighting is sometimes furnished by reflecting units (equipped with 100-watt lamps) having detachable heads which make lamp renewals from the floor possible. They are mounted over the driveway.

The lights in dairy barns usually should be located just over or back of the cows' rumps, preferably with at least one light to each four cows.

Both the silo and silo chute can be reasonably well lighted by one 100-watt lamp and reflector properly mounted at the top of the ladder.

The **average energy consumption** for farm lighting outside the house is around 10 kwhr per month, very little being used during the summer. On some dairy farms the consumption is several times higher.

Yard and Protective. Yard lighting should be controlled as required, for example, from the house, barn, and garage. The equipment should be weatherproof. Yard lights also furnish considerable protection against thievery, and in some cases 200- to 250-watt flood lights are also used.

Special. Under favorable conditions lighted electrocutors over ponds furnish ducks with considerable insect food. (See also under Insect Traps.)

Poultry House. Lights are used to lengthen the feeding day for poultry, especially during the winter. They hasten the development of pullets, control the molt of hens, increase winter egg production (may even slightly increase the total yearly production), and are also used to push hens to the limit just before they are sold for meat. All-night lighting eliminates stampeding in duck houses.

The system used varies: (1) morning lighting; (2) combination morning and evening lighting (thought by many to be most suitable); (3) evening lighting; (4) midnight lunch (feeding all the scratch grains hens will eat when the lights are turned on at, say, 9 P.M. for 20 or 30 min—longer for first few days); (5) all-night lighting (regarded by some as not suitable for hens which are to be kept another season). Some method of dimming is generally used where the lights are turned off at night, automatic or manually controlled switches and resistance (small-wattage lamps sometimes placed in series with regular lamps), or small-wattage lamps on a separate circuit being most frequently used.

A light with reflector is located every 10 ft along the length of the house (one 40-watt lamp for each 200 sq ft) half way between the edge of the dropping board and the front of the henhouse. In some cases 25-watt lamps are used; in others, where each unit serves 300 or even 400 sq ft, 100-watt lamps are used. For all-night lighting usually a 15-watt lamp is placed over each feed hopper; 60 watt CX Mazda lamps have been used with great success.

A 12-hr day is used for breeders, a 13-hr day for completely molted high-producing birds, and a 13- or 14-hr day for late August or early September molters and mature pullets of good vitality but not of the highest production quality, neither of which are to be used for breeders the following spring.

On the basis of 3 $^1/_2$ or 4 sq ft per bird the wattage per 100 birds will range from 30 or less to about 120, and the energy consumption per 100 birds per month for the lighting season from 2 to 12 kwhr (reaches the latter figure only with all-night lighting), depending on lighting plan and the particular month.

ULTRA-VIOLET LIGHT. Poultry. Ultra-violet light is having increased use by poultrymen as, under most producing conditions, it increases the vigor of birds, both young and old, lowers mortality and increases the number and hatchability of eggs.

Cows. Udder treatment hastened recovery from mastitis—15 min daily treatment with either a carbon arc or a mercury-vapor lamp. University of Wisconsin appears to have increased the vitamin D content of milk by direct irradiation of cows, but other stations have failed to substantiate this.

Hogs. Extensive treatments of both hogs and pigs seem to have no effect whatsoever.

Horses. Race-horse owners find ultra-violet lamps of considerable assistance in maintaining the health and general condition of the animals during the winter months. Such treatments also increase the rate of growth for colts. On one farm where race horses, polo ponies, etc., are kept, ultra-violet light and portable infra-red ray hand-sets have proved very helpful in speeding up the healing of cuts, bruises, and other minor injuries.

Lambs. Ultra-violet light is of considerable assistance in increasing the number and rate of growth of " hothouse " lambs.

Sheep. Treating ewes' feed with a mercury-vapor lamp at a distance of 30 in. for 30 min changed their calcium balance from negative to positive.

8. IRRIGATION AND WATER SUPPLY

IRRIGATION AND IRRIGATION DRAINAGE. Outside of the arid regions with their large developmental projects irrigation is an individual farm problem. Even in humid and semi-humid areas having water available at critical periods sometimes results in saving enough of the crop that otherwise would be lost, to entirely pay for an irrigation system in a single season. However, irrigation practice in such areas is generally limited to the raising of high-priced crops reasonably close to good markets.

Cost and Value of Irrigation. The first cost of irrigation plants pumping from adjacent streams or shallow wells does not run below \$10 or \$20 per acre, and the initial cost for the least expensive deep well pumping installations is around \$100 per acre—under less favorable conditions it may be several times higher. However, the water rights on some of the contemplated western irrigation projects would amount to \$158. For spray systems a first cost of at least \$300 per acre is expected.

For surface irrigation, estimating 20 per cent for interest, depreciation, and taxes on an average investment of \$75 per acre—\$15; \$10 per acre for fuel; \$5 per acre for repairs and incidentals, and \$5 per acre for labor (assuming a labor cost of \$4 per day, 2 acres irrigated per day per man, and 2 1/2 irrigations per season), we have a total irrigation cost of \$35 per acre. One man can irrigate from 1 1/2 to 3 acres per day by the furrow method and somewhat less with portable pipe. A conservative estimate for the total cost of spray irrigation is \$50 per acre. The average total irrigating cost for a typical sub-irrigation installation in Florida (35 acres) is \$47.60 per acre. A good average cost for surface irrigation is \$1 per acre-inch.

Not infrequently one irrigation at a critical period during a week or 10 days' drought will result in saving enough of the crop to pay for the irrigation plant in one year. A Virginia orchardist estimates that his \$4880 irrigation system, serving 50 acres of apples, paid for itself during its first year of operation (the dry year of 1929). In dry years (humid areas) small fruits without supplemental irrigation are frequently a total failure owing to a lack of moisture.

Where the irrigation system is used for emergencies (droughts) rather than regularly, efficiency of equipment is of less importance than first cost.

Energy Consumption. For surface irrigation from 2 to 4 kwhr per acre-foot (12-acre inches) are actually required for each foot of lift, theoretically only about 1 kwhr being required. Because of the more efficient use of water, the energy consumption per acre-season for spray irrigation is usually considerably lower than for surface irrigation in spite of materially higher requirements per acre-inch. The total energy consumption per installed horsepower per year (surface irrigation) runs from 200 kwhr, or even less in a few cases, to 800 or more kwhr, the latter apparently on farms being operated by the more aggressive farmers.

The seasonal distribution of irrigation energy requirements in Kansas are rather typical: 75 per cent during June, July, and August (20 to 25 per cent in July and 30 to 35 per cent in August); 15 per cent in September, and 10 per cent during the rest of the year.

WATER SUPPLY. A water system is a great labor saver, and, through the accessory plumbing, etc., a major factor in farm sanitation, water also being supplied for fire protection, lawn sprinkling, garden irrigation, milk-house use, etc. The water supply should be adequate in quantity (see Tables VI and VII) and of good quality. A large proportion of farm wells are contaminated, and where there is any chance for surface or subsurface leakage—the latter sometimes coming from a considerable distance—the water should be analyzed.

Table VI. Amount of Water Used Daily Per Individual

	Gallons
When water is carried by hand	6– 8
One pump at kitchen sink	8–10
One faucet at kitchen sink	10–15
Running hot and cold water in kitchen	15–20
Complete plumbing, and water under pressure	20–40

Table VII. Average Unit Water Requirements per Person and per Head of Livestock*

	Gallons per Day
For each member of the family for all uses including hot and cold water services in kitchen, laundry, and bath (45 to 50 gal in some cases, according to data from Illinois)	35
Schools, per person (3 to 15 gal)	7
For each horse, mule, or head of cattle (4 to 20 gal, varying especially with the season)	15
For each cow (summer as high as 40 gal)	25
For each hog	2
For each sheep	1 1/2
For each 100 chickens	2 1/2

* The gallons per person in this table may be somewhat higher than recommendations which are sometimes given, but they represent the use which is normally made of water when sufficient time has elapsed for the farmer and his family to fully appreciate the conveniences offered by the automatic water system. Water requirements preferably should be figured for maximum consumptions so as to take care of the peak demands, generally occurring in the summer.

A complete water system can be installed gradually without materially increasing its total cost, a pump jack and motor with valveless piping to the stock tank and kitchen sink being the first step. Three-way switches are located at the house and well or stock tank, and the three-way frost-proof valve is turned so that water is pumped directly to the house except when the stock tank is being filled. An overhead tank with a check valve below the faucet so that the water is available only at the kitchen sink is generally a second step.

The plumbing system should include a shower in the basement. Plans for the septic tank can usually be obtained from the State farm bureau or college of agriculture. Milk waste may require a capacity increase in the septic tank of 100 per cent or more. The disposal tile are usually 12 to 18 in. deep, 30 to 50 ft being provided for each person in the home.

Soft water can usually be supplied at lower total cost by water softeners than by cisterns and pumps, the annual total costs according to typical data being $25 and $30 respectively. Zeolite softeners readily remove common lime hardness, due to calcium and magnesium, but ozonators seem to be the only type effective with iron salts.

Pumping Units. Shallow well pumps can be used where the maximum depth to water does not exceed 22 ft. Deep well cylinders should be 15 to 20 ft below the water surface, when the water is at its lowest point for the year. Small centrifugals are not adapted to pumping against heads of more than 25 or 30 lb, and the suction lift should not exceed 15 or at most 20 ft. Air systems are comparatively inefficient but always furnish fresh water. Pump jacks should be of the quick return type. Outdoor faucets in areas subject to freezing weather should be of the anti-freeze type. A float switch set at the low-water mark on the water tank permits the windmill to pump considerable water, the motor pumping only when the water supply becomes excessively low. Ordinary water systems are easily equipped with fresh water taps.

It is seldom advisable to install a system with a capacity of less than 400 gal per hr unless the water supply is inadequate, in such cases more storage being essential. For fire protection a 2-hp motor and a tank supplying 2000 or more gallons of water probably constitute the smallest installation that will furnish reasonably adequate fire protection, though it should be remembered that some fires can be controlled only by sand, chemicals, or other suitable materials. Frost-proof outlets should be provided on every side of the barn and at other strategic points, and two $^5/_{16}$-in. nozzles, a 50-ft length and 100-ft length of 1 $^1/_2$-in. rubber hose should be available in some definite location which is free from fire risk. The wiring and the pumping equipment itself should not be subject to fire hazard.

The overall efficiency of water systems varies from 5 to 35 per cent, 25 per cent being considered very good. The efficiency of pumps, piston types particularly, depends quite largely upon the state of repair.

The energy consumption of farm water systems ranges from 0.5 to 60 kwhr per month (50 kwhr for a typical 60-cow wholesale dairy), 25 kwhr being a fair average. In the South the average is 15 to 20 kwhr per month. The average consumption for home use is 4.5 to 5 kwhr per month but may climb to 8 or 10 kwhr per month with more liberal use of water. Low lift centrifugals have very low energy requirements, for example, 0.55 kwhr per 1000 gal for a $^3/_4$-in. centrifugal lifting water 17 ft into an open stock tank.

Water pumps and systems should be on separate electric circuits and should be provided with switches and reliable inverse time relays, fuses being unsatisfactory.

9. DRYING AND DEHYDRATION

Drying

See also under Dehydration, p. 19-23.

Corn. Corn may be dried, or else the temperature may be kept low enough to prevent spoilage until it is fed. A Minnesota farmer, for example, prevented spoilage by storing his corn to a depth of 5 ft in a crib with 16-in. screened air vents at 2-ft intervals along laterals 3 or 4 ft apart, the long distributing pipe being connected with the 18-in. 144-watt 1500-cu-ft-per-min fan used to ventilate the cow stable. Outside air was used. Only 3 kwhr were consumed, the fan being operated 1 $^1/_2$ hr daily for 2 weeks. The fan was also turned on for a few days in the spring. Generally a fan used for drying is operated at intervals as necessity demands.

For real drying, heated air (above 125 deg fahr lowers germination and does not materially increase drying efficiency) is advisable—absolutely essential during moderately cold damp winters. In a typical case the moisture content was reduced in 183 hr from 38 to 22.6 per cent by forcing hot air through a longitudinal slotted core running through the center of the crib, at a cost of 9.8 cents per bushel (0.93 gal of oil at 7 cents per gal and 0.66 kwhr at 5 cents per kwhr), or $5.57 per lb of water evaporated, an improved direct heat portable dryer reducing this cost to $3.25.

Grain and Small Seed. The combine has greatly increased the demand for drying. Sweet clover has been successfully dried by permitting it to flow from a storage bin over baffles while hot air from an enclosed coke-heated brooder stove was forced up through it, an elevator carrying the seed from the bottom of the shaft to the bin. Similarly a batch dryer developed in Sweden has a sloping bottom so arranged that grain is drawn from the bottom, blown through a pipe with heated air, and scattered over the top of the grain bin.

Unless grain is stored on the farm, drying is generally done most economically at the elevator. In some cases wheat can be kept from spoiling by moving to another bin as required. In Kansas it has been found possible to reduce the temperature of the grain to about two-thirds the difference in temperature between the grain and the outside air—six movements reducing the moisture content by 2 per cent with an energy consumption per 1000 bu moved, of only 6 kwhr with chain and tubular elevators, or twice as much for blower-type elevators. Wheat, to keep safely, must not contain more than 12.5 per cent of moisture. Passing the grain through a fanning mill on its way to another bin greatly increases the drying and cooling effect. For drying, 130 deg fahr is just as effective as higher temperatures, and 5 or 6 per cent of moisture can be removed per hour with an air flow of 65 cu ft per sq ft per min, with 1/2 bu of wheat per sq ft of area.

Hay. About one-half (by weight) of good alfalfa hay is leaves, and a properly managed acre is almost equal to an acre of corn. Hay from immature cereals, as well as alfalfa and other legumes, has a protein content above 20 per cent (see Table VIII); in fact, feeders using such hay have been able to reduce the protein content of their concentrates from 18 to 12 per cent without reducing the milk flow. In two typical cases the substitution of artificially dried for sun-dried alfalfa hay resulted in increases of 2/3 and 1 quart respectively in the milk flow per cow per day. Artificially dried corn with no succulent feed produces as much milk per pound of dry matter as corn silage.

Table VIII. Average Composition of Alfalfa at Different Stages of Maturity *

Feeding Stuff	Water	Ash	Crude Protein	Carbohydrates		Fat
				Fiber	N-free Extract	
Alfalfa—all analyses	8.6	8.6	14.9	28.3	37.3	2.3
Alfalfa—before bloom	6.2	10.0	22.0	20.5	37.1	4.2
Alfalfa—in bloom	7.5	10.0	15.0	30.2	35.5	1.8
Alfalfa—in seed	10.4	7.0	12.2	27.6	40.3	2.5
Alfalfa leaves	6.6	13.6	22.5	12.7	41.2	3.4

* Data from University of Wisconsin.

The total cost of drying hay (overhead, fuel, labor, etc.) runs from $3.50 to $10 per ton. In actual practice one-half of the water is often removed in the field. The fuel requirements run as low as 26 gal of oil, 3000 cu ft of gas, or 200 lb of coke or coal per ton of dry hay. The total horsepower requirements vary with design, ranging from 5.5 to 135 per machine, the average energy consumption probably being around 40 kwhr per ton of dry hay. It is considered necessary to dry at least 500 tons of hay annually if the cost per ton is to be reasonably low, unless the dryer is also used for drying other products such as grain, small seeds, apple pomace, beet tops, orange peel and pulp, pea vines, salt, seaweed, sugar cane or corn stalk refuse, peat moss, or manure. In several cases manure is being dried. See Fig. 4.

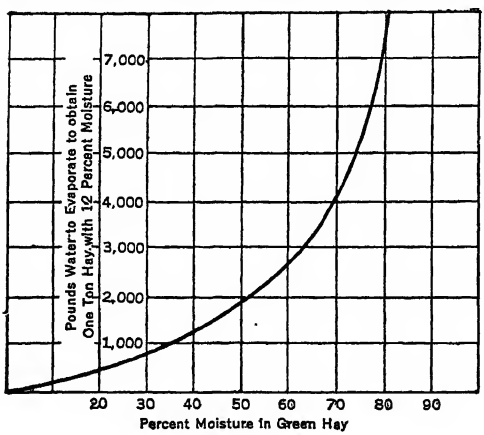

FIG. 4

Manure. Both chicken and cow manure are being successfully dried, but the drying costs per ton are higher for the latter. Peat moss is used for bedding; 100 lb absorbs 1500 lb of water as compared to 550 lb of water for straw.

In a typical case a machine ordinarily used as a hay dryer has a 6 by 40 ft drying drum, with a slope of 1/4 in. per ft towards the outlet which revolves at 11 rpm, has a capacity of 0.6 ton of dried cow manure per hour, a demand of 66 hp (94 hp when used for drying hay), a light oil consumption of 100 gal per dry ton (about 8000 lb of water evaporated per ton of dried product), and requires a crew of three. The hot air, at 1800 to 2000 deg fahr, enters at the wet end, as dry manure is very inflammable. The dried product is generally run through a hammer mill; it is odorless, and 7 bu weigh only 100 lb.

Rice. The combining and drying of rice results in a higher market price and materially lower field losses, the total cost of drying in a typical case being around 6 cents per bushel. However, unless the drying is done in steps, permitting the rice to season before it is further dried, the rice may even be lowered in milling quality and grade by checking and cracking of the kernels.

STRAW FLOWER DRYING. A 10 by 10 by 6 ft high cabinet automatically heated by 12 kw on the pipeless furnace principle (heated air diluted with fresh air and cold air circulation also provided) has a capacity of 8000 to 10,000 flowers every 8 hr (three batches each day), and an average energy consumption of a little less than 1 kwhr per hr of operation.

Dehydration

See also under Drying, p. 19-21.

Fruit. Dehydrated fruit (dried with temperature, humidity, and air velocity control) retains its natural flavor and quality to a very much greater degree than ordinary evaporated fruit; it also refreshes to almost the original weight, upon proper soaking, as compared to a loss of about 20 per cent with ordinary evaporated fruit. Apples, apricots, blackberries, blueberries, crabapples, loganberries, peaches, pears, plums, prunes, and raspberries are successfully dried, but gooseberries are not; cherries bleed badly, and drying of strawberries is not recommended. In many cases the drying plant should be operated in close cooperation with or as a part of an undertaking meeting the needs of the entire industry, for example, a fresh fruit warehouse, cider and fruit juice mill, and jam, jelly, and marmalade plant.

Most fruits, except berries, require preparation for drying. For example: the bloom on prunes and plums is cut by dipping in a lye solution; apricots are halved and pitted; apples are peeled, cored, trimmed, and sliced; peaches are split, pitted, and may or may not be peeled; pears are halved and cored and may or may not be peeled. (See also Calif. Bul. 485; Dom. of Canada Dept. of Agr. Bul. 90, Table 2.)

Grape dehydration in California is limited largely to Thompson's golden bleached and some seedless, no wine or juice grapes being dried except to prevent rain damage or to salvage slightly damaged fresh fruit. Prune dryers which are flexible enough to meet the greater heat and air demands (air velocity of 700 to 1000 lin ft per min) can be used. The finishing temperature should not exceed 165 deg fahr, at the same time relative humidity being around 25 per cent. At an average total cost of $9.51 and a 3 1/2 to 1 shrinkage ratio, drying costs amount to $35.66 per ton of dry raisins, the operating costs of $5.06 per fresh ton equaling $18.98 per ton of raisins, on the average. (See Calif. Bul. 500.)

Table IX. Drying Ratios for Fruits

Apples	8 : 1
Apricots	4–7 : 1
Figs	1 1/2 : 1
Grapes (Thompson's golden bleached)	3 3/4 : 1
Peaches	4–7 : 1
Pears	4–7 : 1
Prunes	2–2 1/2 : 1

Prune dehydrator data from Oregon on modern air-blast and natural-draft air dryers show average fixed charges of $3.65 and $3.43 and total operating costs of $7.76 and $7.64 per fresh ton, respectively (about 1 cent per lb of dried fruit); likewise for forced-draft and sun dryers a ground area of 1 acre for tray space takes care of 400 acres and 20 acres of prunes respectively. Fans increase the capacity of natural draft dryers by about 50 per cent. The fruit enters the cooler end where the temperature is kept between 120 and 140 deg fahr, and leaves at the hot end where the temperature should not exceed 165 deg fahr, the humidity being kept at around 25 per cent; the dried prunes are stored for at least 2 weeks in bins (for moisture equalization) before delivery to the packing house. The drying time ranges from 20 to 36 hr—from 28 hr up for large prunes of 40 or less per pound, and around 24 hr for 50- to 60-per-lb sizes. The energy consumption per ton of dried prunes for fan operation ranges from 80 kwhr in California to 95 kwhr in Oregon. The average horsepower requirements per ton of capacity (in fresh fruit) are 1 1/2 in California and 1.87 in Oregon; in California prune dryers have a capacity of 4 to 40 tons of fresh fruit daily—an average of 16.5 tons daily, or 350 tons during the 3 weeks' season; in Oregon the season capacities range from 30 to 800 tons and average around 300 tons

for the 3 weeks' season. California and Oregon prunes differ in size, the average weights per square foot of freshly trayed fruit being 3 1/2 and 4 1/2 lb respectively. Homemade dryers of simple design seem on the average to operate as efficiently as the more elaborate and expensive manufactured types.

Hops. Hop kilns are generally 30 ft square, one room, and the drying floor is 14 to 20 ft above the ground, the hops being placed 14 to 18 in. deep on this lattice floor. In a particular case a 15-hp motor drove the ventilating fan, a total of 50,000 lb of hops being dried in the 20-day season. It is estimated that an electrically ventilated hop dryer uses 125 to 150 kwhr per 1000 lb of hops (dry weight) dried, five 1000-lb bales being an average production per acre. Forced draft reduces the drying time per batch to 9 hr as compared to 16 hr for natural draft, enabling the grower to reduce his dryer space by 45 per cent.

Vegetables. Properly dried beans, beets, carrots, peas, pumpkin (first class for pies), potatoes, squash, spinach, and turnips regain practically all their fresh appearance and flavor when refreshed. Beans, corn, and peas are better if blanched before drying; potatoes require sulfuring. (See also under Dehydration, fruit.)

Walnuts. Large numbers of walnut dehydrators are electrically ventilated and a few are electrically heated. This method of heating is made possible by: (1) dividing up the high demand, the electricity when not needed for drying also being used for other purposes such as irrigation; (2) the small amount of moisture removed (12 to 25 per cent before and 8 per cent after curing); (3) equipment of twice the ordinary efficiency (95 per cent of air recirculated in a typical case), 44 per cent as compared to 22 per cent (however, the unit costs about $5000 as compared to $2500 for the average); (4) handling of larger tonnages per dryer, 150 as compared to 50 tons on the average. Several growers have made quite a saving in overhead by using their prune equipment for drying walnuts even though the walnuts have a maximum drying temperature of about 112 deg fahr as compared to around 165 deg fahr for prunes. The available data for electrically heated dryers shows total overall operating costs ranging from about $7 to $11 per ton of dry walnuts for the compartment type, typical energy figures per dry ton being 32 kwhr for power and 160 kwhr for heating. The connected load for heating bin and compartment-type dryers averages around 20 and 10 kw per ton of capacity in dry walnuts, respectively, and the fan load in both cases varies from 1 to 3 hp per ton of capacity (dried walnuts). It takes from 12 to 24 hr per dehydration, the season lasting about 3 weeks.

Prune, walnut, and hop dryers, if developed together, apparently offer the power company an attractive load; for example, in Oregon prune drying usually comes during the first 3 weeks of September, hop drying begins around the middle of September, and walnut drying around the first of October.

10. HOTBEDS

HOTBEDS. Seeds germinate, plants grow, and cuttings root in 20 to 30 per cent less time in electric hotbeds than with the other methods in common use. Furthermore, electric heat lends itself to automatic or manual control, and plants can also be grown in the fall when maximum heat is required at the end of the growing season. Considerable frost protection is also easily provided for. The beds do not need rebuilding each year, only the top soil being replaced every few years as required.

A cubic yard of ordinary 2-horse load of manure (enough for a 6 by 6 ft bed) furnishes about the same amount of heat as 90 kwhr of electricity. The average total first cost of equipment is about $12 per sash, and the average energy consumption (also varying widely) around 2 kwhr per day per sash, data from Ithaca, N. Y., for example, showing a range of 1.1 to 4.8 kwhr per day per sash. Each installed kilowatt is estimated to use an average of 1000 kwhr per season or in most areas from 10 to 15 or more kwhr per actual day of operation. Very little energy is required for frost protection. In cold climates good insulation will reduce operating costs about 30 per cent. Cinders outside, and some say also below the bedsoil, and two sets of single sash, one on top of the other, are recommended. In some sections banking with soil and the use of double burlap mats at night have proved satisfactory.

A thermostat saves energy and gives closer temperature regulation.

For ordinary frost protection 50 to 60 watts per sash are adequate; for ordinary service 120 to 150 watts per sash are satisfactory, and for very cold climates 200 to 250 watts per sash are used.

Cable must be used in approximately the lengths for which it is designed, less cable giving more wattage (danger of burning out) and vice versa.

Lead-covered cable is decidedly the most popular source of electric heat for hotbeds,

but space heaters, loop heaters, and open coil heaters (all but the cable located in air spaces below the bedsoil) are also used.

Table X. Maximum, Minimum, and Optimum Germinating Temperatures and the Corresponding Germination Period for Some of the Commoner Vegetables *

	Temperature, Lowest–highest, in deg fahr	Corresponding Days for Germination, Lowest–highest, days	Most Suitable Temperature, Lowest–highest, in deg fahr	Corresponding Days for Germination, Lowest–highest, days
	1	2	3	4
Radishes	39–77	23–2	50–59	7–3
Lettuce	41–79	20–3	59–68	6–3
Cauliflower	41–77	23–4	50–68	11–4
Peas	39–77	25–4	50–68	10–4
Onions	43–79	30–7	54–72	14–8
Parsley	45–77	35–9	57–72	15–9
Celery	45–82	40–9	57–75	15–9
Beans	52–81	26–3	59–72	10–4
Tomatoes	52–82	25–5	63–75	10–6

Cantaloupes	61–86	20–5	72–82	6–5

* Data from Maurice W. Nixon. Columns 1 and 2 refer to maximum and minimum temperatures and corresponding average germinating periods; columns 3 and 4 refer to optimum temperature ranges and corresponding average germination periods.

Temperature is the most important consideration in the successful operation of hotbeds, cutting benches, etc. (See Table X.) Plants raised in such equipment require regular watering, and during the daytime (warm or hot days) the sash in hotbeds must be raised at the lower end, as required, so as to prevent damping off.

11. MISCELLANEOUS

ALARMS: Burglar, Fire, and No-voltage. A burglar alarm preferably should work on the closed-circuit principle, and the relay, after even the shortest possible current interruption, should require resetting by hand. In this way the alarm bell will continue to ring until it is reset.

The alarm should be so arranged that no matter how the wires are tampered with, especially by " bonding " and " cutting," the system will still give the alarm. If the resistance (high-voltage type) is placed out of reach in the protected building, the bonding of the wires would short the holding coil of the relay and blow out the fuse in the relay circuit, assuming proper relationship between resistance of relay coil and wires, and a suitable size of fuse or circuit breaker. This, of course, would give the alarm. Placing the transformer or relay in one of the protected buildings will prevent effective bonding if the system is properly installed (Fig. 5).

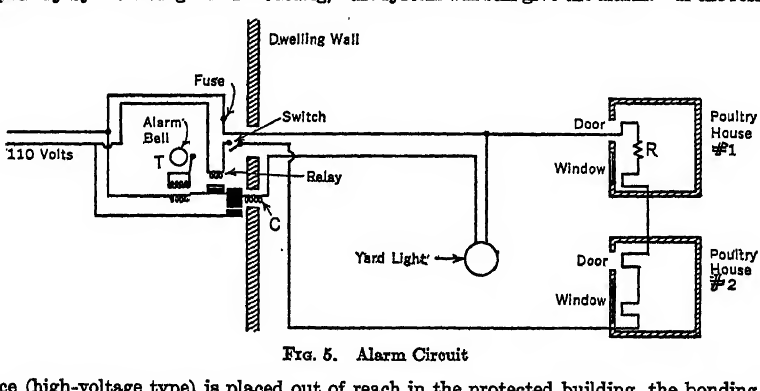

FIG. 5. Alarm Circuit

In Fig. 5 the equipment is in the closed position (switch shown open) and relay set. T is a bell-ringing transformer and bell; C a flexible wire connection, the weight keeping the contacts closed when the switch is open; R a resistance—sometimes one or more lamps in series; and at each door and window are switches the opening of which gives the alarm and at the same time instantly floods the yard with light. Resistance is not ordinarily used with low-voltage modern relays. With batteries in the secondary circuit and the use of temperature relays the alarm will also serve to warn of no-voltage, fire, and low and high temperatures.

The wiring costs as a rule are materially lower for low-voltage than for 115-volt systems. A separate system is required for each building if the building tampered with is to be indicated. An annunciator may be cheaper than separate systems for large installations.

BONE AND SHELL GRINDING. Bone grinding requires considerable power as compared to feed grinding. In a typical case a 5-hp motor ground between 100 and 150 lb of bone per hr (20 to 30 lb per hr per hp) with an energy consumption of about 1.1 kwhr per 100 lb.

Oregon data show an energy consumption of 2 kwhr per ton for grinding oyster shell for baby chicks, coarse grinding requiring still less energy. A hammer mill would be expected to produce a higher percentage of finely powdered material.

BULB COOKING. Insect pests affecting bulbs are kept in check by cooking the bulbs in a water bath at 109.5 to 111 deg fahr for 2 1/2 hr; electricity readily adapts itself to such close temperature control. The machine tested (Oregon) has a demand of 2 kw for heating, a 1/4 hp motor on the agitator, and a capacity of 150 lb of bulbs (1000 average bulbs). It used about 2 kwhr per 100 lb of bulbs treated. With the insulated tank used, the heat may be turned off for as much as an hour at a time during the cooking process. Where steam is used for the initial heating of the water and electricity for maintaining the temperature (cooker insulated with 1 in. cork board), the consumption was 1.2 kwhr per 100 pounds of bulbs cooked.

CIDER MAKING. A typical small hand-press cider mill operated by a 1/2-hp motor crushed 144 1/2 boxes of apples from which 306 1/2 gal of cider were obtained, with an energy consumption of 2.5 kwhr (0.8 kwhr per 100 gal of cider).

CONCRETE MIXING. Most small concrete mixers can be satisfactorily operated by a 1/4-hp motor, in some cases 1/2-hp being needed. From 0.4 to 0.5 kwhr will ordinarily mix a cubic yard of concrete, more energy being required with finer aggregate.

COTTON GIN. Cotton gins require three-phase service, and the season extends from September 1 to January 1, the peak load coming in October. About 0.3 hp is required per saw, and available data show an average energy consumption of 16.67 kwhr per 500-lb bale for ginning and pressing.

ELECTRIC TRUCKS. Electric trucks are more economical for daily hauls of a possible maximum of 50 miles than ordinary gasoline trucks. In a typical case a dairyman's total costs ran between 3 and 4 cents per mile (87.5 kwhr per 100 miles of travel—3 cents per kwhr).

FERTILIZER GRINDING AND MIXING. Lumpy fertilizer is easily crushed or ground by burr mills set for coarse grinding. Hammer mills could also be used. Afterward the mill should be cleaned by running rock-free soil or grain through it. Fertilizer is sometimes mixed in concrete mixers, but the same facilities used for feed mixing (see Art. 3) can also be used, the equipment subsequently requiring careful cleaning.

GRADING. See also Grain and Seed Cleaning and Grading.

Apples. A grader with a capacity of 25 boxes per hour can be operated by an experienced crew of four or five packers, two graders, and one nailer; and assuming a first cost of $800, a grower would need an average annual crop of 4000 to 6000 bu (enough for one month's operation) to justify its purchase. The energy consumption ranges from 0.5 to 1.5 kwhr (an average of 1.0) per 100 bu or boxes graded. Most graders are operated by 1/2-hp motors, although 1/3 hp is ordinarily sufficient.

Bulbs. Graders save much time on market sizes, even though the mother bulbs with the small ones attached do go in with the large ones, and are entirely satisfactory for the bulbs to be planted for the second and third year—it usually requires 3 years to grow bulbs to market size. In a typical case a machine operated by a 1/4-hp motor and equipped with 1-in., 1 1/2-in., 2-in., and 2 1/2-in. screens, graded 177 lb of bulbs in 6 1/2 min.

Potatoes. A 1/2-hp motor on a potato grader will handle from 600 to 700 or more bu of potatoes per kwhr used, and save the labor of at least one man.

HONEY EXTRACTING. A 1-hp motor will operate most honey extractors.

HORSE-RADISH SHREDDING AND MUSTARD SEED GRINDING. A combination farm plant of this type is operated by a 15-hp motor.

INSECT TRAPS. Flies while still sluggish from the early morning chill can be sucked up with a vacuum cleaner, and an ordinary fan is often used to keep them away

from open cans of milk, cream, etc. The gnat population near summer resorts has been materially reduced by luring them with lights, to the vicinity of an electric fan exhausting into a canvas bag. Electric screens and screen doors are quite effective, and a typical fly trap in Texas captured 6 gal of flies in 4 days, from that time on the number of flies about the dairy being noticeably less. Such traps (unlighted) have a demand of about 8 watts, furnish about 4000 volts, and use about 5 or 6 kwhr per month, continuous use. Some tests in apple orchards with light traps of different kinds show the electrocutor type mounted in the top of every other tree in alternate rows to be most effective. In fact, fully as good results were obtained as by spraying, and where apples were protected by both traps and spraying, twice as many good apples were obtained as by either alone. However the data have not as yet been generally accepted as completely conclusive. In Japan, lights were found to reduce materially the insect losses in the rice and tea crops and to lessen the damage to mulberry trees. (See also under Special Lighting, p. 19.).

LADYBIRD BUG HATCHING. A typical ladybird bug or Limoniera ranch (Southern California) has 25 rooms, each 8 by 16 ft with 8-ft ceiling and usually insulated with $1/2$ in. of celotex. Each room has a capacity of 125,000 beetles per crop, and an energy consumption of about 23.2 kwhr per day of operation, or 0.068 kwhr per beetle. The rooms are automatically kept at 70 deg fahr during the three weeks occupied in raising potato sprouts; at 80 deg fahr for a like period when the sprouts are infected with mealy bugs, and at 75 deg fahr during the next seven weeks when a few ladybird bugs are liberated and propagated. As the bugs mature they fly to the light and gather on a piece of muslin over the window, where they are collected and placed 10 in a capsule. They are sold for about $1/3$ cent per bug to owners of Valencia and navel orange and lemon orchards one capsule being used to a tree. The bugs are always available except during the rainy season.

MOTORS. See Portable Motors.

MUSHROOM HOUSES. Packed mushrooms and prepared spawn are held in electrically cooled storages. Electric pumps furnish water and in some cases electricity lights the houses. Some growers have installed refrigeration so as to keep their summer temperatures around 55 deg fahr and as a result are able to sell mushrooms the year around.

MUSTARD SEED GRINDING. See under Horseradish Shredding and Mustard Seed Grinding.

PAINT SPRAYING. Seven times as much area can be covered in a given length of time by an experienced operator with a good gun as by a good painter with a hand brush. Furthermore, paint losses are no higher, and with a guard, trim can be added, little retouching by hand being necessary. About 800 sq ft of straight wall surface can be covered in an hour (experienced operator) with an average energy consumption of 1 to 1 $1/2$ kwhr. An Illinois farmer, operating a machine for the first time, covered 2000 sq ft of barn surface in 8 hr, using 0.42 kwhr per 100 sq ft.

Whitewash has been successfully removed by using a $1/32$-in. nozzle and an air pressure of 160 lb. The air is also used to inflate automobile tires. Smaller and less expensive equipment is also available.

PEA VINERS. Twenty-horsepower motors are commonly used. Wisconsin figures for 1926 show a consumption of 4 kwhr per 100 lb of peas shelled, and plant consumptions ranging from 2751 to 3145 kwhr. The season lasts from the middle of June to the last week in July, the plants usually being operated from daylight until dark.

PORTABLE MOTORS. Two portables, a $1/4$- or $1/2$-hp motor and a 5- or 7 $1/2$-hp motor, will operate all the usual farm machines not provided with attached motors. In some cases the small type is provided by various companies with one or more other features such as gear reduction, a tripod, a multistep, V, or flat pulley, a belt tightening base fastened with a wing nut and flexible direct drive. Belts on the large portables are tightened and kept tight in various ways: by blocking, telescoping tongues on the truck, bases moved by screw cranks, fence stretchers, block and tackle, and by a hinged base arrangement which automatically adjusts the portion of the motor's weight resting in the belt to suit the torque required—this type of base also being used on small motors (not expensive). Flat belts should be pliable and preferably endless; at least the lacing must be light. Higher belt speeds are possible with V-belts. Owing to first cost, standard 1800-rpm motors are most commonly used. Motors having high starting torque without starting clutches give trouble less frequently than other types.

SHAVING, ELEVATING. See Elevating Grain and Shavings, Art 3.

SHELL GRINDING. See Bone and Shell Grinding.

SHOP EQUIPMENT. A 1-hp motor is large enough for most farm shops but driving several machines from inefficient line shafting may make a larger motor necessary. A large motor in a well-equipped shop on a large farm will use 4 or 5 kwhr per month, but on a moderately sized farm in South Dakota a 3-hp motor in a shop equipped with a steel

drill, wood lathe, grindstone, small circular saw, large meat grinder, two or three emery wheels, and a buffer, all operated through a line shaft, used only 52 kwhr in a year.

SOYBEAN COOKING. When soybeans are cooked (not nearly so satisfactory a feed when uncooked) they are a very good substitute for tankage and considerably cheaper. A well-insulated electric cooker holding 2 bu of raw beans and 20 gal of water is heated by 2 kw in heating elements, and about 15 kwhr are required to cook a batch, the total cooking time being 10 hr. Cooked soybeans will save cash outlay for tankage and shorten feeding period for hogs by 2 or 3 weeks.

STATIONARY SPRAY PLANTS. With stationary spray plants the spraying can be done in one-half to one-third the time that would be required with portable equipment (a saving of 38.8 per cent in a typical case); spraying can be done regardless of the ground condition (has been done from boats); in irrigated sections the irrigation ditches are not injured; fruit is not knocked off or trees injured; the soil is not packed; the plant does not jar out of adjustment, and it lasts longer; spraying can be done on extremely rough ground; and last, but certainly not least, each man can spray at his own gait.

Cost of Equipment. The average cost per acre of stationary spraying equipment ranges from $50 to $90, frequently being no greater than the cost of portable equipment for the same area. Approximately 6.35 kwhr are required per spray per acre, or close to 50 kwhr per acre per year for an average of 7.5 sprays (Washington data).

transformer, 10–14
Cooper-Hewitt mercury-vapor lamp, 15–19
Coordinated insulation, 14–110
Coordinated transpositions, 14–116
Copal, 2–28
Copel, 2–09, 18–22
Copper, 2–02, 2–05, 2–07, 2–50, 6–06
alloy wires, 14–153, 14–161
cables, 14–156 to 14–163 (see also **Cables**)
coefficient of linear expansion, 14–58
hard-drawn, 2–05, 14–168
hydrometallurgy, 18–09

Copper, loss (see article on particular device)
mechanical characteristics, 14–58
modulus of elasticity, 14–58
plating, 18–04
refinery electrolytic, 18–07
relative weights of systems, 14–07
sheets, 1–61
standard, 14–143
tube, electrolytic, 18–06
ultimate strength, 14–58
weight, 14–58, 14–226
wire, 14–167 to 14–171
tables, 14–144 to 14–148
yield point, 14–58
Copper-clad steel, 14–152
Copper-clad wire tables, 14–152
Copper-graphite, 2–10
Copper-nickel heating units, 18–22
Copper-oxide rectifier meter, 5–30
Cord, 14–172
Cord (of wood), 1–43
Core, armature, 8–10
carbon, 15–17
Core baker, 18–26
Core loss, 2–38, 3–21 (also see article on particular device)
measurement, 5–77
Core-type transformer, 10–03
Cork, 2–04, 2–50
Corn, seed, testing of, 19–10
Corn husking and shredding, 19–06
Corn shelling, 19–06
Corona, 2–08, 3–25, 12–59
leakage conductance due to, 14–19
limit of high-voltage lines, 14–35
on transmission lines, 14–32, 14–163
Corona voltmeter, 5–67, 14–33
Corrosion of lead sheath, 14–131, 14–267
Corrugating rolls, motor for, 16–21
Cos, 1–07, 1–20
Cosecant, 1–07, 1–64
Cosh, 1–10, 1–25
Cosine, 1–07, 1–20, 1–64
Cosine law, 15–03
Cost, relative, of cooking, 15–46
of heating, 15–55
of light, 15–16
of power station, 13–12, 13–28, 13–33
Cot (cotangent), 1–07
Coth, 1–10, 1–25
Cotton, 2–20, 2–50
braid, 14–174
Cotton insulation, 14–174
Cottrell precipitation process, 18–31
Couillie rail bond, 17–66
Coulomb, 1–37, 1–52
Counter emf, 8–32
Counterpoise ground, 14–261
Coupler, train line, 17–33
Covered electrode, 18–44
Covering, of cables, 14–223
on overhead wires, 14–136
Cow, light for, 19–19
Crackage, 15–51
Cranes, motors for, 16–08, 16–11, 16–29
Cream separators, 19–03
Creosote, 14–85
Crest factor, 3–03
Crest gates, 13–17
Crime, 15–39
Critical damping, 5–03
Critical voltage, 14–33
Crook, 14–83
Cross incline, 17–43
Cross-arms, 14–88, 14–102
wood for, 14–33
Cross-magnetization, 8–13
Cross magnetizing force, 9–12
Cross-rail motors, 16–22
Crossing of waterway, 14–138
Crucible steel cable, 14–165
Crude petroleum, 14–85
Cruising economy, 17–117
Cruising turbines for ships, 17–112
Crushers, motors for, 16–08
Csc, 1–07
Csch, 1–10, 1–25
Cubic equation, 1–03
Cubic measure, 1–43
Cubical expansion, coefficients of, 2–58
Cumulative compound motor, 16–05
Cupron, 2–09
Cup-shakes, 14–83
Curling iron, 14–244
Current, 1–53, 1–65
alternating, 3–02
collectors, 17–38
density, 1–53, 12–59
sensitivity of galvanometer, 5–03
transformers (see **Instrument transformers**)
Current-carrying capacity, 41–166, 14–192, 14–215
a-c versus d-c, 14–194
aerial cable, 14–200, 14–210
bare copper wire, 14–166
cables buried in earth, 14–214
impregnated-paper insulated cable, 14–193
insulated wires, 14–192
interior conductors, 14–214
paper cables, 14–193
rubber-insulated cable, 14–213
sheath losses, 14–215
shielded cables, 14–197, 14–203
underground cable, 14–194, 14–203, 14–213
variable load, 14–215
varnished-cambric insulated cable, 14–202
Current-limiting reactors, 4–24, 12–48
Current-limiting relay, 17–33
Current-limiting resistors, 12–11
Current-reducing devices, 16–06
Current-time curve, 17–12
Curves, and grades, 17–07
equation of, 1–05
railway, 17–60
Customer's loop, 14–133
Cut-out, 14–04
battery, 17–84
box, 14–241
Cutter, motor for, 16–27
Cyanamide process, 18–21
Cyanide furnace, 18–26
Cycle, 3–02
Cycle of ignition system, 17–81
Cycled batteries, 7–24
Cycloid, 1–16
Cylinder, 1–17
Cylinder control system, 17–29

D

Dairy farming, 19–02
bottle washers, 19–02
buttermilk warmer, 19–02
churning, 19–02
cottage-cheese machine, 19–02
cream separators, 19–03
light for, 15–34
milk pasteurization, 19–04
milking machine, 19–03

Dairy farming, refrigeration, 19–04
sterilization, 19–05
water heating, 19–05
Dam, hydroelectric station, 13–17
Dammar, 2–28
Damping, mechanical, 5–03
Damping constant, transmission line, 14–25
Damping copper, 11–09
Daniell cell, 6–11
Day, 1–37, 1–45
Daylight, artificial, 15–26
Daylight lamps, 15–13
Daylight light, 15–25
D-c (see **Direct current**)
Dead oil of coal tar, 14–85
Dead-load method, 8–24
Dead-end insulator, 14–110
Dead-man, 14–92
Decade bridge, 5–13
Decade resistance box, 5–11
Decay of timber, 14–85
Decigram, 1–48
Decimal wire gage, 1–59
Decimeter, 1–41
Decomposition, electrolytic, 6–13
Decrement, logarithmic, 5–03
Deflection and side swing, 14–66
Deflection type potentiometer, 5–24
Deflection-temperature curve, 14–68
Deformation factor, 3–03
Degree (angle), 1–45
Dehumidifier, 15–61
Dehydration of food, 19–21
De-ion breakers, 12–14
De-ion fuses, 12–06
De-ion grids, 12–17
Dekagram, 1–48
Dekameter, 1–41
Delco-Remy system, 17–86
Delivery, city, 17–102
Delta connection, 3–31
Demagnetization, 8–13
Demand factors, 14–247
form, 19–02
Demand meter, 1–68, 5–50
Demand system of charging, 5–50
Density, 2–03, 2–06
Depolarizer, 6–08, 7–02
Depreciation factor, of lamp, 15–34
Derivatives, 1–12
Design (see article on particular device)
Desks, 12–51
Detarring, gas, 18–33
Determinants, 1–04
Detinning, electrolytic, 18–09
Detonation, 17–72
Diamagnetism, 2–38
Dielectric, 4–09
admittance per mile, 14–26
constant, 1–65, 5–84
of insulating materials, 5–84
flux, 1–52, 1–65
density, 1–53, 1–65
losses, 2–15, 5–84
of insulating materials, 5–84
measurement, 5–81 to 5–86
merits of, 4–11
strength, 2–12, 2–15, 5–81
of insulating materials, 5–81
Diesel engines, 13–29
Diesel-electric drive, for ships, 17–120
Dietzel process, 18–08
Difference of potential, electric, 1–65
Differential compound motor, 16–05
Differential equation, 1–13
Differential motor, 8–31
Diffusion, 15–23
Dilute solution, 6–17
Dilution, 6–04
Dimensions (see article on particular device)
Dining room, light for, 15–38
ventilation, 16–33
Dipping and plating plants, motors for, 16–14
Direct axis synchronous reactance, 3–45
Direct control switchgear, 12–52, 12–60
Direct current, 1–64
bus bar, 12–56
compared with alternating, 14–03
distribution system, 14–05
in buildings, 14–227
galvanometer, 5–02
generator, 8–02 (see also **Generator, d-c**)
lines, design of, 14–12
measurement, 5–23, 5–63
motor, 8–30 (see also **Motor d-c**)
operation of a-c commutator motor, 17–37
potentiometer, 5–19
protection, 12–42
solenoid, 4–33
switchboard, 12–55
trolley circuit, 17–52
Direct lighting, 15–28
Direct radiator, 15–55
Direct suspension, 17–60
Direct-drive Diesel engine, 17–120
Direction of rotation (trigonometric), 1–06
Directional relay, 12–24
Dirt road, surface, 17–104
Disc, heater, 14–244
Disconnecting switches, 12–05, 12–60
Discrimination, color, 15–26
Dishwasher, 14–244
Disk, insulator, 14–108
Dispatching of trains, 17–69
Dispersion, 1–15
Disruptive critical voltage, 14–34
Dissociation, electrolytic, 6–17
Distance between substations, 13–40
Distance-time curve, railway, 17–11
Distant control switchgear, 12–60
Distributed capacitance, 4–18
Distributed core type transformer, 10–03
Distributing substation, 13–37
Distribution curve, light, 15–05
Distribution loop, 14–133
Distribution systems, Section 14
a-c, 14–05, 14–16
automobile, 17–72

secondary, 14–134
sectionalizing, 14–141
substations, 13–37
underground, 14–142
Distributor box, 14–119
Diversity factor, 14–138

Door opener, 14–257
Dope, 17–73
Dote, 14–83
Double arms, 14–89, 14–102
Double bridge, Kelvin, 5–16
Double bus, 12–57, 13–48
Double squirrel-cage motor, 16–07
Double-acting engine, 13–30
Double-secondary transformer, 5–56
Double-truck bogie locomotive, 17–24
Double-truck car, 17–28
Double-wire automobile wiring, 17–97
Douglas fir, 14–82, 14–87
Drachm, 1–44, 1–48, 1–49
Drafting room lighting, 15–34, 15–38
Drag conveyor, motor for, 16–29
Drainage bond, 14–272
Drainage, farm, 19–19
  of manholes, 14–125
Draw-bar pull, 17–06
Drawbridge batteries, 7–23
Draw-off schedule, 15–48
Dredges, 17–122
  hopper, Diesel electric control, 17–122
  motor drive, 16–30
Drift of instruments, zero, 5–26
Drilling, 2–22
Drilling machine, motor for, 16–21
Drip-proof motor, 16–14
Drive, electric, 16–02
  automobile, 17–104
  group, 16–02
  individual, 16–02
Drop hammer, motor for, 16–21
Drop wire, 14–140
Drum controllers, 12–33, 17–30
Drum starters, 12–33
Dry arcing, 14–106
Dry air filter, 15–62
Dry battery tests, 7–04
Dry cells, 7–02
Dry flashover, 14–106
Dry measure, 1–44
Dry rot, 14–82
Dry-process porcelain, 2–20
Drying, of fruit, 19–21
  of grain, 19–21
  of paint, 18–26
  of vegetables, 19–21
  tumbler, motor for, 16–30
Drysdale potentiometer, 5–25
Duchemin formula, wind pressure, 14–61
Duck, 2–22
Duct (see Conduit)
Ductility of welds, 18–46
Dumpers, car, 16–30
Duplex cable, 14–172
Duplex reentrant cable, 8–07
Duplex spot welder, 18–37
Duplicate service, 14–133
Duprene, 2–26
Duration of head, 13–14
Dust precipitation, 18–31
Dwelling, 14–247
Dye houses, motors for, 16–14
Dynamotors, 11–02
  as balancer, 14–11
Dyne, 1–49
  centimeter, 1–50
Dysprosium, 2–02

E

ε (base of natural logs), 1–18
Earth current, 14–268, 17–56
Earth resistance, 14–268
  unit, 14–266
Earthing, see Grounding
Easement, 14–78
Ebonite, 2–04, 2–50, 2–55
Eddy current, 2–39, 3–21
Edger, motor for, 16–32
Edgewound resistor, 12–10
Edison Lalande cell, 7–02
Edison storage battery, 7–24, 17–105
Edison three-wire system, 14–04
Edison wire gage, 1–62
Effective value, 1–65, 3–03
Efficiency, 1–36, 1–64 (also see article on particular device)
Egg storage, 19–16
Einthoven string galvanometer, 5–71
Elastic limit of timber, 14–87
  of wire, 14–161, 14–167
Electric arc, 3–24

Sinusoid, 1–05
Sinusoidal current, 3–04
Six-phase system, 14–06
Six-ring converter, 11–05
Six-wire, three-phase system, 14–06
Sizes (see article on particular device)
Skin effect, 3–21, 14–165,
Slasher, motor for, 16–32
Slate, 2–04, 2–15, 2–18
Sleet, 14–60
Sleeve, splicing, 14–115
Sleeve inductor type magnetos, 17–79
Sleeve joint, 14–120
Slide-wire bridge, 5–12
Sliding shoe, 17–38
Slip, 9–37, 9–46, 16–70
Slip ring, 9–02
Slipper compound, 14–174
Slip-ring induction motor, 16–09
Slip-ring motor control, 16–12
Slot factor, 9–07, 9–19
Slot pitch, 9–04
Slow-burning wire, 14–240
Sludge, 2–30
Slush pump, motor for, 16–28
Smoke precipitation, 18–31
Snake, 14–127

Snap switches, 14–239
Snow, 2–04
effect of surface, 17–104
Soapstone, 2–04, 2–19
Soapstone ducts, 14–120
Socket joint, 14–120
Sodium, 2–02, 6–06
manufacture of, 18–18
Sodium chloride, 18–10
Sodium permanganate manufacture, 18–10
Sodium vapor lamps, 15–20, 15–26
Soft annealed copper, 2–05
Soil resistance, 14–263
Solar day, 1–37
Solar heat, 15–67
Solarium lamps, 15–18
Solder pots, electric, 18–24
Soldered bonds, 17–65, 17–68
Soldering iron, 14–244
Solenoid winding, 4–29
Solid angle, 1–45
Solid filament lamps, 15–07
Solid insulating materials, 2–18
Solid masonry dam, 13–17
Solid protection of welding, 18–45
Solid wire, 14–143 to 14–153
breaking load, 14–162
Solid-vitreous insulators, 2–19
Solidly grounded system, 14–259
Solution, 6–03
of non-electrolytes, 6–15
Solvay cell, 18–11
Solvent, 2–36, 6–03
Solventless varnish, 2–29
Sorging table, motor for, 16–32
Sound knot, 14–83
Southern white cedar, 14–79, 14–84
Southern yellow pine, 14–81, 14–87
Soybean cooking, 19–28
Space factor, 4–31
Space heaters, 15–56, 18–24
Spacing of wires, 14–55
Span, 1–45
length of, 14–55, 17–60
unequal length, 14–71
Spark plugs, 17–82
aircraft, 17–83, 17–84
Spark timing, 17–81
Spark-gap, 5–63
A.I.E.E. standard, 5–64
needle gap, 5–64
spark-over voltage, 5–65
sphere gap, 5–64
Spark-over, 14–33
voltages, 5–65, 17–73
Specific conductance, 6–04
Specific gravity, 2–03
of electrolyte, 7–10
Specific heat, 2–49
Specific inductive capacity, 2–15
measurement of, 5–84
Spectra, 15–23
Spectrophotometry, 5–92
Specular reflection, 15–41
Speed (see article on particular device)
of operation of circuit breakers, 12–28
of rotation, 1–65
Speed control, 8–37, 12–33
d-c motor, 16–04
Speed regulating rheostats, 12–35
Speed regulator, 12–33
Speed-time curves, trains, 17–11, 17–14
Speed-torque curves, 16–06
Sperry process of reduction, 18–10
Sphere, 1–17
(angle), 1–45
Sphere gaps, 2–36, 5–64
Sphere photometer, 5–93
Spherical candlepower, 5–93
Spherical lenses, 15–29
Spherical reflectors, 15–30
Spherical right angle, 1–45
Spherometer, 5–64
Spike knot, 14–83
Spillway, 13–17
Spinning frame, motor or, 16–26
Spirit varnishes, 2–32
Splicing, 14–115, 14–220
chamber, 14–121
Split-conductor cable, 14–172
Split-phase motors, 16–14
Split-phase vector diagram, 9–59
Split-pole converter, 11–04
Spool (wire), 14–168
Spool insulator, 14–108
Spot welding, 18–36, 18–37
Spray plants, stationary, 19–28
Spring wood, 14–82
Springs, weakening of, in plating, 18–04
Sprocket-operated field rheostat, 12–35
Spruce, 14–87
Square, 1–42, 1–64
Squared-tangent law, 5–89
Squirrel-cage motor, 16–05
Squirrel-cage rotor, 9–36
Stability, of hydroelectric generator, 13–22
of power systems, 3–49, 14–28
Stability factor, 8–14
of a motor, 8–33
Stacker, motor for, 16–32
Stage lighting, 15–38
Stainless steel, reflection from, 15–04
Stairway, light for, 15–34
Standard (see Standards)
Standard cell, 5–06
Standard frequencies, 14–229

  conduit, 14–119
  corona, 14–34
  design, 14–12 to 14–31
  distribution, 14–132
  efficiency, 14–12
  inductance, 14–44
  railway, 17–57
  reactance, 14–48
  stability, 14–28
  vector diagram, 14–27
  voltage limits, 14–35
    usual, 14–08
Transport ratio, 6–20
Transportation, Section 17
Transpositions of transmission lines, 14–19, 14–116, 14–139
Transverse forces on overhead wires, 14–63
Trapezoid, 1–16
Trap, insect, 19–26
Trap-rock, 2–04
Trash racks, 13–18, 13–27
Traverse motor, 16–22
Tree, 14–139
Tree distribution, 14–132
Tree wire, 14–136, 14–139
Tree-type feeder, 14–132
Trenching machine, 14–129
Triangle, 1–09, 1–16
Trickle charging, 7–16, 7–31
Trigonometric formulas, 1–07
  relation to hyperbolic, 1–11
Trigonometric functions, 1–20
Trigonometry, 1–09
Trimmer, motor drive, 16–27, 16–32
Triplex cable, 14–172
Trolley, underground, 17–61
  voltages, a-c, 17–57
  wheel, 17–38
Trolley buses, 17–27
Trolley wire, 14–143 (also see Contact wire, Overhead systems, Railways)
  protection, 12–14
Troy weight, 1–48
Truck, electric, 17–102
  on farms, 19–26
Truck panels, 12–64
Truck-type switchboard, 12–65
True ratio, transformer, 5–54
Trunk lines, 14–137
Tubes, for interior wiring, 14–231
Tudor plate, 7–09
Tumbling barrel, motor for, 16–21
Tuned circuit frequency meters, 5–38
Tung oil, 2–36
Tungar rectifier, 11–21
Tungsten, 2–02, 2–04, 2–50, 6–06
  plating, 18–06
Tungsten filaments, 15–08
Tungsten steel, 2–48
Tunnels, 13–18
Turbine, gas, 13–29
  generator, 17–114
  heat cycle, 13–05
  steam, drive, 17–111
Turbo-electric drive of ships, 17–113
Turbo-generators, 9–16, 13–08
Turf, 2–04
Turning of ship, 17–110
Turnout, frog distance on, 17–48
  rail, 17–48
Twin cable, 14–172
Twin ignition, 17–80
Twin-wire, 14–172
Twisted pair, 14–172
Twisting frame, motor for, 16–26
Twisting sleeve, 14–115
Two parallel wires, capacitance, 14–37
  inductance, 14–45
Two-conductor cable, capacitance, 14–38
Two-cycle engine, 1–30
Two-phase system, 3–31, 14–05
  in buildings, 14–227
Two-ring converter, 11–04
Two-spark magnetos, 17–77
Two-stage current transformer, 5–55
Two-wattmeter method, 5–36
Two-wire d-c line, 14–12
Two-wire distribution, 14–04
  railway, 17–57
Two-wire line, inductance, 14–45
Type A.C.S.R. cable, 14–164
Type A.S. and W. cable, 14–163
Type H H cable, 14–163
Type K potentiometer, 5–20

U

Ulbricht-sphere photometer, 5–93
Ultra-violet light, for poultry, 19–19
  on farms, 19–19
Ultra-violet ray lamps, 15–15 to 15–20
Umbrella type of hydroelectric generator, 13–22
Underdamping, 5–03
Underfloor raceways, 14–235
Underground cable, 14–194, 14–203, 14–213
Underground conduits, 14–119 to 14–132 (see also Conduit)
Underground conduit plow, 17–38
Underground distribution circuits, 14–142
Underground structures, electrolysis of, 14–267
Underground trolley systems, 17–61
Underheat brooder, 19–13
Underload, relays against, 12–23
Under-plaster extensions, 14–237
Undervoltage, relays against, 12–23
Undervoltage trip breaker, 12–12
Underwriters Laboratories, 14–229
Unit air conditioner, 15–61
Unit heater, electric, 15–57
Unit switch system, 17–34
Unit ventilators, 15–61
U. S. loading map, 14–60
U. S. standard gage, 1–59
U. S. steel wire gage, 1–62
U. S. units, 1–37
Units, illumination, 15–02
  systems of, 1–36, 5–02
Unit-type press, motor for, 16–23
Unsaturated cadmium cell, 5–07
Unstacker, motor for, 16–32
Uranium, 2–02

Urban distribution, 14–54
Urea resins, 2–27
Usual magnetic densities, 9–19
Utilities regulations, wiring, 14–230
Utilization coefficient of lamp, 15–35
Uviarc lamps, 15–20

V

V-curves, 9–31
Vacuum breakers, 12–16
Vacuum cleaner, 14–244
Vacuum lamp, 15–08
Valence, 6–02
Valves, steam, 13–10
Van de Graf generator, 8–30
Vanadium, 2–02, 2–51
Vanstone pipe flange, 13–09
Vapor heating system, 15–54
Vapor velocity, 13–10
Vaporization, heat of, 2–51
Vapor-pressure thermometer, 5–97
Var, 5–40
Variable inductance, 3–25
Variable speed motor, 16–11
Variometers, 4–23
Varnished cambric, 14–174, 14–186
  cable insulation, 14–202
  insulated wire, 14–240
Varnished cloth, 2–16, 2–21, 14–174
  weight of, 14–226
Varnishes, insulating, 2–32
Varying speed motor, 16–19
Vat, electroplating, 18–02
Vector admittance, 3–10
Vector diagram of transformer, 10–05
Vector diagram of transmission line, 14–27
Vector impedance, 3–10
Vector power, 3–11
Vector representation, 1–65
  of sinusoids, 3–05
Vegetable dehydration, 19–24
Vegetable drying, 19–21, 19–24
Vegetable germination, 19–25
Vegetable shredding, 19–26
Veiling glare, 15–23
Velocity, angular, 1–47
  linear, 1–46
  of ions, 6–21
  of light, 1–70
  of propagation, transmission line, 14–25
  of wind, 14–61
Ventilation, 9–17, 15–65
  barn, 19–11
  coal mine, 16–28
  conduit lines, 14–231
  generator, 9–17, 13–22
  marine, 17–115
  motors, 16–31
  ovens, 18–26
  requirements, 15–66
Versine, 1–08, 1–64
Vertical forces on overhead wires, 14–63
Vertical hyperbola, 1–05
Vertical illumination, 15–03
Vertical lift switchgear, 12–66
Vertical parabola, 1–05
Vertical riser cables, 14–238
Vertical sag, 14–66
Vertical separation of conductors, 14–55
Vibrating reed frequency meter, 5–37
Vibrating regulator, 12–36, 17–87
Vibration, conductor, 14–63
Vibration galvanometer, 5–05
Vibrator, 14–244
Vibrator ignition systems, 17–76
Vinyl resins, 2–27
Virgin curve, 3–19
Virtual coefficient of expansion, 14–58
Virtual modulus of elasticty, 14–58
Viscosity, dielectric, 4–10
Viscous air filter, 15–62
Visibility curve of eye, 15–21
Visicode, 12–75
Vision, 15–21
Visual acuity, 15–22
Visual standards, photometry, 5–88
Volt, 1–38, 1–54
Volt amperes, 3–03
Volta effect, 6–08
Voltage, 1–65 (also see article on particular device)
  control, 14–09, 17–85
  distribution in insulator strings, 14–110
  loss, per cent, 14–12
  measurement, 5–19
  rises at junctions, 14–26
  sensitivity of galvanometer, 5–03
  sparking, 5–65, 17–73
  standard, 14–07
  to neutral, 3–30
Voltage-time curve, 17–12
Voltaic cells, 6–07
Voltmeter, 1–68, 5–30, 16–17
  corona type, 5–67
  rotary, 5–63
  used as ohmmeter, 5–42
Volt-ohmmeters, 5–42
Volume, 1–16
  of geometric figure, 1–16
  of wood poles, 14–83
Volume resistivity, 2–14, 5–84
Vulcanized fiber, 2–22
Vulcanized oil sheath, 14–175

W

Waffle iron, 15–44
Wagner repulsion starting, induction running motor, 9–62
Waidner-Burgess light standard, 5–87
Walker balanced gear drive, 17–105
Walker multiple system of refining, 18–07
Wall, furnace, 18–13
  heat transmission, 15–63
Wall switch, 14–243
Walnut drying, 19–24
Wane, 14–83
Ward-Leonard motor control, 16–05, 16–27
Warehouse, light for, 15–34
Warming engine, Kelvin, 15–59
Warped, 14–83
Washburn and Moen gage, 1–62
Washing machine, power, 14–244, 16–30
  water requirement, 15–47
Washing solution, 18–02
Watchman's clock, 14–257
Water, 2–04, 2–51
  conduit, 13–18
  density, 2–03
  electrolysis, 18–11
  heating, 14–244, 15–46 to 15–50, 19–05
  requirements, 15–47
  resistance, 14–186
  supply for farms, 19–19, 19–20
Water breakers, 12–16
Water rheostat, 4–08
Water-cooled transformer, 10–04, 10–15

Water-gas tar, 14–85
Water-pipe ground, 14–237
Waterproofing, of manhole, 14–125
Waterways, 13–17
crossing of, 14–138
Waterwheel, 13–19
generator, 13–21
Watt, 1–52, 1–64
hour, 1–51, 1–64
second, 1–51
Watthour meter, 1–68, 5–46 to 5–50
Wattless power, 3–06
Wattmeter, 1–68, 5–31 to 5–37
connections, 16–17
Wave, on transmission line, 14–25
Wave analysis, 3–07
Wave winding, 8–06
resistance of, 8–23
Wavelength, 3–48, 14–25
constant, 14–25
Wax, 2–04, 2–28, 2–50
Waxing of fruit, 19–18
Weather strips, effect of, 15–65
Weatherproof wire, 14–136, 14–240
Weatherproofing, 14–175
Web type plate, 7–09
Weber, 1–57
Weber photometer, 5–91
Wedge contacts, 12–17
Week, 1–45
Wehnelt interrupter, 4–44
Weight, of conductor, 1–48, 14–13, 14–17
of insulated cables, 14–225
of materials, 2–02 to 2–04
of wires, 14–144
of wood poles, 14–83
Weighted observations, 1–15
Weld peening, 18–45
Welded bond, 17–67
Welded joints, 13–09
Welding, 18–34 to 18–51
applications, 18–50
arc, 18–41
butt, 18–35
carbon arc, 18–42
control of timing, 18–41
electrodes, 18–44
flash, 18–36
manual vs. automatic, 18–49
metal arc, 18–43
percussive, 18–41
pressure, 18–36
projection, 18–39
protection, 18–45
reduction of stresses, 18–45
resistance, 18–35
seam, 18–35
societies, 18–52
shot, 18–36, 18–37
timing control, 18–41
track rails, 17–66
Well drilling, motor for, 16–27
Welsbach burner, 15–53
Wenner potentiometer, 5–22
Western red cedar, 14–81 to 14–87
Western yellow pine, 14–81, 14–84
Westinghouse frequency meter, 5–38
Westinghouse synchroscope, 5–40
Westinghouse unit-switch control, 17–34
Weston frequency meter, 5–38
Weston illuminometer, 5–91
Weston normal cell, 1–38, 5–06
Weston ohmmeter, 5–42
Weston synchroscope, 5–40
Wet arcing, 14–106
Wet cells, 7–02
Wet-process porcelain, 2–20
Wheatstone bridge, 5–13
Wheel trolley, 17–38
White cedar, 14–79, 14–87
White glass globes, 15–28
White lead, manufacture of, 18–10
White light, 15–25
lamps, 15–20
White northern cedar, 14–87
White potentiometer, 5–22
Whitewash removal, 19–27
Whiting cell, 18–11
Whyte classification of locomotives, 17–24
Willard's rule, heat, 15–52
Wimshurst machine, 8–29
Winchester bushel, 1–44
Wind, 14–83
Wind cracks, 14–82
Wind load, 14–60 to 14–63, 14–87
Windage, 8–18, 9–13
loss (see article on particular device)
Winding connection, 1–66
Winding distribution constant, 9–08
Window, infiltration, 15–65
ventilation, 15–61
Wind-shake, 14–83
Wire, 14–143 to 14–226
accessories, 14–239
aluminum, 14–149, 14–158, 14–163
base, 14–143 to 14–171
breaking load, 14–161
capacitance to neutral, 14–39
cleats, 14–231
control, 13–55
copper, 14–144 to 14–148, 14–156, 14–163, 14–167
copper-clad, 14–152
definition, 14–171
elasticity, 14–161
expansion coefficients, 14–161
for motor branch circuits, 14–252
gages, 1–61
comparison of, 1–63
ground, 14–56
ice loading, 14–60
insulated, 14–171 to 14–226 (also see **Insulated wires and cables**)
interior, 14–240
manufacture of, 2–05
power stations, 13–53
resistance of, 14–143
at various temperatures, 14–160
size calculation, 14–251
solid, 14–143
steel, 14–151
stranded, 14–153
strength, 14–161
susceptance to neutral, 14–42
tables, 14–143 to 14–226
nickel-chromium-alloy, 18–23
tensile breaking load, 14–161
trolley, 14–143
Wireways, 14–235
Wiring (see article on particular device)
automobile, 17–97
diagrams, 1–69
for increasing illumination, 15–33
of buildings, 14–226 to 14–257
of conduits, 14–126
residence, 14–243
systems, 14–227
Wolff potentiometer, 5–22

Wood, 2–04, 2–15, 2–22, 2–50
conductivity of, 14–270
heat conductivity, 15–64
insulators, 14–92
Wood arc-light machine, 8–21
Wood block surface, 17–104
Wood pins, 14–112
Wood poles, 14–78
preservative treatment, 14–84
seasoning, 14–83
standards for, 14–79
weight of, 14–83
Wood pulleys, 16–15
Wood's metal, 2–50
Wooden cross-arms, 14–88
Wood-stave pipe, 13–18
Woodworking industry, light for, 15–34
motors for, 16–26
Wool, 2–50
Work, 1–57, 1–65
Working light standards, 5–88
Working stress, 14–58
Worm drive, 17–105
Wrought-iron gage, 1–60
Wye connections, 3–31

X

Xenon, 2–02

Y

Y connection, 3–31
Yacht batteries, 7–23
Yard, 1–36, 1–41
cubic, 1–43, 1–64
square, 1–42, 1–65
Y-box, 5–36
Yellow longleaf pine, 14–79
Yellow pine, 14–79
cross-arms, 14–104
Yoke, 8–03, 17–62
Ytterbium, 2–02
Yttrium, 2–02

Z

Zero drift of instruments, 5–26
Zero sequence components, 3–33
Zero sequence reactance, 3–45
Zinc, 2–02, 2–04, 2–50, 6–06
plating, 18–04
production, 18–09, 18–18
Zinc chloride, 14–85
Zircon resistor, 4–08
Zirconium, 2–02

WILEY ENGINEERING HANDBOOK SERIES

I. HANDBOOK OF ENGINEERING FUNDAMENTALS

SECTION EDITED BY OVID W. ESHBACH. 1081 PAGES

1. MATHEMATICAL AND PHYSICAL TABLES: SYMBOLS AND ABBREVIATIONS; MATHEMATICAL TABLES; PHYSICAL PROPERTIES OF MATERIALS; TABLES OF CONVERSION FACTORS—UNITS OF WEIGHTS AND MEASURES; GAGES; STANDARD STRUCTURAL SIZES; by Ovid W. Eshbach in collaboration with J. L. Barnes, J. G. Brainerd, R. T. Kent, and H. C. Knutson.
2. MATHEMATICS: ARITHMETIC; ALGEBRA; MATHEMATICS OF FINANCE; GEOMETRY; TRIGONOMETRY; PLANE ANALYTIC GEOMETRY; SOLID ANALYTIC GEOMETRY; DIFFERENTIAL CALCULUS; INTEGRAL CALCULUS; DIFFERENTIAL EQUATIONS; SOLUTION OF LINEAR CONSTANT-COEFFICIENT INTEGRO-DIFFERENTIAL EQUATIONS BY THE LAPLACIAN TRANSFORMATION (OPERATIONAL CALCULUS); FUNCTIONS OF COMPLEX VARIABLES; VECTOR ANALYSIS; ALIGNMENT CHARTS (NOMOGRAMS); PRECISION OF MEASUREMENTS; by J. L. Barnes in collaboration with J. G. Brainerd, C. Eisenhart, M. J. Fish, and J. M. Rice.
3. PHYSICAL UNITS AND STANDARDS: DIMENSION SYSTEMS; UNIT SYSTEMS; UNITS AND STANDARDS; DIMENSIONAL ANALYSIS; by Ernst Weber.
4. THEORETICAL MECHANICS: STATICS; KINEMATICS; KINETICS; by Janvier M. Rice.
5. MECHANICS OF MATERIALS: SIMPLE STRESSES; BEAMS; COLUMNS; SHAFTS; CYLINDERS, PLATES, ROLLERS, AND RIVETED JOINTS; TESTING OF MATERIALS; by Jasper O. Draffin. REINFORCED CONCRETE; by Theodore Crane.
6. MECHANICS OF FLUIDS: PROPERTIES OF FLUIDS, DIVISIONS OF FLUID MECHANICS; FLUID STATICS; FLUID DYNAMICS; by P. E. Hemke.
7. ENGINEERING THERMODYNAMICS: PRINCIPLES OF THERMODYNAMICS; GASES; LIQUIDS AND VAPORS; THE STEAM POWER PLANT; THE INTERNAL-COMBUSTION ENGINE; REFRIGERATION; GAS AND VAPOR MIXTURES, HUMIDITY, AND AIR CONDITIONING; by Milton C. Stuart and Paul J. Kiefer.
8. ELECTRICITY AND MAGNETISM: ELECTRON THEORY; DIRECT-CURRENT CIRCUITS; ELECTROKINETICS AND THE MAGNETIC CIRCUIT; ELECTROSTATICS AND THE DIELECTRIC CIRCUIT; ALTERNATING-CURRENT CIRCUITS; TRANSIENTS; CONDUCTION OF ELECTRICITY IN SOLIDS AND FLUIDS; by Charles Weyl and Irven Travis.
9. RADIATION AND LIGHT: THEORY OF RADIATION; GEOMETRY OF RADIATION; PHYSICS OF RADIATION; PHYSIOLOGY OF RADIATION; by Ernst Weber. ACOUSTICS; by R. B. Lindsay. METEOROLOGY; by Edgar W. Woolard, R. J. Martin, and H. L. Dryden.
10. CHEMISTRY: GENERAL CHEMISTRY; INDUSTRIAL CHEMISTRY; QUALITATIVE ANALYSIS; ELECTROCHEMISTRY; by Joseph Mattiello and Sidney B. Tuwiner.
11. METALLIC MATERIALS: CORROSION OF METALS; by Frank N. Speller. IRON AND STEEL; by Bradley Stoughton. COPPER AND COPPER-BASE ALLOYS; by members of the staff of the American Brass Co. and W. M. Corse. ZINC AND ZINC-BASE ALLOYS; by W. M. Peirce. ALUMINUM AND ALUMINUM ALLOYS; by Junius D. Edwards and Zay Jeffries. NICKEL AND NON-FERROUS NICKEL ALLOYS; by Robert Worthington. MAGNESIUM AND MAGNESIUM ALLOYS; by John A. Gann. TUNGSTEN; MOLYBDENUM; by Zay Jeffries. DIE-CASTING ALLOYS; by J. C. Fox. BEARING METALS; by Christopher H. Bierbaum. WELDING, BRAZING, AND SOLDERING MATERIALS; by Bradley Stoughton and D. F. Miner. ELECTRICAL CONDUCTOR MATERIALS; by H. C. Knutson and D. F. Miner. MAGNETIC MATERIALS, by J. B. Seastone. MISCELLANEOUS MATERIALS.
12. NON-METALLIC MATERIALS: CEMENT, CONCRETE, LIME, MORTAR, AND PLASTER; by Theodore Crane. STONE, BRICK, AND TERRA-COTTA; by Jasper O. Draffin. REFRACTORIES; by J. Spotts McDowell and E. B. Guenther. THERMAL INSULATING MATERIALS. TIMBER; by H. C. Knutson and H. F. Moore. PAINTS, ENAMELS, VARNISHES, AND LACQUERS; by Joseph Matiello. ELECTRIC INSULATING MATERIALS; LUBRICANTS; ADHESIVE MATERIALS; by D. F. Miner. FUELS AND EXPLOSIVES. MISCELLANEOUS MATERIALS.
13. CONTRACTS. By R. L. Sackett.

MECHANICAL ENGINEERS' HANDBOOK

II. POWER

Edited by Robert Thurston Kent

1226 pages

SECTION

1. AIR: Compressed Air; Fans and Blowers.
2. WATER: Hydraulics; Hydraulic Turbines; Pumps and Pumping Engines.
3. HEAT: Measurement of Heat; Heat Transmission; Evaporators and Evaporation; Dryers and Drying; Heat Insulation; Thermodynamics.
4. COMBUSTION AND FUELS: Combustion; Fuels; Solid Fuels; Liquid Fuels; Gaseous Fuels.
5. STEAM.
6. THE STEAM BOILER: Boiler Construction; Superheaters, Economizers and Air Heaters; Moisture in Steam; Boiler Feeding; Feedwater for Steam Boilers; Boiler Furnaces; Chimneys and Draft.
7. THE STEAM ENGINE.
8. THE STEAM TURBINE.
9. CONDENSING AND COOLING EQUIPMENT.
10. REFRIGERATION AND ICE MAKING.
11. HEATING, VENTILATING AND AIR CONDITIONING.
12. INTERNAL COMBUSTION ENGINES: Diesel Engines; Gas Engines; Gasoline Engines.
13. GAS PRODUCERS.
14. TRANSPORTATION: Railroad Engineering; Automotive Vehicles; Aeronautics.
15. ELECTRIC POWER: Purchased Power; Generated Power; Conversion Equipment; Switchboard Equipment; Batteries; Power Factor; Power Distribution.
16. POWER TEST CODES: Instruments and Apparatus; Test Codes
17. MATHEMATICAL TABLES

MECHANICAL ENGINEERS' HANDBOOK

III. DESIGN. SHOP PRACTICE

Edited by Robert Thurston Kent

In press

SECTION

1. ENGINEERING MATERIALS: Iron and Steel; Non-Ferrous Metals; Fabricated Materials.
2. MACHINE DESIGN: Screw Fastenings; Riveted Fastenings; Springs; Axles, Shafts and Spindles; Keys, Cotters, Fits and Tapers; Cranks and Crank Pins; Couplings and Clutches; Bearings and Sliding Surfaces; Ball Bearings; Gearing; Flywheels; Brakes; Governors; Geometrical Constructions for the Designer; Fundamental Formulas for the Designer.
3. VIBRATION AND NOISE.
4. FOUNDRY PRACTICE.
5. FORGE SHOP PRACTICE.
6. WELDING PRACTICE.
7. INDUSTRIAL FURNACES.
8. MACHINE SHOP PRACTICE: Planing; Milling; Turning; Drilling; Abrasive Processes; Metal Cutting Tools; Metal Cutting Fluids; Precision Measurements; Grinding; Polishing; Honing.
9. MATERIAL HANDLING.
10. MECHANICAL POWER TRANSMISSION.
11. ELECTRICAL APPLICATIONS.
12. BUILDINGS: Construction; Illumination.
13. SAFETY.
14. TABLES

HANDBOOK FOR ELECTRICAL ENGINEERS

IV. ELECTRIC POWER

EDITED BY HAROLD PENDER, WILLIAM A. DEL MAR, AND KNOX MCILWAIN
1300 PAGES

SECTION

1. MATHEMATICS, UNITS, AND SYMBOLS: MATHEMATICS; by Carl C. Chambers. MATHEMATICAL TABLES. UNITS AND CONVERSION FACTORS; by J. G. Brainerd and Carl C. Chambers. SYMBOLS AND ABBREVIATIONS. CONSTANTS; by Carl C. Chambers.
2. PROPERTIES OF MATERIALS: WEIGHTS OF MATERIALS; CONDUCTOR MATERIALS; INSULATING MATERIALS; MAGNETIC MATERIALS; THERMAL PROPERTIES OF MATERIALS; by D. F. Miner.
3. ELECTRIC CIRCUITS AND ELECTRIC LINES: ALTERNATING CURRENTS; LINEAR CIRCUITS; NON-LINEAR CIRCUITS; POLYPHASE SYSTEMS AND SYMMETRICAL COMPONENTS; ELECTRICAL MACHINES; TRANSMISSION LINES; STABILITY OF POWER SYSTEMS; by Irven Travis.
4. RESISTORS, REACTORS, MAGNETS: RESISTORS, RHEOSTATS; CAPACITORS—CONDENSERS; INDUCTORS; MAGNETS, MAGNETIC DEVICES; by A. Dexter Hinckley.
5. MEASUREMENTS AND MEASURING APPARATUS: by H. B. Brooks.
6. PRINCIPLES OF ELECTROCHEMISTRY: by H. M. Goodwin, revised by Martin Kilpatrick and Mary L. Kilpatrick.
7. BATTERIES: PRIMARY BATTERIES; by C. F. Burgess. LEAD-ACID STORAGE BATTERIES; by J. Lester Woodbridge. ALKALINE-TYPE STORAGE BATTERIES; by E. W. Allen and F. Brehme.
8. DIRECT-CURRENT MACHINES: DIRECT-CURRENT GENERATORS; DIRECT-CURRENT MOTORS; by Walter I. Slichter.
9. ALTERNATING-CURRENT MACHINES: ALTERNATING-CURRENT GENERATORS; SYNCHRONOUS MOTORS; POLYPHASE INDUCTION MOTORS; SINGLE-PHASE INDUCTION MOTORS; ALTERNATING-CURRENT COMMUTATOR MOTORS; by Walter I. Slichter.
10. TRANSFORMERS; by Walter I. Slichter.
11. CONVERTERS AND RECTIFIERS: ENERGY CONVERTERS; FREQUENCY CONVERTERS; PHASE CONVERTERS AND BALANCERS; RECTIFIERS; by Walter I. Slichter.
12. SWITCHING, CONTROL, AND PROTECTION: CIRCUIT ELEMENTS; CIRCUIT BREAKERS; CONTROLLERS AND REGULATORS; PROTECTION; STATION EQUIPMENT; STATION STRUCTURES AND LAYOUT; by Stephen Q. Hayes.
13. POWER STATIONS AND SUBSTATIONS: STEAM POWER STATIONS; by F. S. Bennett. HYDROELECTRIC POWER STATIONS; by R. A. Hopkins and A. G. Cherry. INTERNAL-COMBUSTION POWER STATIONS; by W. A. Sloan. SUBSTATIONS; by W. I. Slichter. POWER STATION CIRCUITS; by R. A. Hopkins.
14. POWER TRANSMISSION AND DISTRIBUTION: SYSTEMS; CAPACITANCE AND INDUCTANCE TABLES; UNDERGROUND CONDUITS; DISTRIBUTION; BARE WIRES AND CABLES; INSULATED WIRES AND CABLES; ELECTROLYSIS OF UNDERGROUND STRUCTURES; by W. A. Del Mar. ELECTRICAL DESIGN OF TRANSMISSION AND DISTRIBUTION SYSTEMS; by W. A. Del Mar, J. H. Palmer, F. W. Peek, and R. A. Philip. POLE AND TOWER LINES; by Howard Enos. WIRING OF BUILDINGS; by G. W. Zink. GROUNDING OF ELECTRIC CIRCUITS AND ACCESSORIES; by R. F. Abele.
15. LIGHTING AND HEATING: LIGHTING; by F. C. Caldwell. HOUSEHOLD HEATING APPLIANCES AND COOKING; by Frank Thornton, Jr. WATER HEATING; by C. J. Fay and J. F. Reifenberg. HEATING AND AIR CONDITIONING OF BUILDINGS; by Otto W. Walter.
16. INDUSTRIAL APPLICATIONS OF MOTORS; by Francis A. Westbrook.
17. TRANSPORTATION: ELECTRIC TRACTION; by H. A. Currie and Robert S. Rhodes. ELECTRICAL EQUIPMENT OF INTERNAL-COMBUSTION AUTOMOBILES; by H. Chase. ELECTRIC AUTOMOBILES; by W. P. Kennedy. ELECTRIC PROPULSION OF SHIPS; by W. N. Zippler.
18. ELECTROCHEMICAL AND ELECTROTHERMAL INDUSTRIES: ELECTROCHEMICAL PROCESSES; ELECTRIC FURNACES AND THEIR PRODUCTS; by M. de K. Thompson. ELECTRIC RESISTANCE HEATING; by Frank Thornton. Jr. ELECTRICAL PRECIPITATION OF SUSPENDED PARTICLES; by N. W. Sultzer. ELECTRIC WELDING; by H. M. Hobart.
19. ELECTRICITY ON THE FARM; by Lee C. Prickett.

HANDBOOK FOR ELECTRICAL ENGINEERS

V. COMMUNICATION. ELECTRONICS

EDITED BY HAROLD PENDER AND KNOX McILWAIN. 1022 PAGES

SECTION

1. MATHEMATICS, UNITS, AND SYMBOLS: MATHEMATICS; by Carl C. Chambers. MATHEMATICAL TABLES. UNITS AND CONVERSION FACTORS; by J. G. Brainerd and Carl C. Chambers. SYMBOLS AND ABBREVIATIONS. CONSTANTS; by Carl C. Chambers.
2. PROPERTIES OF MATERIALS: CONDUCTING MATERIALS; INSULATING MATERIALS; LUMINESCENT MATERIALS; MAGNETIC MATERIALS; SPECIAL PROPERTIES OF DIELECTRICS; by William F. Diehl with W. R. Dohan, H. W. Leverenz, D. G. C. Luck, and C. R. Nelson.
3. ELECTRIC CIRCUITS, LINES, AND FIELDS: LINEAR ELECTRIC CIRCUITS; GENERAL NETWORK THEORY; RECURRENT NETWORKS; NON-LINEAR ELECTRIC CIRCUITS; ELECTROMAGNETIC RADIATION; ELECTROMECHANICAL SYSTEMS; by Knox McIlwain.
4. RESISTORS, INDUCTORS, CAPACITORS: RESISTORS AND RHEOSTATS; INDUCTORS WITH AIR CORES; FERROUS-CORED INDUCTORS; CAPACITORS, CONDENSERS; by A. Dexter Hinckley.
5. ELECTRON TUBES: THERMIONIC VACUUM TUBES; by B. J. Thompson with J. M. Stinchfield, Bernard Salzberg, and E. W. Herold. GASEOUS CONDUCTION TUBES; by O. W. Livingston. CATHODE-RAY OSCILLOGRAPH TUBES; by G. F. Metcalf. X-RAY TUBES; by S. Reid Warren, Jr. PHOTORESPONSIVE DEVICES; by H. E. Ives.
6. ELECTROMECHANICAL-ACOUSTIC DEVICES: EFFECTS OF THE ACOUSTIC MEDIUM; LOUD SPEAKERS AND TELEPHONE RECEIVERS; MICROPHONES; by Hugh S. Knowles. MECHANICAL RECORDING AND REPRODUCING OF SOUND; OPTICAL RECORDING AND REPRODUCING; MAGNETIC RECORDING AND REPRODUCING; by H. A. Frederick and A. C. Keller.
7. CIRCUIT ELEMENTS: SINGLE MESH AND COUPLED CIRCUITS; by Vernon D. Landon and Knox McIlwain. TRANSFORMERS WITH IRON CORES; by J. I. Cornell and A. J. Rohner. ELECTRICAL WAVE FILTERS; by T. E. Shea and C. E. Lane. RADIO ANTENNAS; by G. C. Southworth. VACUUM-TUBE AMPLIFIERS; by Loy E. Barton. MODULATORS; POWER SUPPLY; RADIO TRANSMITTERS; by J. E. Young. DETECTORS; RADIO RECEIVERS; by Vernon D. Landon. OSCILLATORS; by Carl C. Chambers.
8. HIGH-FREQUENCY TRANSMISSION: WIRE TRANSMISSION LINES; by Knox McIlwain. TRANSMISSION IN SPACE; by John C. Schelleng. MECHANICAL FEATURES OF TRANSMISSION LINES; by C. H. MacDonald. COORDINATION OF COMMUNICATION AND POWER SYSTEMS; by C. H. MacDonald and H. A. Dambly.
9. ACOUSTICS: THE SENSE OF HEARING; SPEECH AND MUSIC; EFFECTS OF DISTORTION ON SPEECH AND MUSIC; by John C. Steinberg. ACOUSTIC PROPERTIES OF ROOMS; SOUND INSULATION; ACOUSTIC DESIGN OF AUDITORIUMS; by Vern O. Knudsen.
10. ELECTRICAL MEASUREMENTS: FREQUENCY MEASUREMENTS; by W. A. Marrison. MEASUREMENT OF PRIMARY ELECTRICAL QUANTITIES; by W. J. Shackelton and J. G. Ferguson. WIRE TRANSMISSION MEASUREMENTS; by F. H. Best. MEASUREMENTS OF TRANSMISSION THROUGH SPACE; by R. K. Potter. WAVE ANALYSIS; by E. Peterson and T. G. Castner.
11. TELEGRAPHY: ELEMENTS OF TELEGRAPH SYSTEMS; D-C TELEGRAPH SYSTEMS; A-C TELEGRAPH SYSTEMS; PRINTING TELEGRAPH SYSTEMS; LOCAL EQUIPMENT; SUBMARINE CABLE TELEGRAPHY; by Allison A. Clokey. RADIO TELEGRAPH SYSTEMS; by J. L. Finch.
12. SOUND-REPRODUCTION SYSTEMS: ACOUSTO-ELECTRIC EQUIPMENT; RADIO TELEPHONE BROADCASTING; by Howard A. Chinn. ELECTRO-ACOUSTIC EQUIPMENT; by W. H. Bohlke and Knox McIlwain. PUBLIC ADDRESS SYSTEMS; SOUND PICTURES; by Knox McIlwain. POLICE RADIO SYSTEMS; by Loren F. Jones.
13. TELEPHONY: SUBSTATION EQUIPMENT AND CIRCUITS; CENTRAL OFFICE SYSTEMS; by Knox McIlwain. TELEPHONE LINES; by C. H. MacDonald. RADIO TELEPHONE SYSTEMS; by A. A. Oswald.
14. FACSIMILE TRANSMISSION AND RECEPTION: SCANNING SYSTEMS; RECORDING SYSTEMS; TRANSMISSION AND SYNCHRONIZATION; COMPLETE FACSIMILE SYSTEMS; by Maurice Artzt.
15. TELEVISION: TRANSMITTING POINT ANALYZER; TRANSMISSION CHANNEL; RECEIVING POINT REPRODUCER; SCANNING SYSTEMS (ELECTRICAL); COMPLETE TELEVISION SYSTEMS; CIRCUIT ELEMENTS PECULIAR TO TELEVISION SYSTEMS; by H. Branson and R. L. Campbell.
16. ELECTRONIC CONTROL AND NAVIGATION EQUIPMENT: FUNDAMENTAL ELECTRONIC CONTROL CIRCUITS; LIGHT-SENSITIVE CONTROL EQUIPMENT; THYRATRON CONTROL EQUIPMENT; by W. R. King. RADIO AIDS TO AIR AND MARINE NAVIGATION; by W. E. Jackson and J. C. Hromada.
17. MEDICAL APPLICATIONS OF ELECTRICITY: ELECTROTHERAPY; DIATHERMY AND HIGH-FREQUENCY SURGERY; ULTRA-VIOLET-RAY THERAPY; PHYSIOLOGICAL ELECTROMOTIVE FORCES; ELECTRO-ACOUSTIC DEVICES; ROENTGEN THERAPY; ROENTGENOGRAPHY AND ROENTGENOSCOPY; HIGH-VOLTAGE SHOCK AND X-RAY BURN; by Charles Weyl.

OTHER WILEY HANDBOOKS

THE ENGINEERS' MANUAL

By Ralph G. Hudson, assisted by the late Joseph Lipka, Dean Peabody, and Howard B. Luther. 315 pages. 5 by 7¾. 227 figures. Flexible binding.

ARCHITECTS' AND BUILDERS' HANDBOOK

By the late Frank E. Kidder. Harry Parker, Editor-in-chief, with the collaboration of a staff of 18 specialists. 18th edition. 2315 pages. 4½ by 7. Flexible binding.

MERRIMAN'S AMERICAN CIVIL ENGINEERS' HANDBOOK

Thaddeus Merriman, Editor-in-chief; Thomas H. Wiggin, Associate Editor-in-chief; with a staff of 21 specialists. Fifth revised edition. 2263 pages. 4¼ by 7. One volume, atholeather; two volumes, real leather.

MINING ENGINEERS' HANDBOOK

Robert Peele, Editor-in-chief. Second Edition. 2523 pages. 4½ by 7. Flexible binding. Two volumes, real leather.

HANDBOOK OF ORE DRESSING

By Arthur F. Taggart and 7 contributors. 1679 pages. 5 by 7¾. Flexible binding.

VEST-POCKET HANDBOOK OF MATHEMATICS FOR ENGINEERS

By the late L. A. Waterbury with special sections by the late G. A. Goodenough and H. H. Higbie. Third edition, enlarged. 278 pages. 3 by 5½. Flexible binding.
